BZDs—diazepam and clonazepam. The BZDs bind $GABA_A$ receptor complexes in neurons located in the brainstem and at the spinal cord level and increase the affinity of GABA for the $GABA_A$ receptor complex. This results in an increase in presynaptic inhibition and the reduction of monosynaptic and polysynaptic reflexes. These drugs may improve passive range of motion and reduce hyperreflexia, painful spasms, and anxiety. Diazepam has a half-life of 20–80 hours and forms active metabolites that prolong its effectiveness. The half-life of clonazepam ranges from 18 to 28 hours.

Sedation, weakness, hypotension, adverse GI effects, memory impairment, incoordination, confusion, depression, and ataxia may occur. Tolerance and dependency can occur, and withdrawal phenomena, notably seizures, have been associated with abrupt cessation of therapy.

Baclofen—oral and intrathecal pump. Baclofen is a GABA agonist, and its primary site of action is the spinal cord, where it reduces the release of excitatory neurotransmitters and substance P by binding to the $GABA_B$ receptor. Studies show that baclofen improves clonus, flexor spasm frequency, and joint range of motion, resulting in improved functional status.

Adverse effects include sedation, ataxia, weakness, and fatigue.

Intrathecal baclofen is approved in the United States for the treatment of spasticity of spinal or cerebral origin. In children, intrathecal baclofen is particularly effective for the treatment of spasticity of the lower extremities. Complications of the procedure are relatively few and usually are limited to mechanical failures of the pump or the catheter. Adverse drug effects are usually temporary and can be managed by reducing the rate of infusion.

CARDIOVASCULAR SYSTEM PHARMACOLOGY

Many cardiovascular medications have the potential to alter responses to both acute and chronic exercise in a predictable manner. Knowledge of how common drugs alter these responses can assist the clinician in assessing the safety and appropriateness of exercise and in determining the effectiveness of exercise training.[39] Most medications that are prescribed for cardiovascular disease have either a direct or indirect effect on the heart or vascular system, including alteration of the myocardial oxygen consumption, peripheral blood flow, and cardiac preload or afterload.[39] Medications may either increase or decrease exercise capacity, or alter the expected changes in heart rate and blood pressure that normally occur with an increase in activity or at rest (Table 9-4).[39]

α-Adrenergic Blocking Drugs (α_1-Antagonists/α-Blockers). These drugs work through the autonomic nervous system (ANS) by blocking α-receptors. α-receptors normally promote constriction of the arterioles. Blocking constriction promotes dilation of vessels and lowers blood pressure as well as reducing the work of the heart in some situations. α-blocking drugs also inhibit the actions of norepinephrine that raises blood pressure as part of the fight-or-flight response. α-blockers are usually prescribed along with other blood-pressure-lowering drugs, such as a β-blocking drug and/or a diuretic. There are now several medications available that combine the effects of blocking both the β- and α-receptors.

Possible adverse side effects. Nausea and indigestion; these usually subside with long-term use. Less frequent effects are cold hands and feet, temporary impotence, and nightmares. Dizziness may occur initially or as the dosage is increased.

Angiotensin-Converting Enzyme Inhibitors. These drugs act to prevent production of a hormone, angiotensin II, which constricts blood vessels. They belong to the class of drugs called vasodilators—drugs that dilate blood vessels, an effective way

TABLE 9-4 Effects of Medications on the Cardiovascular and Metabolic Responses to Exercise

Physiological Response	Specific Example	Medications That Could Alter Response
Cardiac output	Contractility	Increased by digitalis
	Initiation/conduction of cardiac action potential	Decreased by β-blockers
Effects on peripheral circulation	Venodilation or constriction: preload	Decreased by nitrates
	Arterial vasoconstriction or dilation: afterload	Decreased by α_1-antagonists
	Blood volume	Decreased by diuretics
Myocardial oxygen consumption	Heart rate	Decreased by β-blockers
	Blood pressure	Decreased by nitrates
	Systolic wall tension	
Distribution of cardiac output	Blood flow to active skeletal muscles	Decreased by α_1-antagonists
	Blood flow to cutaneous vessels	Decreased by α_1-antagonists
Metabolism	Fatty acid mobilization and oxidation	Decreased by β-blockers
	Glycogenolysis	Decreased by β-blockers

Data from Peel C, Mossberg KA. Effects of cardiovascular medications on exercise responses. Phys Ther. 1995;75:387–396.

to lower blood pressure and increase the supply of blood and oxygen to the heart and various other organs. In addition to dilating blood vessels, angiotensin-converting enzyme (ACE)-inhibiting medications may produce some beneficial effects indirectly by preventing the abnormal rise in hormones associated with heart disease, such as aldosterone. ACE inhibitors are widely used to treat high blood pressure, or hypertension, a major risk factor for cardiovascular disease. Used alone or in combination with other drugs, ACE inhibitors have also proved effective in the treatment of congestive heart failure.

Possible Adverse Side Effects. Common side effects are dizziness or weakness, loss of appetite, a rash, itching, a hacking, unpredictable cough, and swelling.

Antiarrhythmic Drugs. T ese drugs, which are potent medications, correct an irregular heartbeat (arrhythmia) and slow a heart that is beating too fast (tachycardia).

Possible side ef ects. T e most significant common side effects are weakening of heart contractions, worsening of some arrhythmias, weight loss, nausea, and tremors. Other less common effects are fever, rash, dry mouth, depressed white blood cell count, liver inflammation, confusion, loss of concentration, dizziness, and disturbances in vision. About 0.1–0.2% of patients suffer lung inflammation, a potentially serious side effect.

Anticoagulants, Antiplatelets, and Thrombolytics. T ese drugs are sometimes referred to as "blood thinners," but this term is not truly accurate, as they inhibit the ability of the blood to clot—preventing clots from forming in blood vessels and from getting bigger. Anticoagulants, antiplatelet agents, and thrombolytics each have specific indications and uses. Any patient who has had a heart valve replaced with a mechanical valve requires lifelong oral anticoagulants in order to prevent clots from forming on the valve. Patients who develop atrial fibrillation may require anticoagulants; clot formation in the left atrium is a potential hazard of this rhythmic disturbance. Oral anticoagulants are prescribed for patients who develop thrombophlebitis, an inflammation of the veins in the legs or pelvis. One of the dangers of this condition is the development of blood clots that may travel to the lungs and cause pulmonary emboli. Finally, some patients who have a serious heart attack involving the anterior surface of the heart are prescribed an anticoagulant to prevent clots from forming on the inner lining of the scar.

Heparin is an anticoagulant that is administered intravenously when rapid anticoagulation is necessary. All patients undergoing open-heart surgery are treated with heparin while their blood is being oxygenated by the heart–lung machine. At the end of the operation, medication is given to reverse the effects of heparin.

Aspirin is not an anticoagulant but has a profound effect on platelets—blood cells that stick together and cause clots to form. Because of aspirin's ability to inhibit the clotting action of platelets, it is designated as an antiplatelet and is frequently prescribed in patients who have recovered from a heart attack, in order to prevent clots from forming in the veins used for coronary bypass surgery.

T e most recent and exciting classes of drugs that are useful for people with heart attacks are the thrombolytic drugs. T ese agents are given intravenously as soon as possible with the goal of dissolving the offending clot within a coronary artery before it causes permanent, debilitating damage. T e three most commonly used thrombolytics are t-PA, streptokinase, and APSAC.

Possible side ef ects. Adverse effects are rare, but may include nausea, headache, flushing, dizziness or faintness, or rash.

β-Adrenergic Blockers. T ese drugs probably reduce blood pressure by reducing cardiac output (or perhaps by blocking the production of angiotensin). β-blockers are also used to treat hypertension. Specifically, they block responses from the β nerve receptors. T is serves to slow down the heart rate and to lower blood pressure. β-blockers also block the effects of some of the hormones that regulate blood pressure. During exercise or emotional stress, adrenaline and norepinephrine are released and normally stimulate the β-receptors—sensors that transmit messages to the heart to speed up and pump harder. By blocking the receptors, β-blockers act to reduce heart muscle oxygen demands during physical activity or excitement, thus reducing the possibility of angina caused by oxygen deprivation.

Possible side ef ects. Lethargy and cold hands and feet because of reduced circulation may occur. T ese drugs may also cause nausea, nightmares or vivid dreams, and impotence.

Calcium Channel Blockers. Calcium plays a central role in the electrical stimulation of cardiac cells and in the mechanical contraction of smooth muscle cells in the walls of arteries. Calcium channel blockers are relatively new synthetic drugs that work by blocking the passage of calcium into the muscle cells that control the size of blood vessels. All muscles need calcium in order to contract; by preventing the muscles of the arteries from contracting, blood vessels dilate, allowing blood to flow through them more easily, and reducing blood pressure.

Possible side ef ects. Excessively slow heart rate, low blood pressure, headache, swelling of ankle/feet, constipation, nausea, tiredness, dizziness, redness of face and neck, palpitations, and rash.

Digitalis Drugs. Like many drugs, digitalis was originally derived from a plant, in this case, the foxglove. Digitalis has the primary effect of strengthening the force of contractions in weakened hearts and is also used in the control of atrial fibrillation. T e most commonly used digitalis products are digoxin and digitoxin. T e drug penetrates all body tissues and reaches a high concentration in the muscle of the heart. Its molecules bind with cell receptors that regulate the concentration of sodium and potassium in the spaces between tissue cells and in the bloodstream. T ese two minerals determine the level of calcium. Digitalis preparations act by increasing the amount of calcium supplied to the heart muscle and thus enhancing its contractions. Digitalis drugs also affect electrical activity in cardiac tissues. T ey control the rate at which electric impulses are released and the speed of their conduction through the chamber walls. T ese two actions determine the two major uses of digitalis drugs in heart disease—treatment of heart failure and control of abnormal heart rhythms. Digitalis may be given on a short-term basis in acute heart failure or over a long period of time to treat chronic heart failure. Digitalis drugs can be used to treat disturbances of the heartbeat, particularly the abnormally rapid contractions of the

atria referred to as atrial or supraventricular arrhythmias (especially atrial fibrillation). T e drugs restore the normal heartbeat either by interrupting the abnormal rhythm or by slowing down the rapid beats, so that effective and coordinated heart contractions are possible.

Possible side ef ects. Some side effects include tiredness, nausea, loss of appetite, and disturbances in vision.

Diuretics. Diuretics, commonly referred to as water pills, lower blood pressure by increasing the kidney's excretion of sodium and water, which in turn reduces the volume of blood. T ere are several types of diuretics, which are classified according to their site of action in the kidney.

- T iazide diuretics work in the tubules (the structures that transport urine in the kidneys).
- Loop diuretics are more potent than the thiazide diuretics. T ey are so named because they work in the area of the kidney called the loop of Henle. T ey are usually prescribed when a thiazide diuretic proves insufficient or for patients with heart failure or compromised kidney function.
- Potassium-sparing diuretics work in the area of the kidney or distal tubule of the nephrons in the kidney where potassium is excreted. T ey prevent the excessive loss of potassium that sometimes occurs with the thiazides. T ey are most often given in conjunction with a thiazide or loop diuretics.

Possible side ef ects. Although uncommon, lethargy, cramps, rash, or impotence may occur. Some of these effects may be caused by a loss of potassium and may be avoided by including a potassium supplement or potassium-sparing agent in the regimen.

Nitrates. T e oldest and most frequently used coronary artery medications are the nitrates. Nitrates are potent vein and artery dilators, causing blood to pool in the veins and the arteries to open up, thus reducing the amount of blood returning to the heart. T is decreases the work of the left ventricle and lowers the blood pressure. Nitrates may also increase the supply of oxygenated blood by causing the coronary arteries to open more fully, thus improving coronary blood flow. Nitrates effectively relieve coronary artery spasm. T ey do not, however, appear to affect the heart's contractions.

Possible side ef ects. Headaches, flushing, and dizziness may occur.

Pu l MOn ARy Sy STEM PHARMACOl Og y

T e delivery of a drug to the lungs allows the medication to interact directly with the diseased tissue and reduce the risk of adverse effects, specifically systemic reactions, while also allowing for the reduction of dose compared to oral administration. T e prescription of any pulmonary medication is founded on four basic goals:[40]

- Promotion of bronchodilation or relief of bronchoconstriction.
- Facilitation of the removal of secretions from the lungs.
- Improvement of alveolar ventilation or oxygenation.
- Optimization of the breathing pattern.

T e relative importance of each of these goals depends on the specific disease process and the resultant respiratory problem.[40]

Most inhaled drugs are administered through a pressurized metered-dose inhaler. Dry powder inhalers or breath-activated devices are delivery devices that scatter a fine powder into the lungs by means of a brisk inhalation. T e other major drug delivery system for pulmonary problems is the nebulizer, a device that dispenses liquid medications as a mist of extremely fine particles in oxygen or room air, so that is inhaled.

Bronchodilator Agents. Bronchodilator agents are a group of medications that produce an expansion of the lumina of the airway passages of the lungs. T e primary goal of bronchodilator therapy is to influence the ANS via two opposing nucleotides: cyclic adenosine monophosphate (cAMP) and cyclic guanosine monophosphate (cGMP).[40] cAMP facilitates smooth muscle relaxation and inhibits mast cell degranulation, resulting in bronchodilation.[40] cGMP facilitates smooth muscle contraction and may enhance mast cell release of histamine and other mediators, resulting in bronchoconstriction.[40] Bronchodilator agents, which either stimulate (sympathomimetics) or inhibit (sympatholytics) adrenergic receptors, are central to the symptomatic management of chronic obstructive pulmonary disease (COPD) and asthma (Table 9-5).

Ancillary Pulmonary Medications. In addition to bronchodilators, several other drug groups are frequently used in the treatment of respiratory disorders, including decongestants, antihistamines, antitussives, mucokinetics, respiratory stimulants and depressants, and paralyzing and antimicrobial agents.[40]

Antitussives. Antitussives are drugs that suppress an ineffective, dry, hacking cough by decreasing the activity of the afferent nerves or decreasing the sensitivity of the cough center. T e stimulus for a cough is relayed to the cough center in the medulla and then to the respiratory muscles via the phrenic nerve. T e primary adverse effect of antitussive agents is sedation, although GI distress and dizziness may also occur.[40]

Decongestants. Decongestants are used to treat upper airway mucosal edema and discharge by binding with the α-1 receptors in the blood vessels of the mucosal lining of the upper airways thereby stimulating vasoconstriction.[40] Primary side effects include a headache, dizziness, nausea, nervousness, hypertension, and cardiac irregularities.[40]

Antihistamines. Histamines play a role in the modulation of neural activity within the CNS and the regulation of gastric secretion by means of two types of receptors:

- H_1-receptors. T ese are primarily located in vascular, respiratory, and GI smooth muscles and are specifically targeted for blockade by antihistamines in the treatment of asthma. H_1-antagonist drugs decrease the mucosal congestion, irritation, and discharge caused by inhaled allergens. T e adverse effects most often attributable to antihistamines include sedation, fatigue, dizziness, blurred vision, loss of coordination, and GI distress.

TABLE 9-5 Drugs That Have a Positive Influence on Bronchial Intralumenal Diameter

Group	Action	Mechanism of Action	Side Effects
β-sympathomimetics	Bronchodilation	Increases cyclic AMP, decreases intracellular calcium concentrations, thus relaxing smooth muscle	Tremor, palpitations, tachycardia, headache, nervousness, dizziness, nausea, hypertension
Methylxanthines (a substance found in coffee, tea, and chocolate)	Bronchodilation	Blocks the degradation of cyclic AMP Used for patients who do not respond to the standard asthma agents, and is occasionally used in the treatment of spinal cord injury	Agitation, tachycardia, headache, palpitations, dizziness, hypotension, chest pain, nausea, possibly diuresis
α-sympatholytics	Bronchodilation	Blocks the decrease of cyclic AMP	Agitation, tachycardia, headache, palpitations, dizziness, hypotension, chest pain, nausea, possibly diuresis
Parasympatholytics	Prevents bronchoconstriction	Blocks parasympathetic stimulation, which prevents an increase in cyclic GMP, allowing cyclic AMP to increase; blocks the activity of the enzyme phosphodiesterase, which prevents the degradation of cyclic AMP	Central nervous system stimulation with low doses, depression with high doses; delirium, hallucinations, decreased gastrointestinal activity
Glucocorticoids	Bronchodilation	Administered systemically or topically Blocks the release of arachidonic acid from airway epithelial cells, which in turn blocks production of prostaglandins and leukotrienes Decreases inflammatory response	Cushingoid appearance; obesity; growth suppression; hyperglycemia and diabetes, mood changes, irritability, or depression; thinning of skin; muscle wasting; osteoporosis; hypertension; and immunosuppression
Cromolyn sodium (extract of a Mediterranean plant)	Bronchodilation	Prevents influx of calcium ions into the mast cell, thus blocking the release of mediators responsible for bronchoconstriction Used prophylactically to prevent exercise-induced bronchospasm and severe bronchial asthma via oral inhalation	Throat irritation, hoarseness, dry mouth, cough, chest tightness, bronchospasm

AMP, adenosine monophosphate; GMP, guanosine monophosphate.
Data from Cahalin LP, Sadowsky HS. Pulmonary medications. Phys Ther. 1995;75:397–414.

- H_2-receptors. These act via G-proteins (guanine nucleotide binding proteins) to stimulate adenylate cyclase, the enzyme that synthesizes cAMP from adenosine triphosphate (ATP). Among the many responses mediated by these receptors are gastric acid secretion, smooth muscle relaxation, inotropic and chronotropic effects on the heart muscle, and inhibition of lymphocyte function.

Mucokinetics. This class of drugs is responsible for promoting the mobilization and removal of secretions from the respiratory tract.[40] There are four basic types of mucokinetics agents:[40]

- Mucolytics act by disrupting the chemical bonds in mucoid and purulent secretions, decreasing the viscosity of the mucus and promoting expectoration. The primary adverse effects of these drugs include mucosal irritation, coughing, bronchospasm, and nausea.
- Expectorants increase the production of respiratory secretions, thus facilitating their ejection from the respiratory tract.
- Wetting agents make expectoration easier for the patient and are delivered by either continuous aerosol or intermittent ultrasonic nebulization.
- Surface active agents (surfactant) lower the surface tension of the medium in which these are dissolved. They are primarily used to stabilize aerosol droplets thereby enhancing their efficacy as carrier vehicles for nebulized drugs.

Antimicrobial Agents/Antibiotics. Penicillins are the mainstay in the treatment of respiratory infections.[40] First,

second- and third-generation cephalosporins are generally considered as alternatives to the penicillins, when penicillins are not tolerated by the patient or when they are ineffective.[40]

Oxygen

Oxygen should be considered a drug when it is breathed in concentrations higher than those found in the atmospheric air. T e therapeutic administration of oxygen can elevate the arterial oxygen tension and increase the arterial oxygen content, improving peripheral tissue oxygenation.[40] When used judiciously, oxygen therapy has few side effects.

Metabolic and Endocrine System

Physical therapists routinely treat patients who are diagnosed with diabetes mellitus (DM). People with DM are at increased risk of developing chronic complications related to ophthalmic, renal, neurological, cerebrovascular, cardiovascular, and peripheral vascular disease.[41,42] T e major classes of DM are insulin-dependent diabetes mellitus (IDDM), also known as type 1 DM, and noninsulin-dependent diabetes mellitus (NIDDM), also known as type 2 DM, and subclassed as obese or nonobese.[43] Type 1 DM results from autoimmune beta cell destruction, whereas type 2 DM is related to deficiency in insulin production or a condition of insulin resistance. Malnutrition-related DM, gestational DM, and other types of DM associated with specific conditions complete the classification. By its action on carbohydrate, protein, and lipid metabolism, insulin exerts a dominant effect on the regulation of glucose homeostasis.[43] T rough various actions, insulin, a hormone which is secreted by the beta cells of the pancreas, lowers blood glucose by either suppressing glucose release from the liver, or by promoting uptake of glucose into peripheral tissues, especially muscle. Insulin also affects adipose tissue by activating lipogenesis (conversion of glucose into triglyceride).[43] Glucagon, catecholamines, glucocorticoids, and growth hormone act in opposition to insulin by increasing blood glucose.

T e classic intervention approach to DM is the triad of diet (weight management), exercise, and drug therapy.[43] Patients with IDDM require insulin replacement, with diet and exercise completing the treatment plan, whereas patients with NIDDM are often managed by diet and exercise prior to any use of pharmacological agents.

Drugs for Diabetes. Because patients with type 2 (NIDDM) diabetes have both insulin resistance and beta cell dysfunction, oral medication to increase insulin sensitivity is often given with an intermediate-acting insulin at bedtime or a long-acting insulin given in the morning or evening. T e medications prescribed for DM have a variety of actions.

Exercise has the effect of increasing glucose uptake by insulin-sensitive tissues by two mechanisms:[43]

- Increasing blood flow and thus enhancing glucose and insulin delivery to muscle.
- Stimulation of glucose transport by muscle contraction.

In a nondiabetic person, insulin levels fall during acute exercise, and hepatic glucose production rises to meet the demands of the exercising muscle. In a diabetic patient, exercise lowers blood glucose concentration and transiently improves glucose tolerance during acute exercise. T e metabolic response to exercise is based on the fitness level of the individual, the intensity and duration of the exercise, and timing of exercise in relation to insulin administration and meals.[43]

Additional benefits of exercise in a diabetic population include improved whole-body insulin sensitivity, improved glycemic control, reduction of certain cardiovascular risk factors, and an increase in psychological well-being.

ERg Og En IC AID

Ergogenic aid is a term used to describe a broad category of topics including physiologic, pharmacologic, psychologic, and nutritional enhancement.[44] T e most common pharmacologic enhancement used by athletes are anabolic–androgenic steroids, a synthetic derivative of the male hormone testosterone. T e more appropriate term "anabolic–androgenic steroids" is frequently shortened to anabolic steroids.

Anabolic–Androgenic Steroids. T e use of anabolic steroids for nonmedical purposes has been in existence for over 50 years. T ese synthetic agents have a core steroid structure that gives them both anabolic (tissue building) and androgenic (masculinizing) effects, although physiologically these effects are inseparable.[45] Anabolic steroids may be taken orally or parenterally. Orally ingested steroids are well absorbed from the stomach, excreted fairly rapidly from the body because of their short half-lives, are more toxic to the liver than injectable steroids, and are highly potent.[44,46–48] Injectable steroids are characterized by delayed uptake from the body, slower excretion, increased detectability in drug tests for longer periods of time, reduced liver toxicity, and have less potency than oral steroids.[44,46–48]

Studies on the effects of anabolic steroids on muscle strength provide inconsistent results.[44] Muscular strength increases will result from anabolic steroid use only if the following criteria are met:[44,49]

- T e athlete must have been intensively trained in weightlifting immediately prior to the steroid regimen and must continue with intense weightlifting during the steroid regimen.
- T e athlete must maintain a high-protein, high-calorie diet.
- Strength must be assessed with a single repetition, a maximal-weight technique using the specific exercises with which the athlete trains, as opposed to single-joint, isolation-testing techniques.

Weight gain is commonly associated with anabolic steroid use. Whether these gains are reflected in muscle mass increases or fluid retention remains unclear.[44]

Although the potential benefits associated with anabolic steroid use remain questionable, the immediate and long-term side effects are well-established and include:[44]

- increased risk of myocardial infarction and stroke;
- liver toxicity;
- significant decreases in plasma testosterone, testicular atrophy, impotence, prostate enlargement, decreased

sperm counts, and a decrease in testosterone production from the testes;

- gynecomastia, characterized by a subareolar, button-like unilateral or bilateral plaque of tissue, and/or the development of breast tissue;
- increased musculotendinous injury;
- premature closure of the epiphysis in children, resulting in decreased adult height;
- alterations in lipid profiles—a significant rise in total serum cholesterol level and a decrease in high-density lipoprotein (HDL); and
- alterations in mental status including, euphoria, aggressiveness, irritability, nervous tension, changes in libido, mania, depression (with withdrawal from steroids), and psychosis.

Amphetamines

The phenylethylamine structure of amphetamines is similar to catecholaminergic, dopaminergic, and serotonergic agonists (biogenic amines), which may explain their actions, with the clinical presentation being dependent on the type of amphetamine used. For example, methamphetamine lacks much of the peripheral stimulant properties of amphetamine while still offering euphoric and hallucinogenic properties. These actions are similar to those of cocaine; however, while effects of cocaine last for 10–20 minutes, duration of amphetamine action is much longer, lasting as long as 10–12 hours.

The routes of amphetamine administration may be oral (ingestion), inhalation (smoke), or injection (IV). Oral use is associated with an approximate 1-hour lag time before the onset of symptoms, whereas inhaled and IV methods yield effects within a few minutes. Peak plasma concentrations occur within 5 minutes with IV use, 30 minutes with nasal or IM use, and 2–3 hours postingestion.

Central Nervous System. Amphetamine compounds cause a general efflux of biogenic amines from neuronal synaptic terminals (indirect sympathomimetics). They inhibit specific transporters responsible for the reuptake of biogenic amines from the synaptic nerve ending and presynaptic vesicles. Amphetamines also inhibit MAO, which degrades biogenic amine neurotransmitters intracellularly. The net effect is an increase of monoamine neurotransmitter release into the synapse. Physiological adaptation occurs through receptor or coupling down regulation; this tolerance and an accompanying psychological tolerance can lead to escalating use of the drug and increased toxicity. Chronic use can lead to a depletion of biogenic amine stores and a paradoxical reverse effect of the drug—a wash out.

Elevated catecholamine levels usually lead to a state of increased arousal and decreased fatigue. Increased dopamine levels at synapses in the CNS may be responsible for movement disorders, schizophrenia, and euphoria. Serotonergic signals may play a role in the hallucinogenic and anorexic aspects of these drugs.

Other serotonergic and dopaminergic effects may include resetting the thermal regulatory circuits upward in the hypothalamus and causing hyperthermia. The hyperthermia produced by amphetamines is similar to that of the SS.

Peripheral Nervous System. Catecholaminergic (sympathomimetic) effects of amphetamines include inotropic and chronotropic effects on the heart, which can lead to tachycardia and other dysrhythmias. The vasoconstrictive properties of the drugs can lead to hypertension and/or coronary vasospasm.

The serotonergic action of amphetamines on peripheral vasculature can lead to vasoconstriction, which is especially problematic in placental vessels. Animal studies have shown that serotonergic actions of amphetamines effect changes in plasma levels of oxytocin, somatostatin, gastrin, and cholecystokinin.

Patients with amphetamine intoxication often are identified by a change in mental status alone or associated with another injury and/or illness. These changes include disorientation, headache, dyskinesias, agitation, symptoms of stroke, cardiovascular signs and symptoms (chest pain, palpitations), GI problems (dry mouth, nausea and vomiting, diarrhea), genitourinary dysfunction (difficult micturition), and skin changes (diaphoresis, erythematous painful rashes, needle marks, infected deep ulcerations [ecthyma]).

CHAPTER 10 Manual Techniques

CHAPTER OBJECTIVES

At the completion of this chapter, the reader will be able to:

1. Give definitions for commonly used biomechanical terms used in manual therapy (MT).
2. List the criteria that are important for the correct application of a manual technique.
3. Summarize the various types of MT.
4. Describe the importance of knowing the shapes of the various articular surfaces and how that determines the direction of the application of a technique.
5. Apply the knowledge of the various MTs in the planning of a comprehensive rehabilitation program.
6. Recognize the manifestations of abnormal tissue and develop strategies using manual techniques to treat these abnormalities.
7. Categorize the various effects of MT on the soft tissues.
8. Make an accurate judgment when recommending an MT technique to improve joint or muscle function.

OVERVIEW

Touch has always been and continues to be a primary healing modality. The first written records of massage go back to Ancient China, and wall paintings in Egypt depict hands-on healing techniques that go back 15,000 years.[1] From this early "laying on of hands" evolved many of the techniques used today.

The techniques of MT fall under the umbrella of therapeutic touch. MT has become such an important component of the intervention for orthopaedic and neurologic disorders that it is considered by many as an area of specialization within physical therapy.

Of the approaches commonly applied, the Cyriax,[2] Mennell,[3] and osteopathic techniques[4,5] (Table 10-1) originated from physicians, whereas the Maitland,[6,7] Kaltenborn,[8] and McKenzie and May[9] approaches (Table 10-2) were derived by physical therapists.[10–12]

Within these major philosophies, a number of subsets have also emerged, including myofascial release (MFR), positional release techniques, neurodynamic mobilization techniques (see Chapter 11), manually resisted exercise, proprioceptive neuromuscular facilitation (PNF), joint mobilization, and high-velocity thrust (manipulation) techniques.

MT techniques have traditionally been used to produce a number of therapeutic alterations in pain and soft-tissue extensibility through the application of specific external forces to decrease pain and improve motion quality in an area with restriction.[13] Some of these therapeutic alterations may be neurophysiologic and are therefore difficult to clinically assess. Unfortunately, the therapeutic efficacy of many MT techniques remains undetermined. Thus, many of these techniques have not been developed with the same scientific rigor as fields such as anatomy and physiology, and much of their use is based on clinical outcomes, rather than evidence-based proof. There are numerous concerns with determining the validity of studies addressing the efficacy of manual techniques:

- The selection of a particular technique is typically made on an ad hoc basis.
- The strong placebo effect associated with the laying on of hands. Complicating the measurement of outcome and the effectiveness of an MT is the placebo effect (a response resulting from the suggestion that something is beneficial, even though it may be inert). Although MT is not alone in its use of the placebo effect, it is increasingly important that clinicians determine the specific effects of everything they do.[14]
- Many musculoskeletal conditions are self-limiting so that patients may improve with time regardless of the intervention.
- The difficulty of blinding clinicians and subjects to the intervention the subjects are receiving.
- Clear-cut definitions as to when one technique is more efficacious than another are lacking.
- Overreliance on MT techniques to improve a patient's status is a passive approach in an era when patient independence is stressed.

Although it is generally agreed that manual techniques are beneficial for specific impairments, such as a restricted joint glide and adaptively shortened connective tissue, there

TABLE 10-1 Manual Therapy Approach—Physician Generated

	Cyriax (Orthopaedic Medicine) Assertions	Mennell Assertions	Osteopathic Assertions
Philosophy	All pain has an anatomic source and, therefore, all treatment must reach that anatomic source If the diagnosis is correct, the treatment will be of benefit to the source	Dysfunction indicates a serious pathologic process or joint disease Loss of normal joint movement or joint play can lead to dysfunction Joint manipulation can restore normal joint-play movements	Neuromusculoskeletal system is connected with other systems; therefore, disease processes can be evident in musculoskeletal system An abnormality in structure (somatic dysfunction) can lead to abnormal function of related components Manipulative therapy can restore and maintain normal structure and function relationships
Key concepts	Diagnosis of soft-tissue lesions Categorization of referred pain Differentiation between contractile and noncontractile lesions	Assessment of joint play	Diagnosis of somatic dysfunction Examination focuses on presence of asymmetry, restriction of movement, and palpation of soft-tissue texture changes (i.e., palpation of skin, muscle, and other connective tissue for feeling of thickness, swelling, tightness, or temperature change)
History	Observation and history Age and occupation Symptoms (site and spread, onset and duration, and behavior) Medical considerations Inspection	Present complaint Onset Nature of pain Localization of pain Loss of movement Past history Family history Medical systems review	History Knowledge of physical trauma, past history of visceral, and soft-tissue problems Present complaint Establish relationship from patient's history between time and mechanism to adaptation, and decompensation
Physical examination	Active movements Passive movements Resisted movements Neurologic examination Palpation Inspection	Inspection Palpation Examination of voluntary movements Muscle examination Special tests (e.g., roentgenography) Examination of joint-play movements	Postural analysis Regional screening functional units Pelvic girdle Foot Vertebral column Shoulder girdle Hand
Interpretation of evaluation	Identification of anatomic structure associated with lesion	Joint dysfunction	Determination of dysfunction: – Positional fault – Restriction fault Segmental or multisegmental
Treatment strategies	Injection Friction massage Manipulation Mobilization Physical therapy (e.g., exercise and modalities) Patient education	Manipulation Mobilization Physical therapy (e. g., exercise and modalities) Patient education	Manipulation Mobilization Muscle energy Myofascial techniques Counterstrain Exercise therapy Patient education

Data from Di Fabio RP. Efficacy of manual therapy. Phys Ther. 1992;72:853–864.

is less agreement on which technique is the most effective. T e decision about which approach or technique to use has traditionally been based on the clinician's belief, training, the level of expertise, and decision-making processes. T is has led to widespread opinions on which tools to use to measure outcome; how to apply a particular technique in terms of patient setup, intensity, and duration; and how to gauge an individual's response to a technique. Indeed, research studies

TABLE 10-2 Manual Therapy Approach—Physical Therapist Generated

	Maitland (Australian) Assertions	Kaltenborn (Norwegian) Assertions	McKenzie Assertions
Philosophy	Personal commitment to understand patient Consideration and application of theoretical (e.g., pathology and anatomy) and clinical thinking (e.g., signs and symptoms) Continual assessment and reassessment of data	Biomechanical assessment of joint movements Pain, joint dysfunction, and soft-tissue changes are found in combination	Predisposing factors of sitting posture, loss of extension range, and frequency of flexion contribute to spinal pain Patients should be involved in self-treatment
Key concepts	Examination, technique, and assessment are interrelated and interdependent Grades of movement (I–V) Strong emphasis on use of passive movement testing (testing accessory and physiologic joint movements) Differential assessment to prove or disprove clinical working hypothesis	Application of principles from arthrokinematics (e.g., concave–convex rule and close- and open-packed positions) to determine existence of somatic dysfunction Grades of movement (I–III)	During movements of spine, positional change to nucleus pulposus takes place Strong emphasis on use of active motions Flexed lifestyle leads to a more posterior position of nucleus Intervertebral disk is common source of back pain
Evaluation framework	Subjective examination (as defined by Maitland)[14,15] Establish kind of disorder Area of symptoms Behavior of symptoms Irritability Nature Special questions Planning objective examination (as defined by Maitland)[14,15] Physical examination Observation Functional tests Active movements Isometric tests Other structures in plan Passive movements (e.g., special tests, physiologic and accessory joint movements, and relevant adverse neural tissue tension tests) Palpation Neurologic examination Highlight main findings	History ("five-by-five scheme") Immediate case history (e.g., assess symptoms for localization, time, character, etc.) Previous history (e.g., assess for kind of treatment, relief of symptoms, presence of similar symptoms or related symptoms) Social background Medical history Family history Patient's assessment of cause of complaint Physical examination Inspection Function (active and passive movements; testing with traction, compression, and gliding; and resisted tests) Palpation Neurologic tests Additional tests	History Interrogation (e.g., where did pain begin, how, constant or intermittent, what makes it better or worse, previous episodes, and further questions) Posture (sitting and standing) Examination of movement (flexion, extension, and side gliding) Movements in relation to pain Repeated movements Test movements Other tests (e.g., neurologic and other joints)
Evaluation	Initial assessment relates examination findings Behavior of patient's symptoms—pain or stiffness (somewhat analogous to McKenzie's derangement and dysfunction syndrome, respectively) Diagnosis, although no specific structure designated Stage of disorder Stability of disorder Irritability of disorder	Biomechanical assessment (i.e., restriction of joint mobility) and assessment of soft-tissue changes	Diagnosis according to syndrome, as opposed to specific structure Postural syndrome (end range strain on normal tissues) Dysfunction syndrome (adaptive shortening of structure) Derangement syndrome (disturbance of normal anatomic relationship)

seem to agree that the most efficacious approach is a combination of manual techniques with other interventions, such as progressive exercises, the use of therapeutic modalities, and patient education about proper body mechanics, positions, and postures.[15–17] Regardless of which MT technique is used, all patients should undergo a full examination/evaluation before any technique is performed.

CLINICAL PEARL

An absence of evidence does not always mean that there is evidence of absence (of effect), and there is always the risk of rejecting therapeutic approaches that are valid.[18]

CORRECT APPLICATION OF MANUAL TECHNIQUES

Despite the varied approaches and rationales, there is general agreement concerning the criteria for the correct application of a manual technique. These include:[19]

- Knowledge of the relative shapes of the joint surfaces (concave or convex). The concave–convex pattern of arthrokinematics, based on arthrology studies by Maitland,[7] Kaltenborn,[8,20] and MacConaill and Basmajian,[21] have been taught in physical therapy schools in the United States for about 30 years.[22] These patterns describe the roll and slide relationships that naturally occur between two moving articular surfaces, which depends on whether the convex or concave articular surface of the joint is considered the moving segment. For example, if the moving articular surface is convex relative to the other surface, the joint glide occurs in the direction opposite to the osteokinematic movement (angular motion). If, on the other hand, the moving articular surface is concave, the joint glide occurs in the same direction as the osteokinematic movement. It is important to remember that the concave–convex rule was not intended to establish the direction of the manual glide applied to the joint, but merely to describe the arthrokinematic pattern that minimizes the inherent migration of the center of the convex member in the direction of the roll.[22] For example, a number of kinematic studies of the glenohumeral joint appear to conflict with the expected arthrokinematic for concave–convex surface movement by maintaining that the humeral head actually remains nearly stationary or, in fact, translates superiorly when performing 90–120 degrees of shoulder abduction.[23,24] However, the net superior translation of the humeral head is only a few millimeters and is offset by a concurrent inferior slide of the humeral head.[22]
- Duration, type, and irritability of symptoms[6,7] (Table 10-3). This information can provide the clinician with some general guidelines for determining the intensity of the application of a selected technique (see "Indications for MT" later in this chapter).

TABLE 10-3 Indications for Selection of Manual Technique Based on Duration of Symptoms

	Acute	Subacute	Chronic
Muscle energy	Strongly indicated	Strongly indicated	Used to prepare tissue for joint manipulation and prevent recurrence of dysfunction
Joint mobilization	Grades I and II	Grades II and III	Grades III and IV
Joint manipulation	Rarely indicated	Moderate-to-strong indication if muscle energy technique unsuccessful	Strong indication if muscle energy technique ineffective

Data from Ellis JJ, Johnson GS. Myofascial considerations in somatic dysfunction of the thorax. In: Flynn TW, ed. The Thoracic Spine and Rib Cage: Musculoskeletal Evaluation and Treatment. Boston, MA: Butterworth-Heinemann; 1996:211–262.

- **Patient and clinician position.** Correct positioning of the patient is essential both to help the patient relax and to ensure safe body mechanics from the clinician. When patients feel relaxed, their muscle activity is decreased, reducing the amount of resistance encountered during the technique. If appropriate, thermotherapy can be used prior to the treatment to warm the tissues around the joint, improve circulation, and relax the muscles.
- **Position of structure to be treated.** The position of the structure to be treated must be appropriate for the stage of healing, the technique to be applied, and the skill of the clinician. It is recommended that the resting position of the joint be used when the patient has an acute condition, or the clinician is inexperienced. The resting position, in this case, refers to the position that the injured joint adopts, rather than the classic resting (open-packed) position for a normal joint. Other positions for starting the mobilization may be used by a skilled clinician in patients with nonacute conditions. As the treatment progresses, the joint is positioned at or near the end of the available range prior to the application of the mobilization force so as to place the restricting tissue in its most stretched position.
- **Hand placement.** Accurate hand placement is essential for efficient stabilization and for the accurate transmission of force. The hand should conform to the area being treated so that the forces are spread over a larger area. This larger contact surface is more comfortable for the patient. Typically, the proximal bone is stabilized using the clinician's hands, a belt, or an assistant, and the distal bone is moved.

CLINICAL PEARL

A gentle and confident touch inspires confidence in the patient.

- **Specificity.** Specificity refers to the exactness of the procedure and is based on its intent. Whenever possible, the forces imparted by a technique should occur at the point where they are needed. The clinician should check one joint at a time, one movement at a time.
- **Direction and type of force.** The treatment force is applied as close to the opposing joint surface as possible. This necessitates that the clinician be able to identify anatomical landmarks as guides. Distraction techniques are perpendicular to the treatment plane, whereas gliding techniques are applied parallel to the treatment plane. When possible the clinician should work with the force of gravity rather than against it. The direction of the force can be either direct, which is toward the motion barrier or restriction,[25] or indirect, which is away from the motion barrier or restriction.[26,27] Although the rationale for a direct technique is easy to understand, the rationale for using an indirect technique is more confusing. A good analogy is a stuck drawer that cannot be opened. Often the movement that eventually frees the drawer is an inward motion, followed by a pull.[19]
- **The amount of force.** The amount of force used depends on the intent of the manual procedure and a number of other factors, including but not limited to

TABLE 10-4 Appropriate Technique Based on Barrier to Motion and End-Feel

Barrier	End-Feel	Technique
Pain	Empty	None
Pain	Spasm	None
Pain	Capsular	Oscillations
Joint adhesions	Early capsular	Passive articular motion stretch
Muscle adhesions	Early elastic	Passive physiologic motion stretch
Hypertonicity	Facilitation	Hold–relax
Bone	Bony	None

  - the age, sex, and general health status of the patient;
  - the barrier to motion and end-feel (stage of healing) (Table 10-4); and
  - the type and severity of the movement disorder.
- **Reinforcement of any gains made.** It has been demonstrated that movement gained by a specific manual technique performed in isolation will be lost within 48 hours, if the motions gained are not reinforced.[28] Thus, the motions gained by a manual technique must be reinforced by both the mechanical and the neurophysiologic benefits of active movement, self-stretching, automobilization, and functional activities using the new range.[29] These active movements must be as precise as possible to the involved segment or myofascial structure.

Reassessment is an integral part of any intervention. The clinician must be able to gauge how effective a technique has been so that necessary modifications can be made. Measurement procedures used by the clinician to determine the effectiveness of manual intervention must adequately reflect changes in pain level, impairments, and functional ability. Although measurements of range of motion (ROM), pain, and strength are valid and reliable,[30–32] the functional measurement selected should be related to the particular functional limitation that the clinician is expecting to change with the intervention.[33]

INDICATIONS FOR MT

MT is indicated in the following cases:

- Mild musculoskeletal pain
- A nonirritable musculoskeletal condition demonstrated by pain that is provoked by motion, but that disappears very quickly
- Intermittent musculoskeletal pain
- Pain reported by the patient that is relieved by rest
- Pain reported by the patient that is relieved or provoked by particular motions or positions
- Pain that is altered by changes related to sitting or standing posture

CONTRAINDICATIONS TO MT

Contraindications to MT include those that are absolute contraindications and those that are relative.[34,35]

Absolute

- Systemic or localized infection (e.g., osteomyelitis), febrile state
- Acute circulatory condition
- Malignancy
- An open wound at the treatment site, or sutures over the treatment site
- Recent fracture
- Hematoma
- Hypersensitivity of the skin
- Inappropriate end-feel (spasm, empty, and bony), or evidence of joint ankylosis, or joint hypermobility
- Advanced diabetes
- Rheumatoid arthritis (in a state of an exacerbation)
- Cellulitis
- Constant, severe pain, including pain at rest or that disturbs sleep, indicating that the condition is likely to be very irritable or in the acute stage of healing
- Extensive radiation of pain
- Any condition that has not been fully evaluated

Relative

- Joint effusion or inflammation
- Rheumatoid arthritis (not in a state of an exacerbation)
- Presence of neurologic signs
- Osteoporosis
- Pregnancy, if a technique is to be applied to the spine
- Dizziness
- Steroid or anticoagulant therapy

SOFT-TISSUE TECHNIQUES

Soft-tissue techniques can address multiple structures simultaneously to include, but are not limited to muscles, tendons, ligaments, fascia, and/or venous lymphatic structures.[13] Increasing the length of tissue, breaking up fibrous scar tissue, breaking up adhesions, remodeling of collagen fibers, increasing circulation, and improving venous function and/or lymphatic function, decreasing pain, can all be included as goals for soft-tissue mobilization.[13]

Transverse Friction Massage

Transverse friction massage (TFM) is a technique devised by Cyriax, whereby repeated cross-grain massage is applied to a muscle, tendon, tendon sheath, or ligament. TFM has long been used by physical therapists to increase the mobility and extensibility of individual musculoskeletal tissues, and to help prevent and treat inflammatory scar tissue.[2,36–41]

CLINICAL PEARL

TFM is indicated for acute or subacute ligament, tendon, or muscle injuries; chronically inflamed bursae; and adhesions in ligament or muscle, or between tissues. TFM also can be applied before performing a manipulation or a strong stretch to desensitize and soften the tissues.

TFM is contraindicated for acute inflammation, hematomas, debilitated or open skin, and peripheral nerves, and in patients who have diminished sensation in the area.

TFM is purported to have the following therapeutic effects:

- *Traumatic hyperemia.*[2] According to Cyriax, longitudinal friction to an area increases the flow of blood and lymph, which, in turn, removes the chemical irritant by-products of inflammation. In addition, the increased blood flow reduces venous congestion, thereby decreasing edema and hydrostatic pressure on pain-sensitive structures.
- *Pain relief.* The application of TFM stimulates type I and II mechanoreceptors, producing presynaptic anesthesia. This presynaptic anesthesia is based on the gate theory of pain control (see Chapters 3 and 8). However, if the frictions are too vigorous in the acute stage, the stimulation of nociceptors will override the effect of the mechanoreceptors, causing the pain to increase. Occasionally, the patient may feel an exacerbation of symptoms following the first two or three sessions of the massage, especially in the case of a chronically inflamed bursa.[42] In these cases, it is important to forewarn the patient.
- *Decreasing scar tissue.* The transverse nature of the friction assists with the orientation of the collagen in the appropriate lines of stress and also helps produce hypertrophy of the new collagen. Given the stages of healing for soft tissue (see Chapter 2), light TFM should only be applied in the early stages of a subacute lesion, so as not to damage the granulation tissue. These gentle movements theoretically serve to minimize cross-linking and so enhance the extensibility of the new tissue. Following a ligament sprain, Cyriax recommends immediate use of gentle TFM to prevent adhesion formation between the tissue and its neighbors, by moving the ligamentous tissue over the underlying bone.[2]

The application of the correct amount of tension to a healing structure is very important. The tissue undergoing TFM should, whenever possible, be positioned in a moderate but not painful stretch. The exception to this rule is when applying TFM to a muscle belly, which is usually positioned in its relaxed position.[2,43] Lubricant is not typically used with the application of TFM. However, ultrasound can be applied to a tissue before TFM.

Beginning with light pressure, and using a reinforced finger (i.e., middle finger over the index finger), or thumb, the clinician moves the skin over the site of the identified lesion back

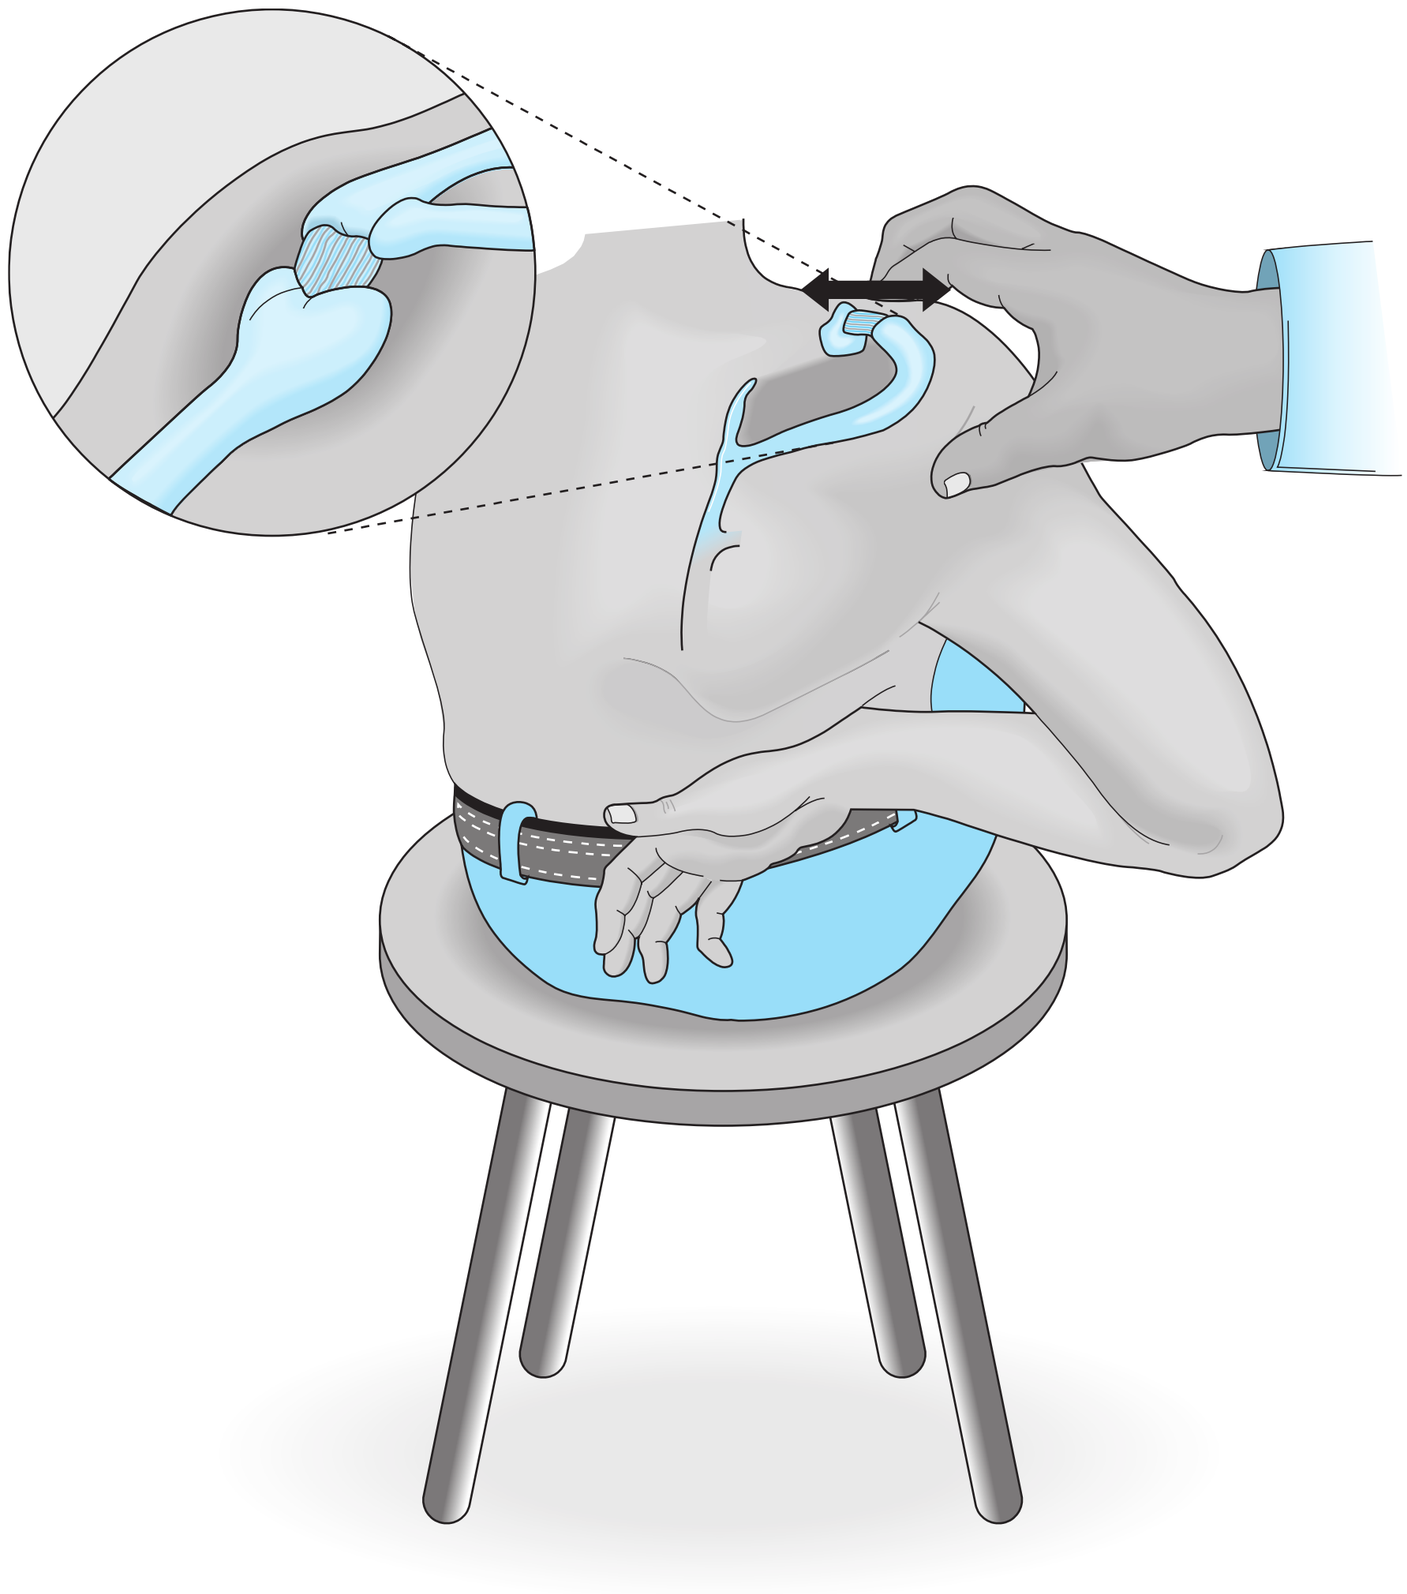

FIGURE 10-1 Transverse friction to the supraspinatus tendon. The tendon is brought into a more sagittal position just below the anterior acromion by placing the patient's hand behind the back. The forefinger of the clinician is reinforced by the middle finger while applying the massage perpendicular to the tendon fibers, in an anterior-posterior direction.

and forth, in a direction perpendicular to the normal orientation of its fibers (Fig. 10-1). It is important that the patient's skin move with the clinician's finger to prevent blistering.

CLINICAL PEARL

The application of TFM is condition and patient dependent. The intensity of the application is based on the stage of healing. The pain induced by TFM should be kept within the patient's tolerance. Light pressure should be used in the early stages, before building up the pressure for a few minutes to allow for accommodation.

The amplitude of the massage should be sufficient to cover all of the affected tissue, and the rate should be at two to three cycles per second, applied in a rhythmical manner.

The duration of the friction massage is usually gauged by when desensitization occurs (normally within 3–5 minutes). Tissues that do not desensitize within 3–5 minutes should be treated using some other form of intervention. If the condition is chronic or in the remodeling stage of healing, then the frictions are continued for a further 5 minutes after the desensitization, in an effort to enhance the mechanical effect on the cross-links and adhesions. Following the application of TFM, the involved tissue is either passively stretched or actively exercised, taking care not to cause pain.

Most conditions amenable to TFM should resolve in 6–10 sessions over 2–8 weeks. When possible, patients should be taught how to apply TFM on themselves so that treatments can be continued at home. Tissues that do not show signs of improvement after three treatment sessions should be treated using some other form of intervention.

Myofascial Release

MFR is a series of techniques designed to release restrictions in the myofascial tissue and is used for the treatment of soft-tissue dysfunction. The development of a holistic and comprehensive approach to the evaluation and treatment of the myofascial system of the body is credited to John Barnes, who was strongly influenced by the teachings of Mennell[44] and Upledger and Vredevoogd.[45]

CLINICAL PEARL

Fascia is a tough connective tissue, composed of collagen, elastin, and a viscous gel, that exists in the body in the form of a continuous three-dimensional web organized along the lines of tension imposed on the body (see Chapter 1).[46]

According to myofascial theory, the collagen provides strength to the fascia, the elastin gives it its elastic properties, and the gel functions to absorb the compressive forces of movement. Three types of fascia are considered to exist (see Chapter 1):[35,46]

1. Superficial, lying directly below the dermis.
2. Deep, surrounding and infusing with muscle, bone, nerve, blood vessels, and organs to the cellular level.
3. Visceral, which is the deepest layer comprising the dura of the craniosacral system, which encases the central nervous system and brain (see Chapter 3).

The theory of MFR is based on the principle that trauma or structural abnormalities may create inappropriate fascial strain, because of an inability of the deep fascia to absorb or distribute the forces.[46] These strains to the deep fascia can result in a slow tightening of the fascia, causing the body to lose its physiologic adaptive capacity.[46] Over time, the deep fascial restrictions begin to pull the body out of its three-dimensional alignment, causing biomechanically inefficient movement and posture.[46] In addition, because of the association of the deep fascia at the cellular level, it is theorized that trauma to or malfunction of the fascia can lead to poor cellular efficiency, disease, and pain throughout the body.[35,46] Three theoretical models for the manifestation of myofascial dysfunction are a contraction, contracture, and cohesion–congestion (Table 10-5).

Thus, the purpose of MFR techniques is to apply a gentle sustained pressure to the deep fascia, in order to release fascial restrictions, thereby restoring normal pain-free function.[35] Clinicians use the elbow, knuckle, or fingertips creating localized hyperemia through deep friction. MFR relies entirely on the feedback received from the patient's tissues, with the clinician interpreting and responding to the feedback. This feedback is based on the Upledger concept of the natural body rhythm, called the craniosacral rhythm.[45] It is this rhythm that is theorized to guide the clinician as to the direction, force, and the duration of the technique.

It is not unusual for a patient to experience muscle soreness following MFR techniques. This soreness is thought to result from postural and alignment changes or from the techniques themselves.

Myofascial Stroking

The soft-tissue techniques used in MFR are purported to break up cross-restrictions of the collagen of the fascia. Three of the more commonly used techniques involve stroking maneuvers:[35]

- J stroke. This technique is used to increase skin mobility. Counterpressure is applied with the heel of the hand, while a stroke in the shape of the letter J is applied in the direction of the restriction, with two or three fingers, which creates some torque at the end of the stroke.
- Vertical stroke. The purpose of vertical stroking is to open up the length of vertically oriented fascia. As in the J stroke, counterpressure is applied with one hand, while the stroking is performed with the other.
- Transverse stroke. As its name suggests, the transverse stroke is applied in a transverse direction to the body. Force is applied downward into the muscle with the fingertips of both hands, and the force is applied slowly and perpendicular to the muscle fibers.
- Cross-hands technique. The cross-hands technique is used for the release of deep fascial tissues. The clinician places crossed hands over the site of restriction. The elastic component of the fascia is then stretched until the barrier is met. At this point, the clinician maintains a consistent, gentle pressure at the barrier for approximately 90–120 seconds. Once the release is felt, the clinician reduces the pressure.

It is important to remember that the claimed benefits and effectiveness of MFR techniques are largely anecdotal because at the time of writing there is no scientific experimental research to validate these claims.

Soft-Tissue Mobilization

Soft-tissue mobilizations (STMs) are used in many of the manual techniques described within this chapter, including MFR, muscle energy (ME), and PNF. The techniques of STM are based on the concept that tissue restrictions occur at different layers, ranging from superficial to deep.

The general principles behind STM are that the superficial layers are treated before deep layers, with the force used

TABLE 10-5 Theoretical Models for the Manifestation of Myofascial Disorders

Model	Manifestation	End-Feel
Contraction	Muscle hypertonicity or spasm	Reactive, firm, and painful end-feel
Contracture	Inert or noncontractile tissues that have undergone fibrotic alteration	Abrupt, firm, stiff, or hard end-feel
Cohesion–congestion	Fluidochemical changes in microcellular transport systems, resulting in impairment	Boggy, stiff, or reactive end-feel lymphatic flow, vascular stasis, or ischemia

Data from Ellis JJ, Johnson GS. Myofascial considerations in somatic dysfunction of the thorax. In: Flynn TW, ed. The Thoracic Spine and Rib Cage: Musculoskeletal Evaluation and Treatment. Boston, MA: Butterworth-Heinemann; 1996:211–262.

applied in the direction of the maximum restriction, and where the choice of technique is dependent on the extent of the restriction, amount of discomfort, and degree of irritability. Deep tissue massage is recommended to reduce spasm[47] and promote pain reduction.[48] Several well-recognized STM techniques are described next.[49]

Sustained Pressure

T is technique is applied to the center of the restricted tissue at the exact depth, direction, and angle of the maximal restriction. T e sustained pressure technique can be modified by applying a force in either a clockwise or a counterclockwise direction while maintaining the sustained pressure. T is spiral motion increases the tissue tension in one direction while easing it in the other. Sustained pressure can also be applied perpendicular or parallel to the restriction.

Ischemic Compression

Ischemic compression, a similar technique to sustained pressure, can be used on both active and inactive trigger points. It is believed that the ischemic compression deprives the trigger points of oxygen, rendering them inactive and breaking the cycle of pain–spasm–pain. Usually, the pressure is applied for 8–12 seconds. If the patient reports a lessening of local and referred pain, the clinician can repeat the treatment. However, if the pain does not lessen, the clinician may need to adjust the pressure or choose an alternative technique.

General Massage

Massage can be defined as the systematic, therapeutic, and functional stroking and kneading of the body.[50] T e French are credited with the introduction of massage, and many of the terms associated with massage still bear French names. Massage has long been a central part of the physical therapy curriculum. Studies have demonstrated that deep massage increases the circulation and skin temperature of the massaged area, as a result of dilation of the capillaries.[51–54] A number of traditional massage techniques are used, including:

- Ef eurage. T is is a general stroking technique applied to the muscles and soft tissues in a centripetal direction (from distal to proximal), to enhance relaxation and increase venous and lymphatic drainage. T e clinician applies a firm contact with the patient using the palms of the hand and, at the end of the stroke, lifts the hands from the patient's skin and replaces them at the starting position.[55] Oil or cream can be used to aid the stroking.
- Stroking. Stroking techniques are applied superficially along the whole length of a surface. T ese techniques are typically applied previous to the deeper techniques of massage to enhance relaxation.[54]
- Petrissage. T is term is used to describe a group of techniques that involve the compression of soft-tissue structures and include kneading, wringing, rolling, and picking-up techniques, to release areas of muscle fibrosis and to "milk" the muscles of waste products that collect from trauma or abnormal inactivity.[56]
- Strumming. T e technique of perpendicular strumming involves the application of repeated, rhythmic deformations of a muscle belly in a strumming fashion.

Acupressure

Acupressure is based on the ancient arts of shiatsu and acupuncture, involving manual pressure over the acupuncture points of the body, to improve the f ow of the body's energy, known as Qi. T is energy is thought to circulate throughout the body along a series of channels, called meridians. Traditional Eastern medicine is based on the concept that all disorders are ref ected at specific points, either on the skin surface or just beneath it, along these channels. By careful manipulation of these points, the clinician can theoretically strengthen, disperse, or calm the Qi, enabling it to f ow smoothly.[57] Modern acupressurists use traditional meridian acupuncture points; nonmeridian or extrameridian acupuncture points, which are fixed points not necessarily associated with meridians; and trigger points, which have no fixed locations and are found by eliciting tenderness at the site of most pain.[58] When acupressure is applied successfully, the patient is supposed to experience a sensation known as teh chi, defined as a subjective feeling of fullness, numbness, tingling, and warmth with some local soreness and a feeling of distention around the acupuncture point.[58] Western scientific research has proposed a number of mechanisms for the effect of acupressure on relieving pain, as follows:

- T e gate control theory of pain (see Chapter 3).
- Diffuse noxious inhibitory control. T is theory implies that noxious stimulation of heterotopic body areas modulates the pain sensation originating in areas where a subject feels pain.[58]
- Stimulation of the production of endorphins, serotonin, and acetylcholine in the central nervous system, which enhances analgesia.[59–67]

Muscle Energy

T e origin of ME techniques is credited to Fred Mitchell, Sr.[68] ME techniques combine the precision of passive mobilization, with the effectiveness, safety, and specificity of reeducation therapies and therapeutic exercise.[69]

CLINICAL PEARL

Muscle energy techniques require the active participation of the patient and are thus viewed as mobilization techniques, which utilize muscular facilitation and inhibition.[70]

ME techniques, which involve positioning a restricted muscle–joint complex at its restricted barrier, can be used to mobilize joints, strengthen weakened muscles, and stretch adaptively shortened muscles and fascia. Optimal success with these techniques is more likely in the acute or subacute stages of healing before prolonged joint changes have had the opportunity to occur.

According to the teachings of ME, muscles function as f exors, extensors, rotators, and side benders of joints, as well

as being restrictors or barriers to movement. In other words, muscles both produce and control motion. Although it is obvious that muscles produce motion, it is easy to forget that they also resist motion. T is resistance to motion is related to muscle tone, a complex neurophysiologic state governed by both cortical and spinal ref exes and by the afferent activity from the articular and muscle systems. Afferent input from types I and II mechanoreceptors located in the superficial and deep aspects of the joint capsule is projected to the motor neurons (see Chapter 3). Exaggerated spindle responses are provoked by any motions that attempt to lengthen the muscle, creating an increase in resistance to those motions. Stretching or lengthening of the muscle also stimulates the Golgi tendon organs, which have an inhibitory inf uence on muscle tension, leading to muscle relaxation. In addition, it has been demonstrated that cutaneous stimulation of certain areas of the body can produce inhibition or excitation of specific motor neuron pools.[71]

It is theorized that the neuromuscular system is "scarred" by pain and impairment, producing asymmetry in the musculoskeletal system and resulting in a disruption of the harmony and rhythm of the body, referred to as somatic dysfunction.[69] Somatic dysfunctions can be described or named in one of three ways:[25]

1. T e direction of increased freedom of motion.
2. T e position of the lesion.
3. T e direction of limitation of motion.

In the presence of a somatic dysfunction, there is usually an asymmetric pattern of motion, with restriction in one direction and increased freedom in the opposite direction.[25] T e triad of ART (asymmetry, range of motion restriction or barrier, and tissue texture)[27] helps to describe the characteristics of somatic dysfunction. Primary somatic dysfunctions, which may result from trauma, are reversible, as long as they are treated correctly and do not become chronic in terms of abnormal fibrosis or adhesions. Secondary somatic dysfunctions result from the consequences of visceral pathology, or from the adaptations made by somatic structures in response to forces or stresses imposed on them.

T e consequence of a somatic dysfunction can be a change in the length of the tissues that surround a joint. Some of these tissues adaptively shorten, whereas others adaptively lengthen. T ese changes in length are theorized to produce changes in the neurophysiologic makeup of the muscle, affecting tension development, as well as changes in the angle of pull.

T ere is some commonality between ME and several procedures used in orthopaedic MT, such as PNF.[72] Greenman[27] summarizes the requirements for the correct application of ME techniques to be control, balance, and localization.

- T e technique, which involves a controlled effort in a controlled direction, commences from a controlled position. Eccentric, concentric, and isometric contractions, at varying levels of effort, are used in ME, within a range of movement controlled by the clinician.
- T e clinician balances the degree of force used, depending on the intention.
- T e force used is localized as much as possible to the joint in question. T e localization of force is more important than the intensity of the force.

T e intent of ME is to treat somatic dysfunctions by restoring the muscles around a joint to their normal neurophysiologic state, through either stretching or strengthening the agonist and antagonist. Somatic dysfunctions include those in which the motion barrier is encountered before the physiologic barrier is reached.[69] T e type of motion barrier is determined by the end-feel (see Chapter 4).

A normal end-feel would indicate normal range, whereas an abnormal end-feel would suggest abnormal range, either hypomobile or hypermobile, with the latter characterized by a loss of end-feel resiliency and an abrupt approach to the anatomic barrier. All ME techniques are classed as direct techniques because they engage the barrier.[26] Indirect techniques form the basis for the strain–counterstrain (positional release) techniques,[73] and the functional techniques,[74–76] both of which are discussed later.

T e position of the clinician during the performance of the technique must allow easy access to the structures involved while maintaining proper body mechanics. In each of the recognized methods of ME, the setup is identical. T e clinician positions the bone or joint so that the muscle group to be used is at its resting length. T e patient is then given specific instructions about the direction in which to move, the intensity of the contraction, and the duration of the contraction.[72,77–79] T e amounts of force and counterforce are governed by the length and strength of the muscle group involved, as well as by the patient's symptoms.[77] T e clinician's force can match the effort of the patient, thus producing an isometric contraction and allowing no movement to occur, or it may overcome the patient's effort, thus moving the area or joint in the direction opposite to that in which the patient is attempting to move it, thereby incorporating an eccentric or isolytic contraction.[72] T ere appears to be no consensus as to whether to use the relaxation of the agonist or the antagonist to gain motion.[27,70,80–82]

Strain–Counterstrain (Positional Release)

Strain–counterstrain is a passive positional technique used in the treatment of musculoskeletal pain and related somatic dysfunction. According to strain–counterstrain theory, myofascial tender points (Fig. 10-2) are located and then monitored during which a position of comfort, or ease, is established to evoke a therapeutic effect.[73,83,84] It is worth noting that to date no experimental studies have been published to confirm the existence of these tender points or the effectiveness of strain–counterstrain.

A possible neurophysiologic explanation of how and why these techniques work was first suggested by Korr,[85] who postulated that an injured joint and its related tissues behaved differently from those of an uninjured joint in that the γ motor neuron activity in the former became increased. Bailey[86] later refined the theory by suggesting that an inappropriate high "gainset" of the muscle spindle (see Chapter 3) resulted in changes characteristic of somatic dysfunction.[87] T us, the techniques of strain–counterstrain appear to serve to effect the muscle spindle–γ loop, by allowing the extrafusal muscle fibers to lengthen to their normal relaxed state, thereby decreasing spindle output and interrupting the pain–spasm cycle.[87–89] Strain–counterstrain is also thought to improve blood f ow to the area through a circulatory f ushing of previously ischemic tissues.[88,90]

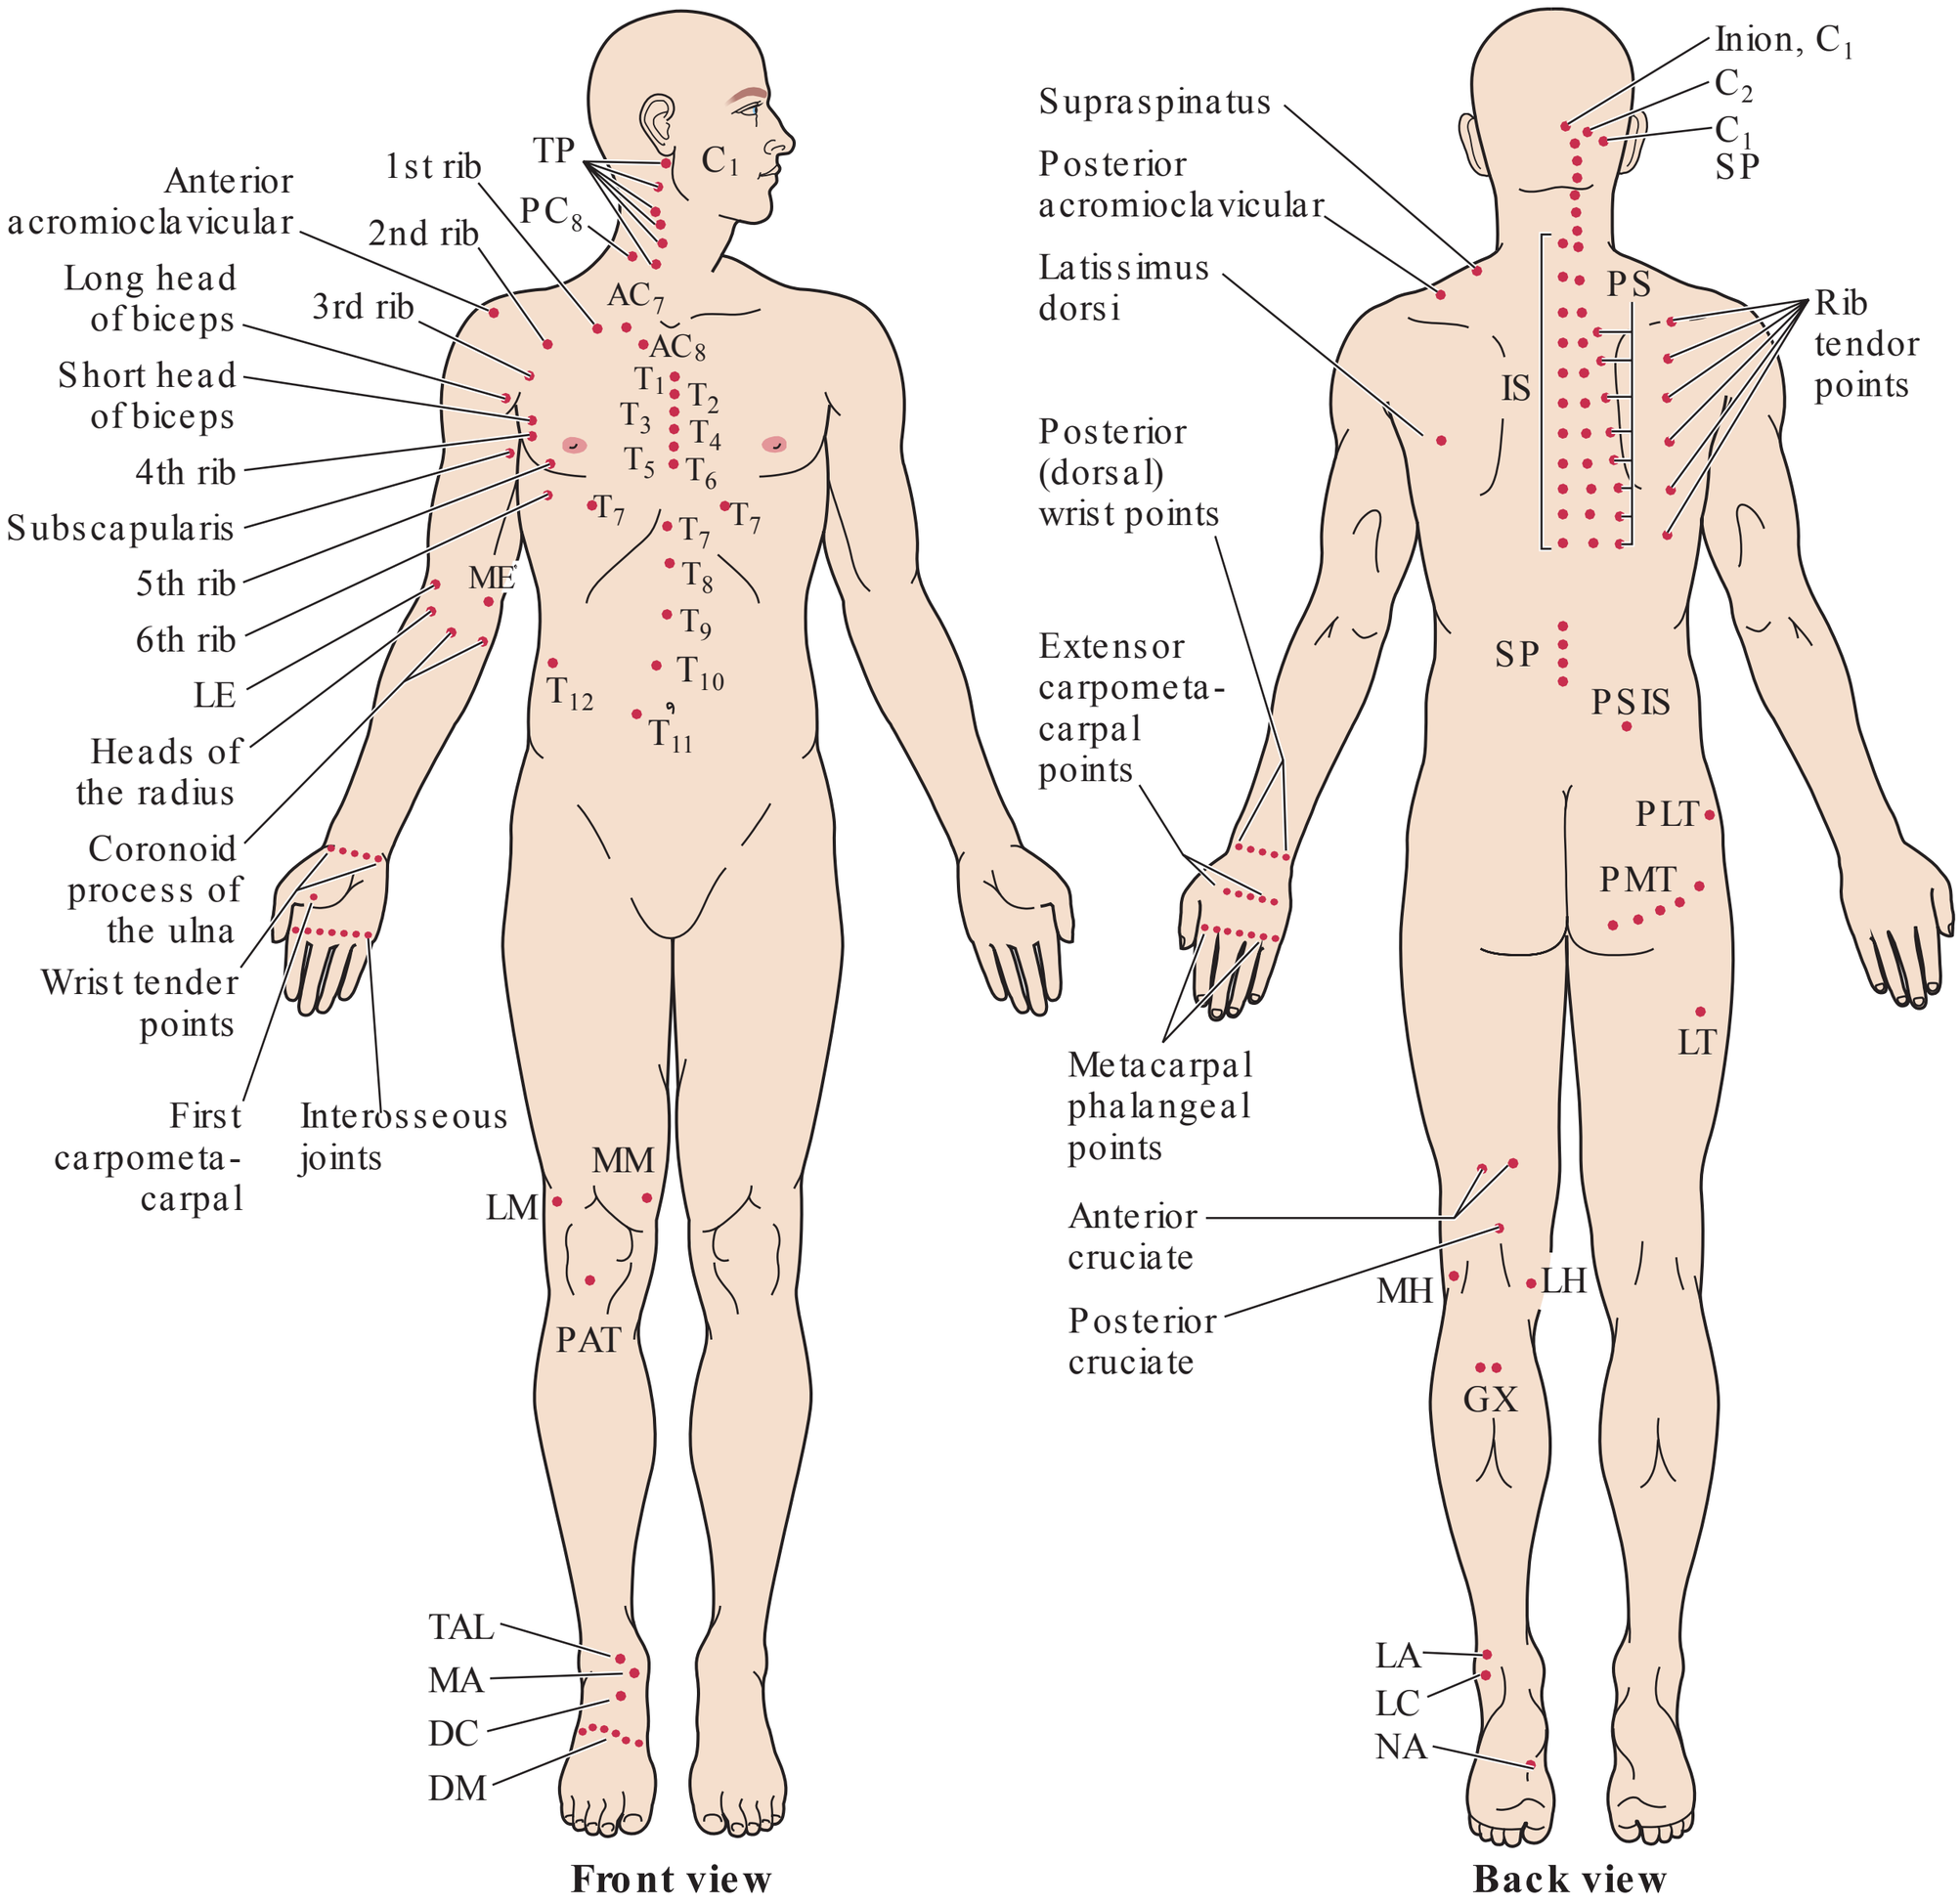

FIGURE 10-2 Strain–counterstrain tender points of the body. AC, anterior cervical; PC, posterior cervical; LH, lateral hamstring; MH, medial hamstring; GX, gastrocnemius; LA, lateral ankle; LC, lateral calcaneal; NA, navicular; LT, lateral trochanter; SP, spinous process; TP, transverse process; PS, paraspinal; LE, lateral epicondyle; ME, medial epicondyle; LM, lateral meniscus; MM, medial meniscus; PAT, patella; TAL, talus; MA, medial ankle; DC, posterior (dorsal) cuboid; DM, posterior (dorsal) metatarsal; IS, interspinal; PSIS, posterior superior iliac spine; PLT, posterolateral trochanteric; PMT, posteromedial trochanteric.

CLINICAL PEARL

The skill and success of strain–counterstrain techniques relies on the ability of the clinician to find the tender point and then to position, or move, the patient in such a way as to release muscular tension as well as relieve pain.[88]

When treating the spine, the first step in the examination procedure is a modification of the sagittal posture of the patient to produce a flattening of the lordosis–kyphosis in the region to be examined.[87] In the extremities, the body part is placed in a position of relaxation. This is position *of* ease (mobile point), which involves a shortening or folding of the tissues around the myofascial tender point, usually corresponds to the point of maximum relaxation. Any movement from this position produces an increase in tissue tension under the monitoring hand at the selected tender point site.[73,83,84] Tissue texture abnormalities and areas of tenderness are then sought. The position of greatest resistance and pain is usually the position that is directly related to that of the original mechanism of injury; thus, the position of ease is usually opposite to that direction. For example, if an ankle sustained an inversion injury, the position of comfort is likely to be in eversion. In most cases, the tender point will be in, or near, the area of discomfort. Once the correct position is achieved, it is then maintained for 90–120 seconds before the patient returns slowly to the normal position.[73] For example, if the biceps are being treated, the tender point is monitored, while the elbow is flexed, and the forearm is simultaneously pronated. If the

muscle is being moved in the correct direction, the tenderness should lessen. Slight adjustments from the recommended positions in this text may be needed. If there is more than one tender point, the clinician treats each one at a time, until the dominant one is found.

Once the tender point has been successfully removed, the clinician should focus on lengthening and/or strengthening the involved muscle.

Functional Techniques

Functional techniques are indirect techniques that use positional placement away from the restrictive barrier, similar to the techniques previously described for strain–counterstrain. T e functional techniques were developed in the osteopathic profession in the 1950s, and much credit is given to Dr. Andrew Taylor Still[91] for identifying the dysfunctions that are treated with these techniques.[74,92] Still considered the somatic lesion to be a mechanical involvement of the structure, and his teachings placed primary emphasis on pertinent anatomy, with palpation used to identify the position and arrangement of a particular structure.[75]

Although the term *f*unctional technique is itself somewhat of a misnomer, the criterion that distinguishes functional techniques from most manual techniques is the emphasis on moving the joint being treated away from, rather than toward, the restrictive barrier. As in the case of strain–counterstrain techniques, the joint in question is moved toward the normal physiologic barrier, at the opposite end of the ROM to that of the restriction.

According to functional technique theory, there is a dynamic balance point located between the restrictive barrier and the opposite physiologic barrier, which is the joint position in which the tensions in the soft tissues around the joint become balanced equally in all three planes. If this balance is achieved, the clinician can detect a sense of "ease" under his or her palpating fingers. It is the deep segmental tissues, which support and position the bones of a segment, and their reaction to normal motion demands, that are at the heart of functional technique specificity.[93] If motion in any plane is initiated away from the dynamic balance point, the soft-tissue tension around the treated segment increases, and there will be an increased sense of palpatory tension, or "bind."[94]

Two theories have been proposed to explain the beneficial effects of these techniques[94]:

1. T e afferent input from the proprioceptors is inhibited, which, in turn, suppresses the local protective cord ref exes.
2. T e techniques stimulate the mechanoreceptors sufficiently to inhibit the pain receptors, allowing the tissues to relax.

Once the patient has been positioned correctly, the clinician can use one of two intervention options:

1. Active. In this method, the clinician initiates movement along the path of least resistance through the sequential release of any soft-tissue tension that occurs, until the restrictive barrier is no longer detectable, and normal motion is regained.
2. Passive. In this method, the clinician follows the articular unwinding through sequential releases of the treated joint to the point of full soft-tissue release, until the restrictive barrier is no longer detectable, and normal motion is regained.

Craniosacral Therapy

Craniosacral therapy (CST) is an alternative, complementary MT practiced throughout the United States and around the world by osteopathic and chiropractic physicians; physical, occupational, and massage therapists; and dentists.[95] CST is based on the assumption that cranial bone movement occurs through a respiratory mechanism comprising the brain, cerebrospinal f uid (CSF), intracranial and intraspinal membranes, cranial bones, spinal cord, and sacrum.[96] CST practitioners are of the opinion that restrictions, misalignments, immobility of the cranial sutures, and tension of the intracranial meninges directly impact the health of an individual. In addition, practitioners of CST claim that they can identify alterations in the movement patterns of the sacrum and the cranial sutures through manual palpation. Palpation of the cranium theoretically allows the clinician to perceive the rhythmic impulse resulting from the widening and narrowing of the skull.[95] However, the reliability reports of identifying the rhythmic movement of the sutures using palpation have ranged from worse than a chance to fair.[95,97] CST is also based on the existence of articular mobility at the cranial bones. According to CST practitioners, 5–10 g of force is recommended to manipulate human sutures. Despite the number of studies and the strong claims made by researchers from a variety of fields regarding the mobility of the cranial bones the research on cranial bone motion done to date is far from conclusive.[95] In a study by Downey et al.,[95] a rabbit model underwent incrementally increasing forces through the skull. Movement within the coronal suture did not occur until 500 g of force was applied. Furthermore, forces up to 22 kg were required to cause 1 mm of movement.[95]

It has been suggested that based on the lack of credible evidence, CST should be abandoned as a viable rehabilitative theory (i.e., that cranial sutures move), until such time that the advocates of CST contribute well-designed studies evaluating the efficacy of these techniques to the peer-reviewed literature.[97]

JOINT MOBILIZATIONS

Joint mobilization techniques include a broad spectrum, from the general osteokinematic passive motions (see Chapter 1) performed in the physiologic cardinal planes at any point in the joint range to the semi-specific and specific accessory (arthrokinematic) joint glides (see Chapter 1), or joint distractions, initiated from the open-packed position of the joint.

T ese techniques form the cornerstone of most rehabilitative programs and involve low–high velocity passive movements within or at the limit of joint ROM, to restore any loss of accessory joint motion (roll, slide, or spin—see Chapter 1) as the consequence of joint injury.[98]

T e indications for joint mobilizations include those already mentioned for MT techniques, but the evidence-based indications include the following:

- Increasing joint extensibility and joint ROM. Although, theoretically, the joint capsule and articular surfaces are the structures affected by joint mobilizations, other periarticular tissues, such as tendons, muscles, and fascia are also likely

affected. However, there are still no studies that identify histological joint changes resulting from joint mobilizations. T ere is also no conclusive research providing information regarding the optimal type of mobilization, the amount of time a joint should be mobilized, or the optimal amount of force required to treat any of the so-called joint impairments.

- Increasing joint ROM. A number of studies addressing the effect of joint mobilizations on ROM provide evidence of an association.[99,100]
- Decrease pain. A number of studies have shown that hypoalgesia occurs as a result of joint mobilizations,[101–103] although the effect seems to occur regardless of the technique being used, the joint being treated, or the impairment being addressed.
- Promote muscle relaxation. Although there is some evidence that joint mobilizations can reduce muscle activity in muscles, the specific mechanism is unknown.[101]
- Improve muscle performance. Evidence suggests that joint mobilization can improve muscle performance, regardless of the presence or nature of the muscle impairment.[104]

CLINICAL PEARL

Mobilization techniques that utilize accessory movements and distractions are used primarily on inert tissues, and physiologic movements are used to mobilize both contractile and noncontractile tissues.[105]

T e contraindications and precautions for joint mobilizations include those already mentioned for MT techniques including the presence of joint hypermobility, acute inf ammation, and acute joint effusion.

Joint mobilizations are applied in a direction that is either parallel (slide or roll) or perpendicular (compression or distraction) to the treatment plane (see Chapter 1), to restore the physiologic articular relationship within a joint, thereby reducing hypomobility, and to decrease pain.[106] Additional benefits attributed to joint mobilizations include decreasing muscle guarding, lengthening the tissue around a joint, neuromuscular inf uences on muscle tone, and increased proprioceptive awareness.[107,108]

T ree types of mobilizations are recognized, based on the level of participation by the clinician and patient:

1. Active, in which the patient exerts the force
2. Passive, in which the clinician exerts the force
3. Combined, in which the clinician and patient work together

To apply joint mobilizations, the components can be utilized in a variety of ways, depending on the method employed:

- Direct method. An engagement is made against a barrier in several planes.
- Indirect method. Maigne[109] postulated "the concept of painless and opposite motion," in which disengagement from the barrier occurs, and a balance of ligamentous tension is sought.
- Combined method. Disengagement is followed by direct retracing of the motion.

Several other schools of thought have been put forward to address the concepts of increasing joint ROM. Kaltenborn[8] introduced the Nordic program of MT, which utilizes Cyriax's[2] method to evaluate, and the specific osteopathic techniques of Mennell[3] for intervention. Further inf uence from Stoddard,[4] an osteopath, cemented the foundations of the Nordic system of MT. Evjenth,[110] who joined Kaltenborn's group, brought a greater emphasis on muscle stretching, strengthening, and coordination training.

Kaltenborn Techniques

Kaltenborn refers to the amount of joint play at a joint as slack. Each joint interface has a plane of motion, an imaginary line lying across the joint surfaces. According to Kaltenborn, all joint mobilizations, when performed correctly, should be made parallel or at right angles to this plane of motion, and are based on the arthrokinematics of the joint (see Chapter 1), specifically the concave–convex rule (Figs. 1-8 and 1-9) (Table 10-6).[8] For example, if extension of the tibiofemoral joint is restricted, either the femur (convex) can be stabilized and the tibia (concave) glided anteriorly or the tibia can be stabilized and the femur glided posteriorly. T e concave–convex rule cannot be applied to every situation. Exceptions include movements at plane joints, movements for which the axis of rotation passes through the articulating surfaces, and movements at joints in which the concave side of the joint forms a deep socket.[111]

Kaltenborn's techniques use a combination of distraction and mobilization to reduce pain and mobilize hypomobile joints. T e choice of whether to use a particular grade depends on the patient's response. T ree grades of distraction are defined:

- Grade I—piccolo (loosen). T is grade involves a distraction force that neutralizes pressure in the joint, without producing any actual separation of the joint surfaces. Grade I traction is used with all gliding motions to reduce the compressive forces on the articular surfaces and thereby pain, both in the initial intervention session and with all of the mobilization grades. T e intermittent distractions are applied for 7–10 seconds with a few seconds rest between for several cycles.
- Grade II—slack (take up the slack). T is grade of distraction separates the articulating surfaces and eliminates the play in the joint capsule. It is typically used for the initial treatment to determine the sensitivity of the joint.
- Grade III—stretch. T is grade of distraction is designed to stretch the joint capsule and the soft tissues surrounding the joint to increase mobility. Grade III distraction is used in conjunction with mobilization glides according to the convex–concave rules to treat joint hypomobility in the remodeling stage of healing.[8] For restricted joints, the clinician applies a minimum of a 6-second stretch force followed by a partial release (to grade I or II), before repeating with slow, intermittent stretches at 3–4 second intervals.

Australian Techniques

T e Australian approach was introduced primarily by Maitland,[7] whose grading system is used throughout this text. Under this

TABLE 10-6 Shape, Resting Position, and Treatment Planes of the Joints

Joint	Convex Surface	Concave Surface	Resting Position	Treatment Plane and Relationship of the Osteokinematic Motion (OM) and Arthrokinematic Glide (AG)
Sternoclavicular	For elevation/depression, the sternum is concave, the clavicle is convex For protraction/retraction, the sternum is convex, the clavicle is concave		Arm resting by side	For elevation/depression the OM and AG are in opposite directions For protraction/retraction the OM and AG are in the same directions
Acromioclavicular	Clavicle	Acromion	Arm resting by side	OM and AG are in opposite directions
Glenohumeral	Humerus	Glenoid	55 degrees of abduction, 30 degrees of horizontal adduction	In scapular plane: OM and AG are in opposite directions
Humeroradial	Humerus	Radius	Elbow extended, forearm supinated	Perpendicular to long axis of radius: OM and AG are in the same directions
Humeroulnar	Humerus	Ulna	70 degrees of elbow flexion, 10 degrees of forearm supination	45 degrees to long axis of ulna: OM and AG are in the same directions
Radioulnar (proximal)	Radius	Ulna	70 degrees of elbow flexion, 35 degrees of forearm supination	Parallel to long axis of ulna: OM and AG are in the opposite directions
Radioulnar (distal)	Ulnar	Radius	Supinated 10 degrees	Parallel to long axis of radius: OM and AG are in the same directions
Radiocarpal	Proximal carpal bones	Radius	Line through radius and third metacarpal	Perpendicular to long axis of radius: OM and AG are in opposite directions
Intercarpal	Scaphoid	Trapezium and trapezoid	Midposition	Parallel to joint surfaces: OM and AG are in the same directions
Carpometacarpal joint of the thumb	For flexion/extension, the carpal is convex, the metacarpal is concave For abduction/adduction the carpal is concave, the metacarpal is convex		Midposition	For flexion/extension: OM and AG are in the same directions. For abduction/adduction: OM and AG are in opposite directions
Metacarpophalangeal (2–5)	Metacarpal	Proximal phalanx	Slight flexion	Parallel to joint: OM and AG are in the same directions
Interphalangeal	Proximal phalanx	Distal phalanx	Slight flexion	Parallel to joint: OM and AG are in the same directions
Hip	Femur	Acetabulum	Hip flexed 30 degrees, abducted 30 degrees, slight external rotation	OM and AG are in opposite directions
Tibiofemoral	Femur	Tibia	Flexed 25 degrees	On surface of tibial plateau: OM and AG are in the same directions
Patellofemoral	Patella	Femur	Knee in full extension	Along femoral groove: OM and AG are in opposite directions
Talocrural	Talus	Mortise	Plantarflexed 10 degrees	In the mortise in anterior/posterior direction: OM and AG are in opposite directions

TABLE 10-6 Shape, Resting Position, and Treatment Planes of the Joints (Continued)

Joint	Convex Surface	Concave Surface	Resting Position	Treatment Plane and Relationship of the Osteokinematic Motion (OM) and Arthrokinematic Glide (AG)
Subtalar	Calcaneus	Talus	Subtalar neutral between inversion/eversion	In talus, parallel to foot surface: OM and AG are in the same directions AG are in the same directions
Talonavicular	Talus	Navicular	Midposition	OM and AG are in the same directions
Calcaneocuboid	For flexion/extension the calcaneus is convex, the cuboid is concave. For abduction/adduction, the calcaneus is concave, the cuboid is convex			For flexion/extension: OM and AG are in the same directions. For abduction/adduction: OM and AG are in opposite directions
Metatarsophalangeal	Tarsal bone	Proximal phalanx	Slight flexion	Parallel to joint: OM and AG are in the same directions
Interphalangeal	Proximal phalanx	Distal phalanx	Slight flexion	Parallel to joint: OM and AG are in the same directions

system, the ROM is defined as the available range, not the full range, and is usually in one direction only (Fig. 10-3). Each joint has an anatomic limit, which is determined by the configuration of the joint surfaces and the surrounding soft tissues. The point of limitation is that point in the range that is short of the anatomic limit and is reduced by either pain or tissue resistance.

Maitland advocated five grades of joint mobilization or oscillations, each of which falls within the available ROM that exists at the joint—a point somewhere between the beginning point and the anatomic limit (see Fig. 10-3). Although the relationship that exists between the five grades in terms of their positions within the ROM is always constant, the point of limitation shifts further to the left, as the severity of the motion limitation increases[6]:

- Grade I: a small amplitude technique (about 25%) performed at the beginning of the available ROM.
- Grade II: a large amplitude movement in the middle of the ROM (i.e., the middle 50%).
- Grade III: a large amplitude movement at the end of the ROM (i.e., the last 50%).
- Grade IV: a small amplitude movement at the end of ROM (the last 25%).
- Grade V: a movement that exceeds the resistance barrier, commonly referred to as a high-velocity thrust technique or manipulation.

As with the Kaltenborn philosophy, the direction of the glide incorporated is determined by the concave–convex rule, and the joint to be mobilized is initially placed in its open-packed position. By varying the speed of oscillations, different effects can be produced. For example, many clinicians use a combination of Kaltenborn's grade III distraction with Maitland's grade IV oscillations to decrease pain and increase joint mobility. The difference between oscillations and sustained techniques is related to the rhythm or speed of repetition of the stretch force. While both techniques are applied with a stretching force at the limit of motion, oscillation techniques are vibratory in nature.

Maitland's grades I and II are used solely for pain relief and muscle guarding and have no direct mechanical effect on the restricting barrier, although they theoretically have a hydrodynamic effect. Mobilization-induced analgesia has been demonstrated in a number of studies in humans,[112–114] and is characterized by a rapid onset and specific influence on mechanical nociception. Grade I and II joint mobilizations are theoretically effective in pain reduction and muscle guarding, by improving joint lubrication and circulation in

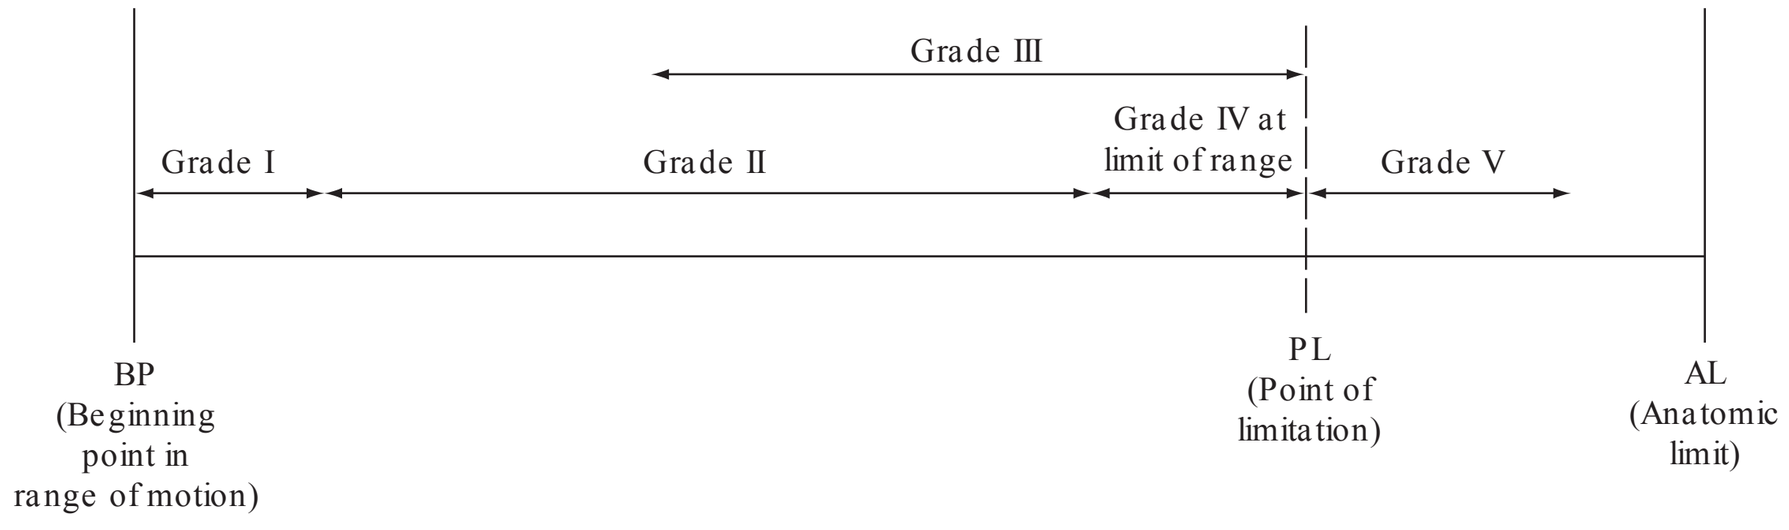

FIGURE 10-3 Maitland's five grades of motion.

tissues related to the joint.[105,115] Rhythmic joint oscillations also possibly activate the articular and skin mechanoreceptors that play a role in pain reduction.[116,117]

Maitland's grades III and IV, which are used primarily as stretching maneuvers, have a mechanical, as well as a neurophysiologic, effect. Grade III and IV joint distractions and stretching mobilizations may, in addition to the above-stated effects, activate inhibitory joint and muscle spindle receptors, which aid in reducing restriction to movement.[105,115–117]

T e selection of the mobilization technique will depend on the barrier to movement felt by the clinician (the end-feel) and the acuteness of the condition (see Table 10-4). T e joint is positioned in its resting position or the position of greatest comfort. Muscle is usually the first barrier and is treated with light hold–relax techniques or a sustained grade II distraction. Often some pain follows this initial mobilization, which is treated with grade III or IV oscillations.[118] At the next session, if there is increased pain and sensitivity, the clinician should reduce the amplitude to a grade I oscillation. As the pain is reduced, the real barrier to movement is approached. If this barrier is periarticular tissue, then grade IV+ rhythmical oscillations are used to stretch the tissue; if the joint is subluxed, erratic, jerky grade III+ are applied.[118]

When joint motion is less than 50% but joint resistance to movement is the dominant dysfunction, a progression from the use of physiologic movements (grade IV; see Fig. 10-3) to stretch the joint limitation, and the use of accessory movements at the limit of the joint, is advocated.[7,105] Grades III and IV have been further subdivided into III+ (++) and IV+ (++), indicating that once the end of the range has been reached, a further stretch to impart a mechanical force to the movement restriction is given. [118] A grade V mobilization, defined as the skilled passive movement of a joint, is a short-duration, small-amplitude, high-velocity thrust that is applied at the physiologic limit of joint range (see Fig. 10-3).

CLINICAL PEARL

If the joint surface is convex relative to the other surface, the slide occurs in the opposite direction to the bone movement (angular motion). If, on the other hand, the joint surface is concave, the slide occurs in the same direction as the bone movement (angular motion).

In the spine, the convex rule applies at the occipitoatlantal joint, but below the second vertebra, the concave rules apply.

This rule is very important to remember for joint mobility testing and for joint mobilizations.

If, during mobility testing, there is a limited glide:

- If the limitation occurs when the concave surface is moving, the restriction is likely due to a contracture of the trailing portion of the capsule.
- If the limitation occurs when the convex surface is moving, the restriction is likely due to an inability of the moving surface to move into the contracted portion of the capsule (may be due to adhesions between redundant folds of the capsule).

It is worth remembering that adhesions between collateral ligaments and the underlying tissue plane may limit movement in more than one direction.

If mobilizing in the appropriate direction according to the convex–concave rule appears to exacerbate the patient's symptoms, the clinician should apply the technique in the opposite direction until the patient can tolerate the appropriate direction.[119]

CLINICAL PEARL

Although sellar surfaces follow the same rules as ovoid surfaces, because of the nature of the curvature of their joint surfaces, the direction of the swing and the glide varies. For example, at the first carpometacarpal joint, the following biomechanics are involved:

Flexion/extension of metacarpal: the moving surface is concave.

1. The swing of the bone occurs in an anteromedial/posterolateral direction.
2. The base glides and rolls in an anteromedial/posterolateral direction.

Abduction/adduction of metacarpal: the moving surface is convex.

1. The swing of the bone occurs in an anterolateral/posteromedial direction.
2. The base glides in the opposite direction to the swing and rolls in the same direction as the swing.

Physiologic movement mobilizations and accessory and distraction mobilizations may be performed at any grade indicated. T e mobilizations are performed both at the site of pain and to joints proximal to the site of pain to produce analgesia.[120]

Whichever technique or grade is employed, a number of further considerations help guide the clinician in addition to those mentioned under Correct Application of Manual Techniques:

- T e position of the joint to be treated must be appropriate for the stage of healing and the skill of the clinician:
  - T e resting or open-packed position is used for the acute stage and/or inexperienced clinician.
  - Other starting positions may be employed by a skilled clinician in the nonacute stages.
- One-half of the joint should be stabilized, while the other half is mobilized. Both the stabilizing and mobilizing hands should be placed as close as possible to the joint line. T e other parts of the clinician involved in the mobilization should make maximum contact with the patient's body, to spread the forces over a larger area and reduce pain from contact of bony prominences. T e maximum contact also results in more stability and increased confidence from the patient. An alternative technique, which produces the desired results, must be sought if the contact between opposite sexes is uncomfortable to either the patient or the clinician.
- T e direction of the mobilization is almost always parallel or perpendicular to a tangent across adjoining joint surfaces and is appropriate for the arthrokinematics of the joint being treated.

- The mobilization should not move into or through the point of pain throughout the duration of the technique.
- The velocity and amplitude of movement are carefully considered and is based on the goal of the intervention, to restore the joint motion or to alleviate the pain, or both.
  - Slow stretches are used for large capsular restrictions.
  - Fast oscillations are used for minor restrictions.
- One movement is performed at a time, at one joint at a time.
- The patient is reassessed after a few movements if the joint is in the acute stage of healing, less frequently for other stages of healing.
- The intervention should be discontinued for the day when a large improvement has been obtained or when the improvement ceases.

Muscle reeducation is essential after mobilization or high-velocity thrust techniques and often produces a noticeable reduction in posttreatment soreness. While the joint is maintained in the new range, five to six gentle isometric contractions are asked for from the agonists and antagonists of the motion mobilized.[118] Recently, the emphasis has shifted from mobilization of the joint in straight planes to mobilizations that incorporate the combined or congruent rotations that occur with normal motion, in order to take up all of the slack in the capsule.

The joint mobilization techniques specific to each joint are described and depicted in the relevant chapters.

Mobilizations with Movements

The concept of mobilizations with movements (MWMs) was introduced by Brian Mulligan.[121,122] MWMs are based on the principles of joint mobilization originated by Kaltenborn used in conjunction with active and/or passive physiological movement.

CLINICAL PEARL

The techniques of MWM combine a sustained manual gliding force to a joint with concurrent physiologic motion of the joint, either actively performed by the patient or passively performed by the clinician, with the intent of causing a repositioning of the so-called bony positional faults.[121,122]

With few exceptions, Mulligan's mobilization techniques are applied parallel to the plane of motion and are sustained throughout the movement until the joint returns to its starting position, with the intention of producing no pain and improving function when applied.[122] Indeed, the golden rule of MWMs is that if the pain is produced with an MWM, the techniques are contraindicated. The most common cause of pain with these techniques occurs when the mobilization is not sustained throughout the whole motion.[122]

The movements used with MWMs are patient dependent and can include active, passive, and resisted movements. Their success is based on the theory that bony positional faults can contribute substantially to painful joint restrictions, which is similar to the theory behind the success of joint manipulations.[122]

Mulligan's MWM techniques were originally designed for the cervical spine but have since been expanded to include virtually every joint in the body. Several studies[121,123–126] that looked at the effects of MWM concluded that MWM is a promising intervention.

Mulligan has devised a number of guidelines when applying these techniques:[121,122]

- The patient is placed in a weight-bearing position.
- Other interventions should be used in conjunction with these techniques.
- When treating hinge joints, the sustained glide or mobilization should be at right angles to the glide that usually occurs with the desired movement. For example, in the case of finger flexion, the glide-mobilization of the distal joint surface is applied in a medial or lateral direction.
- When joint movements involve adjacent long bones, as in the case at the wrist or ankle, it is often necessary for the clinician to adjust the relative positions of the long bones to enable pain-free joint movement to occur.
- The glide-mobilization is always successful in one direction only. The successful glide-mobilization is applied 10 times before reassessing the joint motion.
- Overpressure should be applied at the end range of the available active range of motion (AROM).

Mulligan techniques are described in detail in the relevant chapters of this text.

HIGH-VELOCITY THRUST TECHNIQUES

The earliest physicians to use high-velocity thrust techniques (joint manipulations) were English, and books on the subject were published in the early 1900s.[44,127–129]

Compared with the four grades of joint mobilization (grades I–IV), high-velocity thrust techniques are given the designation grade V. Recently, manipulative therapy has been broadly defined to include all procedures, in which the hands are used to massage, stretch, mobilize, adjust, or manipulate musculoskeletal tissues for therapeutic reasons.[130] However, in this text, high-velocity thrust techniques refer to grade V techniques. Although the grade V technique shares similarities with the grade IV mobilization in terms of amplitude and position in the joint range, grade V differs in the velocity of delivery. Applied at the barrier or point of joint restriction, a grade V technique involves the application of a fast impulse of small amplitude to restore joint play. The terms velocity and amplitude are used to describe the nature of the final activating force or thrust used. Most grades I–IV joint mobilizations use varying degrees of velocity and amplitude, whereas grade V techniques generally employ a high-velocity (quick) and low-amplitude (short-distance) thrust. Unlike mobilizations, which are applied singularly or repetitively within or at the physiologic range of joint motion,[131] joint manipulations involve a thrust to a joint so that the joint is briefly forced beyond the restricted ROM.[98] The speed, force, and correct application of a high-velocity thrust technique are critical if

serious injury is to be avoided. T is is particularly true in the craniovertebral region, where an overzealous technique can result in serious consequences. At the time of writing, there is much discussion as to whether or not a patient should be required to sign an informed consent prior to receiving a high-velocity thrust technique. At the very least, the clinician has an ethical duty to obtain at least verbal consent or agreement after explaining the rationale for the technique and the possible side effects.[132]

CLINICAL PEARL

When performed correctly, a high-velocity thrust may actually be safer than many other repetitive, low-velocity or prolonged stretch techniques. Theoretically, a high-velocity thrust technique minimizes the risk of creep and fatigue failure in normal collagen tissues. If damage does occur to tissues, it is more likely due to excessive amplitude of the thrust, excessive magnitude of force used, or the fact that the thrusting force is passing through a mechanically unsound joint.[132]

High-velocity thrust techniques may consist of long-lever techniques that exert forces on a point on the body some distance from the treatment area, or short-lever techniques that comprise forces directed specifically at an isolated joint.[133] A lesion that might benefit from a high-velocity thrust technique may be defined by movement restriction and pain, especially a joint restriction that elicits pain on provocation. T e decision to use a high-velocity thrust technique is made after first identifying the restriction through the end-feel. For example, when significant excessive collagen density (e.g., chronic capsular fibrosis) is thought to be the cause of the motion barrier, the use of a high-velocity thrust technique is deemed inappropriate.[132] In such cases, the technique utilizing a slow, prolonged stretch would be more appropriate. T e plane or direction of joint restriction determines the type and direction of the high-velocity thrust technique to be used. T e direction of the technique can be delivered either perpendicular to or parallel to the joint surface in question[132]:

- Perpendicular: T ese techniques, more commonly known as distraction (gapping) techniques, aim to separate the joint surfaces and are usually delivered within the joint's pathological position of ease. T is type of technique is only appropriate if the biomechanical assessment suggests an intraarticular inclusion or unstable joint which has become locked up or fixated beyond its neutral zone.
- Parallel: T ese techniques, aimed at improving the joint glide, are performed at the end of available range

Engaging the barrier, which requires a high level of skill, localizes the force, ensuring it will be applied to the restriction, thereby minimizing the magnitude and amplitude of the force. To successfully engage the barrier, a series of maneuvers called joint locking techniques are utilized. Excessive force or failure to localize the technique force results in a dissipation of those forces and, unless the patient is able to absorb these forces, they may prove to be harmful, especially in the spinal regions.[25] T ese harmful effects can include fracture, spinal cord compression, vertebral artery compromise (see Chapter 24), cerebral ischemia, and even death.[134]

CLINICAL PEARL

Cervical manipulations have been linked to vertebrobasilar complications. In a review of the 58 cases in the English language literature of vertebrobasilar complications following cervical manipulation, Grant found the average age to be 37.3 years with a range of 7–3 years.[135] It was estimated from a study by Hosek et al.[136] that one in one million cervical manipulations will result in a serious vertebrobasilar effect whereas Dvorak and von Orelli[137] estimated a much higher incidence of one in 400,000. This latter figure would indicate that a clinician performing cervical manipulations on 15 patients each day for 30 years (allowing for vacations) stands a little better than one in four chance of causing a serious stroke in the course of a career. Put another way, one in four clinicians, manipulating at the same rate, will run into a serious problem from the vertebral artery.

LOCKING TECHNIQUES

T e following two methods of locking are commonly cited for the lumbar spine (see Chapter 28)[136]:

1. Locking *f*rom above. T is technique places the lumbar spine in rotation and side bending to tighten the ligaments and capsule, thus stabilizing the joint, and can be performed in f exion, neutral, or extension of the lumbar spine. Because the clinician can only adequately control rotation motion when this is away from the edge of the bed, whichever side the patient is lying on the dictates the rotation that can be used—in the opposite direction from the patient side-lying position (e.g., left side lying will permit right rotation). T e side-bending motion is achieved by using the patient's lower arm to pull the shoulder girdle in either an inferior or a superior direction. For example, if the patient is lying on the left side, pulling the left shoulder girdle superiorly will produce right side bending of the trunk, whereas pulling the patient's left shoulder girdle inferiorly will produce left side bending. Flexion and extension can only be produced unilaterally in combination with the rotation. For example, with the patient in right side lying, f exion can be produced with left rotation by asking the patient to hold onto the edge of the table with their left hand (keeping the left shoulder girdle stationary), while the clinician pulls the patient's right arm horizontally forward. Extension can be produced with left rotation by placing the patient's left hand onto their waist so that the weight of the patient's arm creates a left rotation with a backward displacement. T is can be further enhanced by pulling the patient's right arm as vertical as possible while maintaining the right shoulder in a relatively stationary position. Neutral rotation (i.e., involving either f exion or extension) can be achieved by pulling the patient's right arm forward at a 45-degree angle. T ese patient positions

enable the clinician to combine up to three components in the locking techniques simultaneously.

2. Locking *f*rom below. As with locking from above, the direction of the rotation is dictated by whichever side the patient lies on (e.g., the spine is rotated to the right if the patient is in left side lying). T e rotation can be enhanced by bringing the non–weight-bearing side of the pelvis anteriorly. Flexion and extension of the lumbar segments are produced by motions of the hip and pelvis as is performed with passive intervertebral joint motion (PIVM) testing. T e following sequence is recommended:

- Produce the necessary f exion or extension motion to the appropriate level:
  - Flexion is facilitated by keeping the knees away from full f exion, thus utilizing tension in the hamstrings to rotate the pelvis posteriorly.
  - Extension is facilitated by keeping the patient's knees as f exed as possible, thereby utilizing the tension in the rectus femoris to rotate the pelvis anteriorly.
- Introduce the necessary side bending using the legs. Side bending is achieved by asking the patient to actively side tilt the pelvis by using commands such as "Push your lower leg down," or "Make your lower leg longer."

T e clinician then carefully adjusts the position of the hips and knees without moving the pelvis until the upper knee is in front of the lower to use rotation for a more secure lock. As with the locking techniques from above, the clinician has seven possible combinations:

- Neutral rotation, f exion, or extension.
- Ipsilateral extension (lower leg extending) or contralateral extension (upper leg extending)
- Ipsilateral f exion (lower leg extending), or contralateral f exion (upper leg extending)

With both locking techniques, the adjacent joints are positioned at the end of the available ROM for f exion/extension, side bending, or rotation. T is positioning prevents further movement at these joints because either the ligaments are taut or the articular surfaces are contacting one another so that any further motion induced by a manual technique is likely to occur at the motion segment that is not immobilized by the lock—the motion segment targeted for treatment.

In the cervical spine, two types of locking techniques are also commonly advocated (see Chapter 25): craniovertebral locking and locking through segmental translation. Because of the potential for vertebral artery compromise in the craniovertebral region, the craniovertebral joints are often "locked" first before continuing motion into the middle and/or lower cervical spine joints. In the following example, a left side–bending technique is used. Although this locking technique may be used with the patient positioned in sitting or supine, if it is used in supine it is important to apply a small amount of compression to compensate for the loss of the spinal loading due to the weight of the head.

While palpating the C2 spinous process, the clinician slowly side-bends the patient's head to the left. If the side bending is performed around a sagittal craniovertebral axis, the C2 spinous process should be felt to move to the right, indicating left rotation of the C2 on the C3. Maintaining the left side-bent position, the head is now rotated to the right until the C2 spinous process regains a central position. T e head is again side bent slightly to the left, and the C2 spinous process de-rotated back to the midline. T ese motions are continued until a firm end-feel is reached. At this point, motion in the craniovertebral joints has now been exhausted, while the rest of the cervical joints remain in neutral. Being careful to maintain the position of the head, especially the right rotation, the side bending is continued left to the middle or the lower cervical level required. As the cervical joints are prevented from rotating to the left, the middle cervical side-bending motion is exhausted very quickly.

When a specific force is applied to the bodily joints, clicking or popping sounds, called cavitations, may be heard. Distraction techniques are undoubtedly the easiest way to get the joint sound, especially from a normal joint. T e actual causes of these cavitations or clicks are unknown but are thought to result from a sudden release of synovial gas during the techniques. T e gas is then reabsorbed by the joint over a period of about 30 minutes, which may explain why joints can only be "recracked" every 20–30 minutes. It is quite possible that these cavitations might produce a neuromuscular or neurochemical effect that will lead to temporary generalized changes, including the relief of pain. T e mechanism behind the pain relief provided by a high-velocity thrust technique is not yet understood, although attempts have been made to explain the possible effects, including the freeing of an entrapped meniscoid or diskal element,[138] an alteration in muscle tone,[139] and a mechanical disruption of intraarticular adhesions.[140–142] Certainly, it is known that restriction of motion at a joint produces joint adhesions, soft-tissue contracture, and degenerative joint disease.[143–145] T erefore, by increasing the motion at a joint, a manipulation is thought to reverse the aforementioned detrimental effects. It is also possible that a high-velocity thrust technique may produce outcomes directly associated with a variety of psychological inf uences.[146] T e only true test of a successful technique is by the determination of objective change in the patient's articular function, as confirmed by active and passive motion tests.[132]

Prior to performing a high-velocity thrust technique, the clinician must attempt to determine the natural history of the joint through a subjective assessment or reaction to previous treatments. Ideally, the clinician should initially attempt to regain the lost motion utilizing other techniques such as joint mobilizations, ME, and ROM exercises prior to giving consideration to a high-velocity thrust technique. Unfortunately, a high-velocity thrust technique often becomes the procedure of choice because it carries a certain aura and is, therefore, often erroneously thought of as a panacea.[147] T e indications and contraindications for high-velocity thrust techniques are the same as those outlined at the beginning of the chapter. Additional contraindications include the following[132]:

- T e inability of the patient to relax.
- A past medical history that includes any condition that can weaken bone or collagen (e.g., rheumatoid arthritis, osteoporosis), any condition that may create abnormal hypomobility (e.g., Marfan syndrome, Ehlers–Danlos syndrome), any condition involving a joint fusion (surgical or otherwise), or any condition involving chemotherapy or radiotherapy for the treatment of cancer.

- Pediatric patient. The risk of damage to developing growth epiphyses and the question of whether the pretreatment explanation is understood make children very precarious candidates for manipulation.

Once the determination is made to perform a high-velocity thrust technique, the clinician should place the joint into a premanipulative position for approximately 10 seconds and assess any change in the symptoms, the patient's reaction, and any localized or distal vascular or neurological signs or symptoms. These include vertebrobasilar artery or spinal cord signs or symptoms. Theoretically, the premanipulative position takes the target joint and its surrounding soft tissues slightly beyond the range through which a high-velocity thrust technique is to be performed. At the end of this hold, the patient is questioned as to the continued willingness of the technique to be performed, and whether this position is comfortable and nonirritating. Under no circumstance should a thrust technique be repeated, if the patient's symptoms are reported to worsen or if the first technique did not succeed with little force.

The evaluation of the effectiveness of high-velocity thrust interventions is difficult because the number of scientific studies on the subject is extremely limited.[148] It appears evident that these techniques can cause an immediate relief of low back pain in patients with acute low back pain,[149] although the degree of improvement varies among individuals. Some patients respond immediately to a high-velocity thrust technique; however, this population cannot be identified in advance, and there are no strong reasons for recommending high-velocity thrust techniques instead of mobilizations.[148]

NEUROPHYSIOLOGIC TECHNIQUES

Proprioceptive Neuromuscular Facilitation

PNF, a manual technique that promotes the response of the neuromuscular mechanism through stimulation of the proprioceptor, was developed at the Kabat Kaiser Institute by Herman Kabat and Margaret Knott during the late 1940s and early 1950s.[150] Initially, the approach was developed as a method of treatment for neurologically weak muscles due to anterior poliomyelitis. The techniques were later expanded for use in general muscle strengthening, joint mobilizations, and the stretching of adaptively shortened muscles.[151] The PNF stretching techniques are described in Chapter 13.

PNF techniques provide the clinician with an efficient means for examining and treating structural and neuromuscular dysfunctions.[152–154] Structural dysfunctions (myofascial and articular hypermobilities and hypomobilities) affect the body's capacity to assume and perform optimal postures and motions.[155] Neuromuscular dysfunctions (an inability to coordinate and efficiently perform purposeful movements) cause repetitive, abnormal, and stressful usage of the articular and myofascial systems, often precipitating structural dysfunctions and symptoms.[155–157] The theory behind PNF is that the human muscular system consists of muscle groups that are classified as agonists, antagonists, neutralizers, supporters, and fixators[158]:

- Agonists: work to produce a movement
- Antagonists: relax to allow movement
- Neutralizers: inhibit a muscle from performing more than one action
- Supporters: stabilize the trunk and proximal extremities
- Fixators: hold bones steady

Within specific movement patterns, these muscle groups must contract in the proper sequence for optimal effectiveness. Muscle contractions are classified as static or dynamic. Static contractions are those in which no motion occurs. Dynamic contractions are concentric, eccentric, or maintained isotonic (a PNF term), the latter of which involves the intention to move, but no motion occurs. Theoretically, the facilitation of total patterns of movement will promote motor learning in synergistic muscle patterns, and these total patterns of movement and posture are important preparatory patterns for advanced functional skills. These patterns are designed to encourage the stronger synergistic muscle groups to assist the weaker ones during functional movements and are concerned with gross motions as opposed to specific motions.

According to PNF theory, muscle function occurs three dimensionally around three planes of movement, with each movement associated with an antagonistic motion:

- Flexion or extension
- Adduction or abduction in the extremities and lateral movement in the trunk
- Internal or external rotation.

Combinations of these movements work together in spiral and diagonal patterns. The patterns, which integrate the motions of sport and daily living, are based on the infant developmental sequences such as rolling, crawling, and walking. There are two diagonal patterns for the lower extremity (Table 10-7), and two diagonal patterns for the upper extremity and scapula (Table 10-8), which are referred to as the diagonal 1 (D1) and diagonal 2 (D2) patterns. These D1 and D2 patterns are subdivided into those that move into flexion and those that move into extension. In addition to the upper and lower extremity patterns, patterns exist for the upper trunk, lower trunk, and cervical spine.

CLINICAL PEARL

PNF patterns can be performed unilaterally or bilaterally. For example, the chop and lift patterns used frequently in recruiting the stabilizing musculature of the trunk (see Chapter 28), are applications of the upper extremity diagonal that involve the use of bilateral upper extremity in which one upper extremity is performing the D1 pattern while the other upper extremity is performing the D2 pattern (Figs. 10-4 and 10-5) with either both moving into flexion, or extension while using spiral and diagonal movements that cross the midline.

PNF simplifies functional movements into these component parts for diagnosis and treatment. Knowledge of the normal functional movement patterns of the body allows the clinician to identify altered patterns of motion. Once the

TABLE 10-7 Lower Extremity Proprioceptive Neuromuscular Facilitation Patterns

Start Position for D1 Pattern	
D1 Extension	D1 Flexion
Hip flexed, adducted, and externally rotated	Hip extended, abducted, and internally rotated
Knee flexed	Knee extended
Tibia internally rotated	Tibia externally rotated
Ankle and foot dorsiflexed and inverted	Ankle and foot plantarflexed and everted

clinician has diagnosed impairments or functional limitation, the clinician makes a decision as to which pattern will be used and the goal of the technique. Basic procedures of facilitation include body positioning the mechanics, manual contacts, manual and maximal resistance, irradiation, verbal and visual cueing, traction and approximation, stretch, and timing.[159] The position of the patient, which often uses developmental positions, allows for consistency of measurement and plays a major role in influencing postural tone. The exercise pattern is initiated after positioning the patient in

such a way as to place the muscle groups in their lengthened position. The muscle groups are then moved through their full range to their shortened position. The key to the success of PNF is the ability of the clinician to apply manual contact with appropriate pressure and exact positioning, which allows for a smooth, coordinated motion throughout the pattern. Manual contacts are used to isolate muscle groups,

FIGURE 10-5 Lift PNF pattern.

provide tactile cues, and influence the strength of the contraction. Appropriate pressure is described as the amount of resistance that facilitates the desired motor response of a smooth, coordinated, and optimal muscle contraction.[153,158] For example, the clinician can apply maximal resistance at specific points in the range to promote overflow to the weaker components of the movement pattern.

The patient is first taught the diagonal PNF pattern from the starting position to the terminal position, using brief and simple verbal cues, such as "push," "pull," and "hold," as well as visual and tactile input while being careful to avoid exceeding the extensibility limits of the musculotendinous unit.

If a dysfunctional movement is identified in any of the diagonals of motion, the clinician can apply appropriate resistance in conjunction with various PNF techniques (Table 10-9) to facilitate the relearning and rehabilitative process.[152–155,158] For example, a quick stretch applied to a muscle before contraction facilitates a muscular response to produce a greater force.

The following PNF techniques can be used for the development of muscular strength, endurance, and coordination.

Rhythmic Initiation

The rhythmic initiation technique is used to teach a patient a specific movement pattern, or with patients who are unable to initiate a movement, or those who have a limited ROM because of increased muscle tone.

The application of the technique involves a progression through the agonist pattern of passive, then active and assistive, then active movement. This technique is applied slowly against resistance through the available ROM while avoiding activation of a quick stretch.

Repeated Contraction

Repeated contraction is a useful technique for patients who have a weakness, either at a specific point or throughout the entire range and to correct imbalances that occur within the range. The patient is asked to push repeatedly by using the agonist concentrically and eccentrically against a maximal resistance until fatigue occurs in the weaker ranges of the motion. The amount of resistance to the motion given by the clinician is modified to accommodate the strength of the muscle group. A stretch can be applied at the weakest point in the range to facilitate the weaker muscles and promote a smoother, more coordinated motion.

Stabilizing Reversal

This technique, also known as an isotonic reversal, can be used for developing AROM of the agonists while also developing the normal reciprocal timing between the antagonists and agonists that occurs during functional movements. The technique involves a concentric contraction of the agonist followed immediately by a concentric contraction of the antagonist, with the initial agonist push contraction facilitating the pull contraction of the antagonist's muscles.

Rhythmic Stabilization

The techniques of rhythmic stabilization, also called stabilizing reversals, emphasize the cocontraction of agonists and

TABLE 10-9 PNF Techniques of Facilitation

Techniques of facilitation	Rhythmic initiation	Designed to improve the ability of the target agonist to direct and begin movement. Technique starts with passive movement in a chosen direction or pattern that encourages gradual patient participation before resisting the patient as performance improves.
	Repeated contractions	Designed to repeatedly elongate the agonist muscle groups to reintroduce reflex output and initiate movement. If the clinician stretch occurs in the fully lengthened range, the technique is called repeated stretch. If the restretch occurs within the active range of motion, it is called repeated contractions.
	Reversals of antagonists	Designed to facilitate contraction of the agonist after contraction of the antagonist thereby improving static and dynamic posterolateral, and reciprocal movements.
	Dynamic reversals of antagonists	Designed to facilitate dynamic contractions of the antagonistic movements reciprocally in a range appropriate to the goal of the exercise. This technique can be used to increase active range of motion, strength in the available range of motion, and improve balance and coordination of the antagonists.
	Stabilizing reversals	Designed to enhance balance and stability by applying alternating resistance to agonist–antagonist muscle pairs.
	Rhythmic stabilization	Designed to enhance cocontraction of the antagonists at any point in a given range of motion.
	Combination of isotonics	Designed to integrate movement by varying the type of agonist contraction (concentric, eccentric, and maintained dynamic) required for the function.

antagonists, which results in an increase in the holding power to a point where the position cannot be broken. This effect is achieved by alternating isometric contractions of the agonist with isometric contractions of the antagonist, to produce cocontraction of the two opposing muscle groups. The command "hold" is always given before movement is resisted in each direction. The goals of this technique are to improve stability around a joint, increase positional neuromuscular awareness, improve posture and balance, and enhance strength or stretch sensitivity of the tonic muscles in their functional range.[155]

The final step is to integrate the gains from the technique into a functional activity.

Myofascial Trigger Point Therapy

The term myofascial trigger point is a bit of a misnomer because trigger points can also be cutaneous, ligamentous, periosteal, and fascial.[160]

An MTrP is a hyperirritable location, approximately 2–5 cm in diameter,[161] within a taut band of muscle fibers that is painful when compressed and that can give rise to characteristic referred pain, autonomic phenomena, tenderness, and tightness. MTrPs are classified as either active or latent (Box 10-1).[162] The patient's reaction to firm palpation of the MTrP is a distinguishing characteristic of myofascial pain syndrome (MPS) (given later) and is termed a positive jump sign.[163] This reaction may include withdrawal, wrinkling of the face, or verbal response. This hyperirritability appears to be a result of sensitization of the chemonociceptors and mechanonociceptors located within the muscle.

Box 10-1 Classification of Trigger Points

- Active trigger points are those that are symptomatic with respect to pain and refer a pattern of pain at rest or during motion (or both) that is specific for that muscle. An active trigger point usually produces restricted range of motion and a visible or palpable local twitch response during mechanical stimulation of the MTrP, but failure to elicit this response does not exclude MPS. MTrPs are always tender and cause muscle weakness.
- Latent trigger points, which represent the majority of trigger points, are usually asymptomatic but may have all the other clinical characteristics of active trigger points. Latent trigger points can persist for years after a patient recovers from an injury and may become active and create acute pain in response to minor overstretching, overuse, or chilling of the muscle.
- Associated trigger points develop in response to compensatory overload, shortened range of motion, or referred phenomena caused by trigger point activity in another muscle. There are two kinds of such trigger points:
  - Satellite trigger points are in the zone of referral of another muscle.
  - Secondary trigger points are activated because the muscle was overloaded as a synergist or an antagonist of a muscle harboring a primary trigger point.

CLINICAL PEARL

Some confusion exists as to the difference between trigger points and tender points. Although MTrPs can occur at the same sites as the tender points of FM, MTrPs can cause referral of pain in a distinct and characteristic area, remote from the trigger point site, not necessarily in a dermatomal distribution.[164] Referred pain is, by definition, absent in the tender points of FM.[65,165]

Healthy tissues do not contain trigger points, are not tender to firm palpation, and do not refer pain. Several possible mechanisms can lead to development of MTrPs, including low-level muscle contractions, an uneven intramuscular pressure distribution, direct trauma, unaccustomed eccentric contractions, eccentric contractions in an unconditioned muscle, and maximal or submaximal concentric contractions.[166] T us, MTrPs are typically located in areas that are prone to increased mechanical strain or impaired circulation (e.g., upper trapezius, levator scapulae, infraspinatus, quadratus lumborum, and gluteus minimus). As with all chronic pain conditions, concomitant social, behavioral, and psychological disturbances often precede or follow their development.[167,168]

Whatever the etiologic factors, it would appear that the development of MTrPs may be a progressive process, with a stage of neuromuscular dysfunction of muscle hyperactivity and irritability that is sustained by numerous perpetuating factors and then followed by a stage of organic dystrophic changes in the muscle bands with MTrPs.[163]

According to Simons,[169] the diagnosis of MPS can be made if five major criteria and at least one out of three minor criteria are met. T e major criteria are

1. localized spontaneous pain;
2. spontaneous pain or altered sensations in the expected referred pain area for a given trigger point;
3. presence of a taut palpable band in an accessible muscle;
4. exquisite localized tenderness in a precise point along the taut band;
5. some degree of reduced range of movement when measurable.

Minor criteria include

1. reproduction of spontaneously perceived pain and altered sensations by pressure on the trigger point;
2. elicitation of a local twitch response of muscular fibers by "transverse" snapping palpation or by needle insertion into the trigger point;
3. pain relieved by muscle stretching or injection of the trigger point.

T e major goals of MTrP therapy are to relieve pain and tightness of the involved muscles, improve joint motion, improve circulation, and eliminate perpetuating factors. When treating a patient for a specific muscle syndrome, it is important to explain the function of the involved muscle and to describe or demonstrate a few of the activities or postures that might overstress it, so that the patient can avoid such activities or postures.

A number of manual interventions for MTrPs are available; these include the following.[64,170–172]

Stretch and Spray or Stretch and Ice

Although not technically a manual technique, the spray-and-stretch technique involves a manual stretch during its application.[67,160]

T e patient is placed in a position of maximum comfort to enhance muscle relaxation. T e part of the body affected is then positioned so that a mild stretch is exerted specifically on the taut band. Parallel sweeps of the vapocoolant spray or ice are applied unidirectionally; then, while one of the clinician's hands anchors the base of the muscle, the other stretches the muscle to its full length.[169] T e spray is held approximately 18 in away from the skin, to allow for sufficient cooling of the spray. One or two sweeps of coolant are sprayed over the area of the involved muscle to reduce any pain. As the muscle is passively stretched, successive parallel sweeps of the spray are applied to the skin from the MTrP to the area of referred pain, covering as much of the referred pain pattern as possible. After each application of the spray-and-stretch technique, the muscle is selectively moved through as full an ROM as possible to normalize proprioceptive input to the central nervous system.[160] Intense cold stimulates cold receptors in the skin, which tends to inhibit pain. T is technique is supposed to help block ref ex spasm and pain, allowing for a gradual passive stretch of the muscle, which decreases muscle tension. Several treatments may be needed to eliminate the pain syndrome; results should be seen after four to six treatments.[160] If vaporized coolants are not available, ice may be used in their place, taking care to prevent chilling of the underlying muscles, which is less likely with the use of vaporized coolants.[160]

Muscle Stripping. Muscle stripping is used after first applying a lubricant to the skin. T e technique involves the slow sliding of the thumb, knuckle, or elbow along the edge of a taut band with firm pressure while at the same time attempting to bow it out.[160] T is technique has the effect of applying brief ischemic compression, as the thumb slowly slides over the MTrPs, and of passively lengthening the taut band. Muscle stripping is as effective as the spray-and-stretch technique, although it is somewhat more painful.[160]

Massage Therapy. Deep massage mechanically helps break up the fibrous bands of MTrPs. T e application of deep pressure produces local ischemia. When the pressure is released, a reactive hyperemia occurs, improving circulation and releasing energy to the area.[173]

Myofascial Release. T ese techniques, discussed in a previous section, combine massage with deep stretch techniques to relax the muscle and break up the MTrPs.[46,67]

Ischemic Compression.[160] Compression can be applied with a thumb, knuckle, or elbow. T e compression serves as the hyperstimulant, and the pain is usually relieved within 20–60 seconds. T e technique involves the application of pressure directly to the trigger point, within the patient's tolerance. As the pain subsides, the clinician slowly increases the pressure until, ideally, the painful stimulus is eliminated, and a softening of the area is felt.

Stretching. Lengthening of the taut band is an effective form of intervention. It is theorized to disengage the actin and myosin filaments of the skeletal muscle (see Chapter 1), allowing more normal muscle length and increased ROM, and results in normal, patterned proprioceptive input to the central nervous system, which may prevent the resumption of pain.[160] Lengthening can be accomplished with gentle stretching of the involved muscles.

Joint Mobilizations. Typically, treatment of a dysfunctional joint leads to spontaneous resolution of soft-tissue tension and the restoration of normal muscle lengths around the joint, thereby allowing the hypertonic muscles to relax.[44,78,82,174]

Nonmanual Interventions. The nonmanual interventions for MTrPs are included here for completeness.[64,170–172]

- Thermotherapy. Moist heat, ultrasound, or a hot-tub session of 5–15 minutes' duration helps relax underlying muscles and increase circulation, thereby improving the supply of nutrients and decreasing tension on the MTrPs.[67] Pain relief is theorized to be related to a washout of pain mediators by increased blood flow, changes in nerve conduction, or alterations in cell membrane permeability that decrease inflammation.[162,175]
- Cryotherapy. Brief, intense cold stimulation of the skin overlying the trigger point and its pain referral area, is effective in releasing taut bands and inactivating trigger points, particularly when done in combination with a passive stretch.[160]
- *T*rigger point injections. Trigger point injections using various techniques have been widely used to inactivate MTrPs by disrupting the fibrous banding, although the injected local anesthetic agent seems less important for inactivation of the trigger point than the needling itself.[62,176,177] Trigger point injections should be followed by stretching and the application of heat.[67] The effectiveness of ultrasound therapy is comparable to trigger point injections and should be offered as a noninvasive treatment of choice for those patients who want to avoid injections.[162]
- Elimination of causative or perpetuating factors, if any. Mechanical and metabolic disorders need to be corrected to prevent further stress and strain on the muscles. Although many people have some degree of imbalanced body structure, the structural imbalance is an extremely common contributing factor to myofascial constrictions and trigger points.[61,170,171,178,179] In addition, patients should be encouraged to limit caffeine intake to less than two caffeinated beverages per day and avoid smoking, both of which directly and indirectly aggravate MTrPs.[67] Nutrition deficiencies may require correction, and supplements of vitamins C, B1, B6, B12, and folic acid have been advocated because of their essential role in normal muscle metabolism.[160]
- Biofeedback and muscle relaxation. Biofeedback and muscle relaxation techniques can be used to avoid chronic muscle tension.
- Exercise. Exercise is important in limiting recurrences of MTrPs.[179]
- Counterirritation. This is very old method of controlling pain has been used for centuries. Its success relates to the fact that it breaks the pain–spasm–pain cycle that so often perpetuates a painful condition through the gate control mechanism of pain control (see Chapter 3).
- Combination therapy. One study,[162] which looked at the combined intervention of ultrasound, trigger point injections, and stretching, found that the combination of these three interventions were effective in the reduction of pain, and improving ROM, independent of the severity or duration of pain present before the treatment. Another study, which examined a combined intervention of ultrasound, massage, and exercise, found that patients who had massage and exercise had a reduction in the number and intensity of MTrPs, whereas ultrasound alone gave no pain reduction.[180]
- Electrotherapy. Electrotherapy has also been found to be an effective therapeutic modality to relieve pain from MTrPs,[60,171,181] although electrotherapy alone is reported not as effective as thermotherapy or intermittent cold with stretching.[171] Electrotherapy is thought to work by producing muscle contractions, which squeeze out the edema from needling, increase blood flow to the area, and relax the muscles.[61] Two major types of electrical stimulation therapy used for soft-tissue lesions are electrical nerve stimulation (ENS) and electrical muscle stimulation (EMS).
- ENS is the application of a low-intensity electrical current to the peripheral nerve. In general, ENS, such as transcutaneous nerve stimulation, is used in reducing pain intensity and increasing the pain threshold of MTrPs (no matter how severe the initial pain).[182,183]
- EMS is the application of electrical current with stronger intensity directly to the involved muscle. EMS can be used to enhance muscle circulation, reduce muscle spasm, eliminate muscle pain, and increase muscle strength.[178,181,183]

According to one study, ENS was found to be more effective than EMS for immediate pain relief, whereas EMS was more effective than ENS for improving ROM.[183]

CHAPTER 11

Neurodynamic Mobility and Mobilizations

CHAPTER OBJECTIVES

At the completion of this chapter, the reader will be able to:

1. Summarize the various types of neurodynamic examination and mobilization techniques.
2. Describe the proposed mechanisms behind the neurodynamic examination and mobilization techniques.
3. Apply knowledge of the various neurodynamic mobilization techniques in the planning of a comprehensive rehabilitation program.
4. Recognize the manifestations of abnormal nervous tissue tension and develop strategies using neurodynamic mobilization techniques to treat these abnormalities.
5. Evaluate the effectiveness of a neurodynamic mobilization technique when used as an intervention.

OVERVIEW

Neurodynamics is the study of the mechanics and physiology of the nervous system. The nervous system is an electrical, chemical, and mechanical structure with continuity between its two subdivisions: the central and peripheral nervous systems (see Chapter 3). In addition to permitting inter- and intraneural communication throughout the entire network, the nervous system is capable of withstanding mechanical stress as a result of its unique mechanical characteristics. Nervous tissue, a form of connective tissue, is viscoelastic. This viscoelasticity allows for the transfer of mechanical stress throughout the nervous system during trunk or limb movements. This adaptation results from changes in the length of the spinal cord during movement and the capacity of the peripheral nerves to adapt to different positions. The peripheral nerves adapt through a process of passive movement relative to the surrounding tissue via a gliding apparatus around the nerve trunk.[1,2] Three mechanisms appear to play an important role in this adaptability:[2]

- Elongation of the nerve against elastic forces. In normal daily movement, nerves may slide up to 2 cm in relation to surrounding tissues and contend with a strain of 10%.[3]
- Longitudinal movement of the nerve trunk.
- An increase and decrease of tissue relaxation at the level of the nerve trunk.

The efficiency of this mechanism partially depends on the capacity of the loose connective tissue around the nerve (adventitia, conjunctiva nervorum, perineurium) to allow any traction forces to be distributed over the whole length of the nerve. If this distribution of forces is compromised, an unfavorable rise in traction forces can occur at certain segments, depending on the anatomic site (see next section).[3]

The role that tension on the neural tissue plays in pain and dysfunction has been studied for over a century. During this time, a number of specific tests have been designed to examine the neurological structures for the presence of adaptive shortening and inflammation.[3–6] The more common of these neurodynamic mobility tests are described in this chapter.

Once detected, any lack of neural mobility that appears to be contributing to a patient's signs and/or symptoms can be addressed using a number of neural mobilization techniques. Neurodynamic mobilizations, which use specific combinations of active or passive movements that aim to reduce mechanosensitivity and restore symptom-free function, have been advocated for certain nerve-related dysfunctions.[7,8]

PROPOSED MECHANISMS FOR NEURODYNAMIC DYSFUNCTION

Until recently, the proposed effects of neural mobilization were based on theory rather than research evidence.[9–11] Most of the studies have examined the influence of neural mobilization exercises on nerve mechanics in cadavers and subsequently in vivo.[12] The spinal dura (see Chapter 3) forms a loose sheath around the spinal cord from the foramen magnum to the level of the second sacral tubercle. From there it continues as the filum terminale to the end at the coccyx. Laterally, the dura surrounds the exiting spinal nerve roots at the level of the intervertebral foramen. There are three areas called tension sites, in which the dura is tethered to the bony canal, providing stability to the spinal cord. These tension sites are found at the segmental levels of C6, T6, and L4; the elbow; the shoulder; and the knee have similar sites.[3,4,13] As a result of these sites of tension, the neurologic tissues move in

different directions, depending on where the stress is applied, and in which order it is applied.[3]

It has been suggested that the nervous system is loaded differently depending on the sequence of joint movement. T is suggestion has been questioned in a study by Boyd et al.[14] which found that varying the movement sequence did not substantially impact excursion and strain in the end position of one of the most common neurodynamic tests—the straight-leg raise (SLR). T eoretically, during movement, neural tissue takes its lead from the movement of joints and muscles, with the physical loading of the nerve dependent on the location of the nerve in relation to the joint axis.[3] Various studies have demonstrated excursion of the nerve complex during movements of the extremity.[12,15–18] Under normal circumstances, the tension sites are not adversely affected by the motion of the extremities. Despite their apparent mobility, nerves, and their microcirculation are vulnerable to tension, friction, and compressive forces at multiple sites along their routes.[19] If the dura becomes adherent, excessive stress may be produced in the areas of adhesion, increasing the length of the dura beyond its normal limit of tension (Table 11-1).[3] T eoretically, increased dural tension may be felt throughout the neuromeningeal system and, potentially, it may affect the range of motion available to the trunk and to an extremity. Pathomechanically, a decrease in the mobility of a nerve along its entire length may make the nerve more vulnerable to additional injuries during repetitive movements.[3,19,20] One study[12] examined the difference in median nerve excursion between different types of nerve gliding exercises (including sliders and tensioners). Sliders utilize combinations of joint movements to encourage peripheral nerve excursion by increasing elongation at one end of the nerve bed, thereby creating tension on the nerve from that end, while simultaneously releasing tension from the other end of the nerve.[11] In contrast, tensioners utilize combinations of joint movements that elongate the nerve bed from both ends in an attempt to stretch the normal connective tissues. Of the two, it was determined that sliders produce greater amounts of nerve excursion compared to tensioners.[12]

CLINICAL PEARL

Neural tissue responds to trauma in the same way that a ligament or tendon does, by evoking the cascade of the inf ammatory process, resulting in pain when stressed.[21,22] In addition to the effect that the inf ammatory process can have on the nerve tissue, fibrous tissue formation can develop within the nerve root sheath causing adhesions between the sheath and the nerve root.[3]

A number of mechanisms (excluding diseases such as diabetes mellitus, hypothyroidism, immune deficiency syndromes, rheumatoid arthritis, and alcoholism) are hypothesized to contribute to an injury of the peripheral nerve trunk. T ese include the following:[23]

- Posture. Sustained postures that produce changes in the natural curves of the spine can result in a shortening of the distance traveled by the peripheral nerve trunk and eventual adaptive shortening of these structures. Correction of this posture, af er sufficient time has elapsed for it to have taken place, may produce a stretching of the neural tissues.
- Direct trauma. Orthopaedic injuries account for some of the injuries to peripheral nerves. For example, the radial nerve is injured through orthopaedic trauma more than any other major nerve.[24] Nerve injuries can occur as the result of a direct blow to the nerve or secondary to damage of an adjacent structure such as a fracture,[25,26] joint dislocation,[27] or tendon rupture.[28] Other causes of direct nerve trauma have included injections,[29] joint manipulations,[30] and surgical procedures.[31] A neurological injury is one of the most serious complications of fracture and dislocation, both in the short and long term. For example, the prevalence of injury to the sciatic nerve af er acetabular fracture or fracture–dislocation of the hip has been reported to be between 10% and 25%.[32]

TABLE 11-1 Sites of Peripheral Nerve and Nerve Root Vulnerability

Site	Description
Tunnels	Hard-sided tunnels, such as the carpal tunnel, increase the probability of spatial compromise of the nerve. Within a tunnel, the contained nervous system always has the potential to rub on the tunnel structure, creating friction, and any trauma or alteration to the tunnel structure can mechanically or chemically compromise the neural structures
Branches	It is more difficult for the nerve to move away from forces at those points where a nerve branches (e.g., radial nerve at the elbow)
Hard interfaces	A nerve is more readily compressed if it lies on a bone or passes through fascia (e.g., radial nerve in the spiral groove of the humerus)
Proximity to the surface	Superficial nerves, such as the sensory radial nerve in the forearm, are more vulnerable to external compression
Adherence to interfacing structures	Some areas of nerve are more firmly adherent to interfacing tissues than others (e.g., the common fibular (peroneal) nerve at the head of the fibula)

Data from Butler DS, Tomberlin JP. Peripheral nerve: structure, function, and physiology. In: Magee D, Zachazewski JE, Quillen WS, eds. Scientif c Foundations and Principles of Practice in Musculoskeletal Rehabilitation. St. Louis, MO: WB Saunders, 2007:175–189.

- Extremes of motion. Given the course of many of the peripheral nerve trunks, it is not difficult to envision movements of the extremities that could place a traction force on these trunks. Indeed, those very same movements are exploited in some of the neurodynamic mobility tests.
- Electrical injury. In a 17-year review of burn unit admissions, permanent nerve injuries were found in 22% of electrocuted patients.[33] T e upper limb was most commonly involved with the median and ulnar nerves most commonly injured.[33] Postneurologic symptoms in such cases can vary from neuropathy to complex regional pain syndrome (CRPS).
- Compression. Compression to a nerve can occur during muscle contraction and as a result of tight fascia, osteochondroma, ganglia, lipomas and other benign neoplasms, and bony protuberances.

CLINICAL PEARL

The sympathetic nervous system is part of the peripheral nervous system, and sympathetic neurons in peripheral nerves are subject to the same deformation and injury potential during movement as somatic neurons.[3]

T e underlying mechanisms associated with clinical improvements following neural mobilization remain unclear.[9]

Double-Crush Injuries

T e double-crush syndrome (DCS) is a general term referring to the coexistence of dual neuropathies along the course of a peripheral nerve. T e concept was proposed by Upton and McComas in 1973[34] who suggested that proximal compression of a nerve may decrease the ability of the nerve to withstand a more distal compression.[35]

From the pathophysiological viewpoint, impairment of neural excursion, loss of elasticity, underlying abnormality of the connective tissue as well as direct pressure on the nerve may lead to disruption of axons, impairment of axonal transport, endoneural edema, or ischemic changes in nerves.[35] For example, according to this theory, a cervical radiculopathy, manifesting as little more than neck pain and stiffness, could precipitate a distal focal entrapment neuropathy.[34] T e term double-crush syndrome is used to describe this mechanism of nerve injury: the serial compromise of axonal transport along the same nerve fiber causing a subclinical lesion at the distal site to become symptomatic.

At least eight etiologic mechanisms have been proposed to explain the relationship between the proximal and distal nerve fiber lesions:[34,36–39]

1. A proximal nerve lesion renders the distal nerve segment more vulnerable to compression because of serial constraints of axoplasmic flow.
2. T e peripheral nerves possess an underlying susceptibility to pressure.
3. Interruption of lymphatic and venous drainage at the proximal nerve lesion site renders the distal nerve segment more vulnerable.
4. Endoneurial edema at one lesion site compromises neural circulation, rendering nerve fibers at the other site more vulnerable.
5. A connective tissue abnormality common to both sites along the nerve fibers.
6. Tethering of the nerve at one site causes injurious shear forces at the other site.
7. Entrapment of the nerve at one site can cause a decrease in the function of the muscle pump, which creates a slight, generalized edema of the limb. T is increases tissue pressure in certain anatomic passages, which causes an additional entrapment nerve lesion.
8. T e initial nerve lesion discharges a metabolite that travels through the intraneural circulation, increasing the vulnerability of other segments of the nerve.

Since its introduction, the double-crush hypothesis has been invoked to explain a great number of coexisting proximal and distal nerve impairments. In fact, it has been expanded in various ways (i.e., to triple-crush, quadruple-crush, and multiple-crush syndromes, as well as the reversed DCS).[37,40,41] Despite its acceptance, there are some clinical situations where the double-crush hypothesis has anatomic and pathophysiologic restrictions that render it inapplicable.[42] For the DCS to occur, there must be anatomic continuity of nerve fibers between the two (or more) lesions sites. If this is lacking, then a sequential impairment of axoplasmic flow obviously cannot occur. Consequently, two focal nerve disorders along the same neural pathway (e.g., cervical root lesions and carpal tunnel syndrome) do not automatically fulfil this anatomic criterion of DCS unless the same axons are compromised at both sites.[42]

Although, experimental studies of the double-crush hypothesis have shown that successive lesions along a peripheral nerve can summate,[38,43,44] studies that have attempted to demonstrate the existence of DCS have as yet proved inconclusive.[45–47]

A neurophysiological examination is critical in distinguishing between a single or a double lesion as well as determining the comparative severity of the two lesions.[35]

NEURODYNAMIC MOBILITY EXAMINATIONS

Both Elvey[48] and Butler[20] have been credited with the initial development of the examination techniques for neurodynamic mobility. Elvey[48] developed what he named the brachioplexus tension test, which was later called the upper limb tension test (ULTT). Similar tests, such as the SLR and prone knee flexion tests, have since been designed for the lower extremity. T e slump test, popularized by Maitland,[49], is considered to be a general test of neurodynamic mobility. T e tension tests are designed to apply a controlled sequential and progressive mechanical and compressive stress to the dura and other neurologic tissues, both centrally and peripherally, thereby assessing the contribution of the spinal nerve roots and peripheral nerves to extremity pain. T e tests place tensile stresses on the dura of spinal nerve roots and peripheral

nerves using a longitudinal traction force of the nerve until the patient's symptoms are reproduced.[3]

The examination of neural adhesions is by no means an exact science, but the principles are based on sound anatomic theory. Knowledge of the course of each of the peripheral nerves is thus essential in order to put a sequential and adequate tension through each of them (see Chapter 3).

Breig's tissue-borrowing phenomenon offers a plausible explanation for the neurodynamic tests.[50] Breig observed that tension produced in a lumbosacral nerve root resulted in the displacement of the neighboring dura, nerve roots, and lumbosacral plexus toward the site of tension. In effect, a borrowing of the resting slack in neighboring meningeal tissues occurs as neural structures are pulled toward the site of increased tension.[51] This displacement of the nerve roots plexi results in a decrease in the available slack and potential mobility of the neural tissues throughout the region.[51]

Positive symptoms for the presence of neuropathic dysfunction include pain, paresthesia, and spasm.[23] Unfortunately, these signs and symptoms are also associated with a host of musculoskeletal injuries. Asbury and Fields[52] hypothesized that the type of pain that results from an injury to a peripheral nerve is characteristic and has two varieties:

1. Dysesthetic pain. This type of pain is felt in the peripheral sensory distribution of a sensory or mixed nerve and results from nociceptive afferent fibers.
2. Nerve trunk pain. This type of pain results from the nociceptors within the nerve sheaths and exhibits a pain distribution following the course of the nerve trunk.

However, relying on the reproduction of a type of pain (a subjective issue at the best of times) is not sufficient to make the diagnosis of neural tissue dysfunction.

Because the subject of neural provocation tests and the intervention of neurodynamic mobilization remain controversial, the clinician should ensure that the results of these tests are always used in conjunction with findings from a complete neuromusculoskeletal examination, including the following:[3,23,53–55]

- Observation. An injury to a peripheral nerve trunk may result in visible atrophy within its motor distribution.
- Palpation. The clinician should carefully palpate along each of the nerve trunks in the region where they are superficial. Physical deformation of an irritated nerve should reproduce pain with palpation.
- The range of motion. In areas of decreased neural mobility, both active and passive range of motion may be diminished in the same direction. However, a lesion to the musculotendinous unit would also reproduce pain with the same maneuver, particularly in muscles that cross two joints.
- Resistive testing. Resistive tests can be used to examine for the presence of weakness in the distribution of a peripheral nerve and to help differentiate between pain reproduced with active or passive range of motion that indicates damage to the musculotendinous unit, and pain that results from neural tension. For example, pain reproduced in the posterior thigh with the SLR may indicate a lesion of the hamstring muscle belly or a lesion to the sciatic nerve. If resisted knee flexion does not reproduce pain, the musculotendinous unit is unlikely to be at fault, leaving the sciatic nerve as the likely cause.

The purpose of the physical examination is to determine which tissue is at fault. This is accomplished by isolating (where possible) each tissue that has the potential to produce those symptoms and selectively stressing that tissue. Part of the problem with this approach lies in the fact that a positive finding for many of the assessment techniques may just produce a sensitive movement, rather than a stretch of the dura.[3] For example, when wrist extension is performed with the elbow in extension and the shoulder abducted, in addition to placing stress on the elbow and wrist joints, wrist flexors, and elbow flexors, the loading of the nervous system is continued proximally, at least up to the level of the axilla.[56]

Some of the so-called dural symptoms could also result from the imparted stretch on the dura during the various maneuvers, producing changes in the axoplasmic flow inside the nerves, provoking the firing of abnormal impulses, and decreasing the vascular supply to the nerve.[57–59]

SLUMP TEST

A neural tension test performed in a sitting position is necessary to simulate the extremes of spinal motion associated with symptom-provoking activities such as slouched sitting or entering and exiting a car.[49,60,61]

The slump test, introduced by Maitland,[49] is a combination of other neuromeningeal tests, namely, the seated SLR, neck flexion, and lumbar slumping. In the slump test, the patient is seated in full flexion of the thoracic and lumbar regions of the spine.[62] Sensitizing maneuvers are then systematically applied and released to the cervical spine and lower extremities while the clinician maintains the patient's trunk position.[51] The slump test assesses the excursion of neural tissues within the vertebral canal and intervertebral foramen[61] and detects impairments to neural tissue mobility from a number of sources as identified by Macnab[63] and Fahrni.[64] Maitland asserted that the slump test enables the tester to detect adverse nerve root tension caused by spinal stenosis, extraforaminal lateral disk herniation, disk sequestration, nerve root adhesions, and vertebral impingement.[60,61]

CLINICAL PEARL

The slump test has been shown to induce sympathetic responses in humans, so clinicians are urged to consider the possibility that the structure and function of sympathetic neurons, either in the trunk or in the peripheral nerve, may be adversely affected, particularly when injuries are long-standing or recurrent in nature.[3]

Over the years, several studies[50,65–67] have demonstrated the effects of the trunk and head position on neural structures within the vertebral canal and intervertebral foramen during slump testing. These studies reported that full spinal flexion or flexion of the cervical, thoracic, and lumbar regions of the spine results in a lengthening of the vertebral canal and transmits tension to the spinal cord, lumbosacral nerve root

sleeves, and nerve roots.[50,65–68] A more recent study by Davis et al.[69] found the slump test had a high false-positive rate in asymptomatic individuals and recommended that the current criteria for determining a positive test should be examined using new range-of-motion cutoff scores. T e study also recommended that the test should be considered positive only when peripheral symptoms are reproduced before 22 degrees of knee extension.[69] A 2011 pilot study by Trainor and Pinnington[70] indicated good inter-tester reliability and suggested that the slump knee bend test has the potential to be a useful clinical test for identifying patients with mid lumbar nerve root compression.

CLINICAL PEARL

One study[71] found that a positive slump test was recorded in 57% of subjects with apparent repetitive grade I hamstring strains reinforcing the relationship between the hamstrings and the sciatic nerve.

Depending on which text is read, there is a wide variety of progressive steps to the slump test, particularly when the lumbar kyphosis stage is introduced. Although the specific order of implementation remains controversial, it is important that the clinician consistently use the same sequence with each patient. For example, when the extension of the cervical spine is introduced, the dura and the nerve roots slacken. Extending the thoracic and lumbar spines increases the slack in the neural tissues.

Because the slump test is a combination of other tests, a choice as to its use needs to be made. Either the classic SLR test or its variations should be performed, or the slump test should be used.[72]

CLINICAL PEARL

- Bechterew's test. Bechterew's test is an abbreviated slump test, performed by asking the seated patient to actively extend his or her uninvolved leg at the knee, to lower that leg and then subsequently extend the involved leg. If symptoms are not produced, the patient is asked to extend both legs at the knee simultaneously. A positive finding includes the reproduction of radicular pain below the knee, inability to attain full knee extension, leaning backward and bracing oneself on the table (tripod sign), or any combination thereof.
- Sitting root test. This is another test similar to the slump test. With the patient seated and his or her neck flexed to the chest, the clinician places one hand on the distal thigh of the tested leg to prevent hip flexion and uses the other hand to extend the lower leg at the knee. Any of the typical SLR responses is considered a positive finding. If the test is negative, the clinician may increase tension placed on neural elements by adding trunk flexion.
- Femoral slump test. This is a sidelying version of the slump test that is sometimes preferred to remove the effects of gravity on the results. The patient is positioned in sidelying, with the leg closest to the bed grasped so that the knee is held at approximately 90 degrees of hip flexion, and with the cervical and thoracic spines flexed (Fig. 11-1). The clinician stands behind the patient and supports the uppermost leg to maintain a neutral hip position and the knee flexed. The clinician then slowly extends the hip of the uppermost leg to the point when symptoms are evoked. Once the symptoms are evoked, the patient is asked to extend the neck while the clinician monitors a change in symptoms.

FIGURE 11-1 The femoral slump test.

As soon as symptoms are reproduced during these tests, the test should be terminated. It is worth remembering that during a dural tension test, the dura itself does not move. It is merely stressed; hence, the name for the tests. One such method of sequencing for the slump test is described next.

T e patient is positioned sitting with the hands behind the back, the popliteal creases just off the edge of the bed and a slight arch in the back (Fig. 11-2), and the head flexed and then placed in neutral. T is initial position is then followed by a slump of the lumbar and thoracic spine with a posterior pelvic tilt as the clinician maintains the patient's neck in neutral (Fig. 11-3). T is maneuver has the effect of tightening the entire dura including the thoracic dura. If the test is still negative, the patient is asked to flex the neck by first applying a chin tuck and placing the chin on the chest and then to straighten the knee as much as possible. Overpressure is then gently applied to the upper thoracic and the lower cervical spine and maintained throughout the examination (Fig. 11-4). T e subject's ankle is then passively dorsiflexed to the point of slight resistance, while the knee is slowly passively extended to full extension or to the point when the subject reports an onset of neural mediated symptoms (Fig. 11-5). If the patient is unable to straighten the knee because of a reproduction of symptoms, he or she is asked to actively extend the neck. Following the extension of the neck, if the patient cannot straighten the knee further, the test can be considered positive.

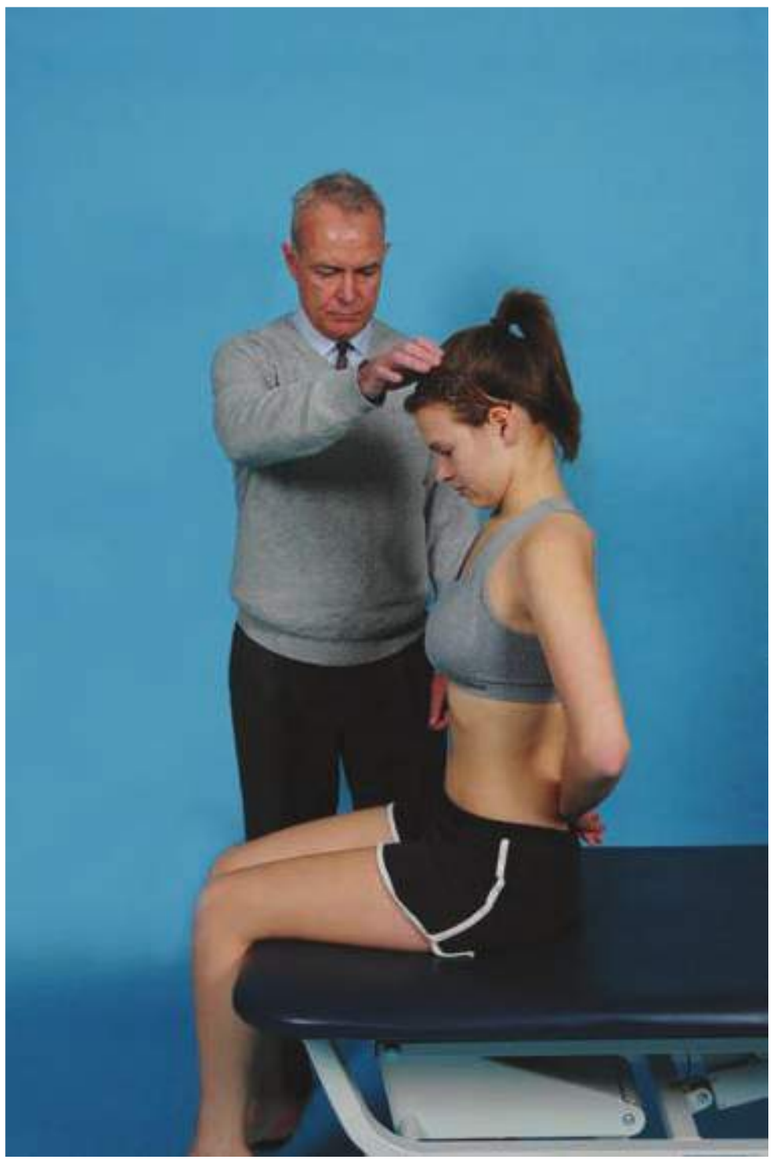

FIGURE 11-2 The slump test 1.

FIGURE 11-4 The slump test 3.

T e test can also be performed in reverse because a positive response may occur in one direction but not the other.

LOWER EXTREMITY TENSION TESTS

Sciatica is defined as pain along the course of the sciatic nerve or its branches and is most commonly caused by a herniated disk or by lateral recess spinal stenosis.[73] Characteristically, patients with sciatica report gluteal pain radiating down the posterior thigh and leg, paresthesia in the calf or foot, and varying degrees of motor weakness. Extraspinal entrapment of the sciatic nerve (i.e., along its course within the pelvis or the lower extremity), although infrequent, is difficult to diagnose because its symptoms are similar to those of the more frequent causes of sciatica.

FIGURE 11-3 The slump test 2.

FIGURE 11-5 The slump test 4.

Straight-Leg Raise

The SLR test is recognized as the first neural tissue tension test to appear in the literature. It was first described by Lasègue well over 100 years ago.[74]

CLINICAL PEARL

The SLR test should be a routine test during the examination of the lumbar spine in patients with sciatica or pseudoclaudication. However, the test is often negative in patients with spinal stenosis.[75]

The patient is positioned supine with no pillow under the head. The patient's trunk and hip should remain neutral, avoiding internal or external rotation, and excessive adduction or abduction. Each leg is raised individually (uninvolved side first). To ensure that there is no undue stress on the dura, the tested leg is placed in slight internal rotation and adduction of the hip and extension of the knee. The clinician holds the patient's heel, maintaining the extension and neutral dorsiflexion at the ankle, and raises the straight leg (Fig. 11-6) until complaints of pain or tightness in the posterior thigh are elicited. At this point, the range of motion is noted, and the clinician then lowers the straight leg slightly until the patient reports a decrease in symptoms.

The evaluation of the findings from the SLR test requires that the range of motion measured and the symptoms produced are compared with the contralateral side and with expected norms.[3] Because sitting knee extension and the SLR culminate in essentially identical positions, symptomatic responses to the two types of maneuvers should be similar although the angle at which pain is elicited may vary.[76]

CLINICAL PEARL

Confounding the results from the SLR test are the nonneural structures such as the sacroiliac joint, lumbar zygapophysial joints, hip joint, muscles (hamstrings), and connective tissue. These structures may limit leg elevation and provoke patient discomfort during testing.[3]

It is generally agreed that the first 30 degrees of the SLR serves to take up the slack or crimp in the sciatic nerve and its continuations. Using symptom reproduction below 40 degrees as a criterion for a positive SLR test result has been found to increase the sensitivity to 72%.[77]

Pain in the 0- to 30-degree range may indicate the presence of:

- acute spondylolisthesis
- tumor of the buttock
- gluteal abscess
- very large disk protrusion or extrusion[78]
- acute inflammation of the dura
- malingering patient
- the sign of the buttock

Between 30 and 70 degrees, the spinal nerves, their dural sleeves, and the roots of the L4, L5, S1, and S2 segments are stretched with an excursion of 2–6 mm.[79] After 70 degrees, although these structures undergo further tension, other structures also become involved. These additional structures include the hamstrings, gluteus maximus, hip, lumbar, and sacroiliac joints. An SLR test is positive if:

- the range is limited by spasm to less than 70 degrees, suggesting compression or irritation of the nerve roots. A positive test reproduces the symptoms of sciatica, with pain that radiates below the knee, not merely back or hamstring pain.[75] When the SLR is severely limited, it is considered diagnostic for a disk herniation.[80]
- the pain reproduced is neurologic in nature. This pain should be accompanied by other signs and symptoms such as pain with coughing, tying shoe laces, and so on but not necessarily by muscle weakness.

CLINICAL PEARL

The SLR test places a tensile stress on the sciatic nerve and exerts a caudal traction on the lumbosacral nerve roots from L4 to S2.[3] During the SLR, the L4–L5 and S1–S2 nerve roots are tracked inferiorly and anteriorly, pulling the dura mater caudally, laterally, and anteriorly. Tension in the sciatic nerve, and its continuations, occurs in a sequential manner developing first in the greater sciatic foramen, and then over the ala of the sacrum, next in the area where the nerve crosses over the pedicle, and finally in the intervertebral foramen.

The inferior and anterior pull on the nerve root and the relative fixation of the dural investment at the anterior wall produces a displacement that pulls the root against the posterolateral aspect of the disk and vertebra. In addition, any space-occupying lesions situated at the anterior wall of the vertebral canal in the fourth and fifth lumbar and first and second sacral segments may interfere with the dura mater or nerve root structures.

The following caveats are important for accurate assessment of the SLR:

- The patient must have the necessarily available range of hip flexion (30–70 degrees).
- The SLR produces a posterior shear and some degree of rotation in the lumbar spine (a region not well suited to shearing or rotational forces). Thus, back pain alone with the SLR is not a positive test.[76]

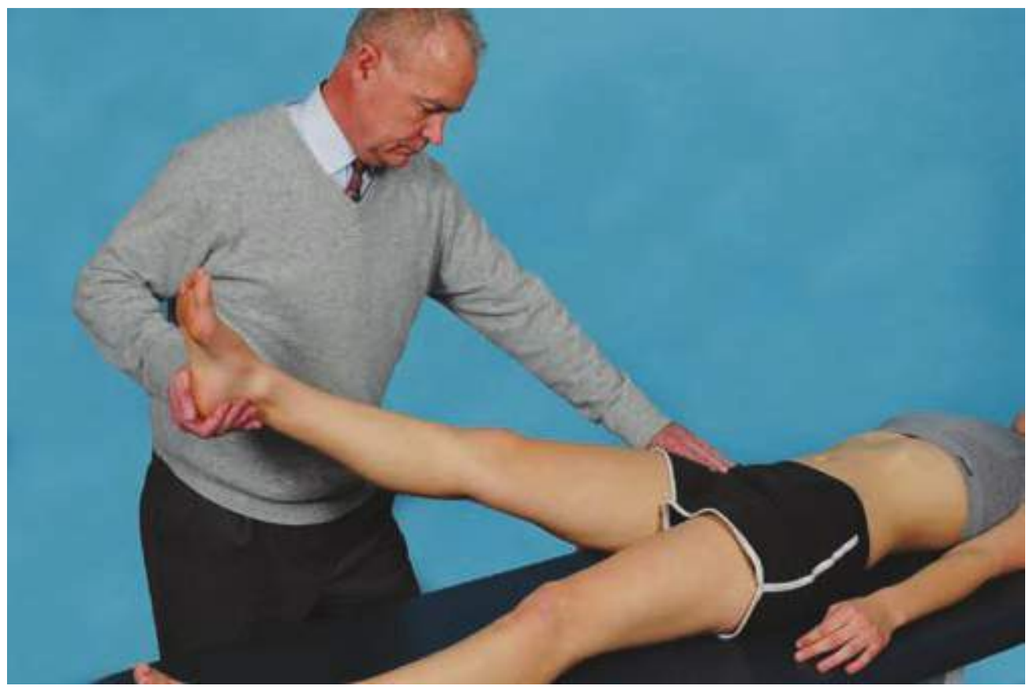

FIGURE 11-6 The straight-leg raise.

CLINICAL PEARL

Ipsilateral SLR has sensitivity but not specificity for a herniated IVD. For example, Deyo et al.[81] noted a sensitivity of 80% and a specificity of 40% for the SLR in the diagnosis of low lumbar disk herniation and van der Hoogen et al.[82] reported a sensitivity of 88–100% and a specificity of 11–44% for the SLR in the diagnosis of lumbar disk herniation.

Sensitizers

Passive dorsiflexion of the ankle (Braggard's test) (Fig. 11-7) and/or passive cervical flexion (Soto-Hall test) may be used as sensitizers for the SLR test. T e cervical flexion can also be performed actively (Fig. 11-8). In addition, further internal rotation or extreme adduction of the hip may also be added to the SLR. T ese additional maneuvers increase the tension exerted on the spinal cord, spinal dura, and lumbosacral nerve roots.[6,20,50,65,83–85] Research studies[50,66,83–86] have demonstrated that cervical flexion lengthens the spinal cord and dura. T is action may provoke radicular symptoms without stressing nonneural tissues in the lower extremity.

T us, the dura can be pulled from below, using dorsiflexion, or from above, using cervical flexion. Further modifications can be incorporated to place stress on different branches of the sciatic and common fibular (peroneal) nerves by adjusting the ankle and foot position. Coppieters et al.[87] evaluated the clinical hypothesis that strain in the nerves around the ankle and foot caused by ankle dorsiflexion can be further increased with hip flexion. In their version of the test, ankle dorsiflexion is performed first to load the neural and local nonneural structures around the ankle and foot before adding hip flexion as the sensitizing maneuver. Linear displacement

FIGURE 11-7 The straight-leg raise with ankle dorsif exion.

FIGURE 11-8 The straight-leg raise with active cervical f exion.

transducers were inserted into the sciatic, tibial, and plantar nerves and plantar fascia of eight embalmed cadavers to measure strain during the modified SLR.[87] Nerve excursion was measured with a digital caliper. Ankle dorsiflexion resulted in a significant strain and distal excursion of the tibial nerve.[87] With the ankle in dorsiflexion, the proximal excursion and tension increases in the sciatic nerve associated with hip flexion were transmitted distally along the nerve from the hip to beyond the ankle.[87] As hip flexion has an impact on the nerves around the ankle and foot but not on the plantar fascia, the modified SLR may be a useful test to differentially diagnose plantar heel pain.[87] Although the modified SLR caused the greatest increase in nerve strain nearest to the moving joint, mechanical forces acting on peripheral nerves are transmitted well beyond the moving joint.[87] Based on these findings, the following ankle and foot adjustments can be made:

- Dorsiflexion, foot eversion, and toe extension stress the tibial branch.
- Dorsiflexion and inversion stress the sural nerve.
- Plantar flexion and inversion stress the common fibular (peroneal) nerve (deep and superficial).

If symptoms are not reproduced with the SLR, but the slump test is positive, numerous reasons have been proposed, and the following are few among them:[72]

- T e presence of a sof disk protrusion, particularly a central sof protrusion. Sof central protrusions need loading through weight bearing and are of en negative in a nonweight-bearing position.
- Acute spondylolisthesis.
- Posterior instability.
- Malingering patient/nonorganic symptoms.

CLINICAL PEARL

Kemp's test uses the patient's trunk as both a lever to induce tension and as a compressive force. The test may be performed with the patient in either the seated or standing position.

- Seated. With the patient seated and arms crossed over the chest, the clinician uses one hand to stabilize the

patient's lumbosacral region on the side to be tested and the other arm to control the patient's upper body movement. The patient is passively directed into trunk flexion, rotation, sidebending, and finally extension. Depending on the patient's response, axial compression is applied in the fully extended and rotated position so as to increase stress on the posterior joints. Radiating pain down the leg provoked anywhere along the arc of movement should be noted, and the test should be discontinued at that point. Often patients will report dull or achy pain stemming from the lumbar spine that may be due to a facet or extraspinal soft tissue irritation.

- Standing. The standing version of Kemp's test is performed by asking the patient to place the back of his or her hand on the ipsilateral gluteal region and then slide the hand distally down the posterior thigh. Axial compression may be applied by pressing downward on the patient's shoulders. For clinicians desiring either more control over patient positioning or less muscle activation, the seated version of Kemp's test may be preferable.

Crossed Straight-Leg Raise Sign

The crossed SLR sign, or Well leg raising test of Fajersztajn,[88] is associated with the SLR test. There are three recognized types:

1. SLR that produces pain in the contralateral leg but not when the contralateral leg is raised.
2. SLR that produces pain in both legs.
3. SLR of either leg that produces pain in the contralateral limb. For example, SLR of the right leg produces pain in the left leg, and SLR of the left leg produces pain in the right leg.

There are many theories as to the cause and significance of the crossover sign. One theory suggests that the neuromeninges are pulled caudally, resulting in compression of the dural sleeve against a large or medially displaced disk herniation. The crossed SLR is considered relatively insensitive but highly specific and is thought to be more significant than the SLR test in terms of its diagnostic powers to indicate the presence of a large disk protrusion.[89] For example, Kosteljanetz et al.[90] found the test to have 24% sensitivity and 100% specificity, and Kerr et al.[91] found the test to have a sensitivity of 25% and a specificity of 95%. One study goes so far as to recommend using the combined results from the SLR and crossed SLR for a more accurate diagnosis.[82]

The following findings are strongly predictive of disk herniation[78,89,92]:

- Severely limited SLR.
- Positive crossover SLR.
- Severely restricted and painful trunk movements.

Bilateral Straight-Leg Raise

Once the unilateral SLR test is completed, the clinician should test both legs simultaneously (Fig. 11-9). A limitation of the unilateral SLR is that it may not highlight the presence of a central disk protrusion, particularly a soft disk protrusion.[93] By

FIGURE 11-9 The bilateral straight-leg raise.

performing a bilateral SLR and incorporating both neck flexion and dorsiflexion, central protrusions may be detected.[72]

Because a central protrusion may mimic a lateral recess stenosis, a differentiation test is needed. The bicycle test of van Gelderen[94] is advocated. The patient is appropriately positioned on a bicycle and asked to pedal against resistance.

- A patient with lateral spinal stenosis tolerates this position well.
- A patient with intermittent claudication of the lower extremities typically experiences an increase in symptoms with continued exercise, regardless of the position of the spine.
- A patient with intermittent cauda equina compression typically has an increase of symptoms with an increase in lumbar lordosis.
- A patient with a disk herniation usually fairs well if the lumbar spine remains extended.

Bowstring Tests

The bowstring tests are named after the technique applied to the nerve under examination. Both the tibial and the common fibular (peroneal) nerves can be tested and although the tests impart an insufficient stretch of the dura to detect chronic adhesions, they can be used to help make a prognosis about acute disk herniations. A strong indicator for surgery is a positive bowstring test, but this test need only be performed if the SLR is positive with the addition of dorsiflexion.[72]

Tibial Nerve Test

The tibial nerve travels down the middle of the posterior thigh between the femoral condyles and down the back and

FIGURE 11-10 SLR bowstring (popliteal space pressure).

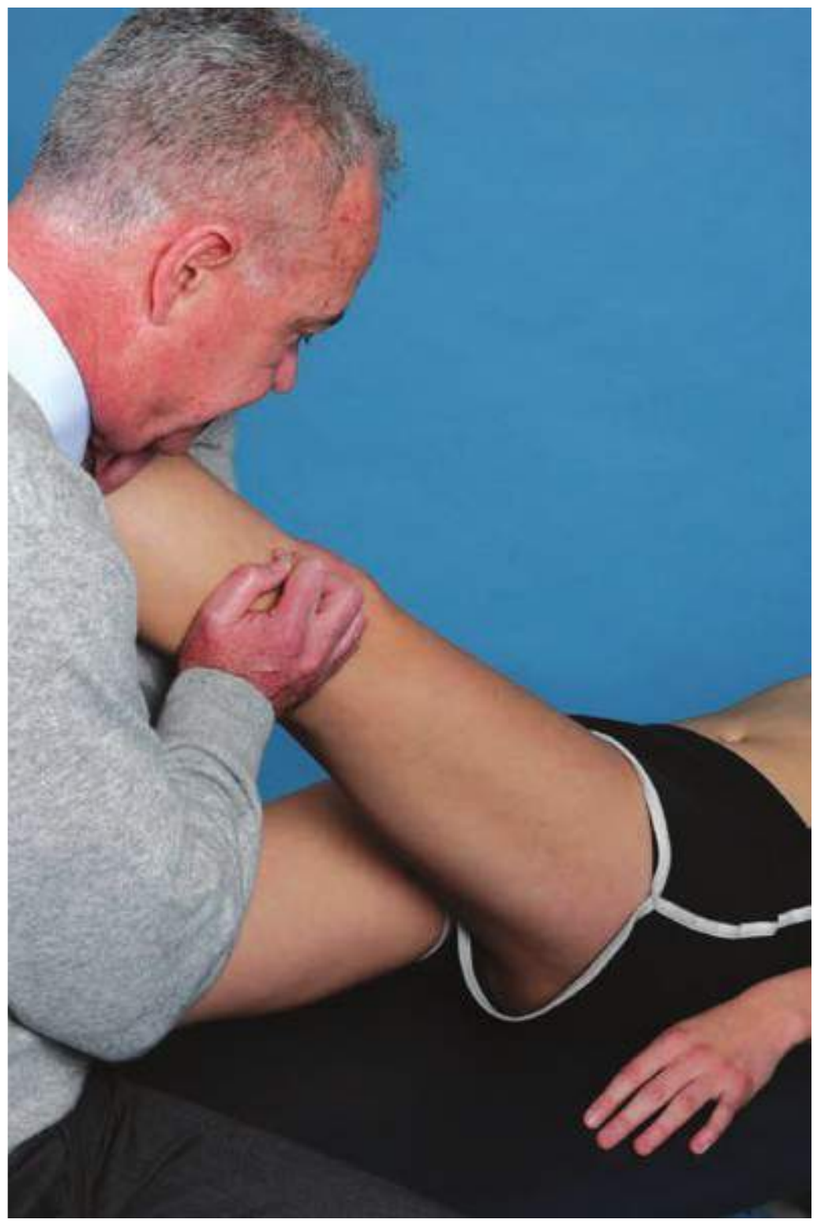

FIGURE 11-11 SLR bowstring (fibular head).

middle of the calf entering the foot under the medial malleolus of the ankle (see Chapter 3). The involved extremity is extended at the knee to the point of pain and then lowered slightly to decrease pain. The clinician supports the patient's leg on his or her shoulder and then applies finger pressure to the popliteal fossa in an attempt to tension the sciatic nerve (Fig. 11-10). If the symptoms return with this maneuver, the test is considered positive.

Common Fibular (Peroneal) Test

Typically, the common fibular (peroneal) nerve travels with the tibial branch to the posterior distal thigh region (see Chapter 3). It then wraps itself around the fibular head and has strong attachments to the tendon of the biceps femoris. The procedure for this test is similar to that of the tibial version of the test except that after the knee is slightly flexed, the clinician pulls the biceps femoris tendon at the fibular head medially and laterally (Fig. 11-11). If this maneuver reproduces the symptoms, it is considered a positive test.

CLINICAL PEARL

The sciatic tension test, also referred to as the Deyerle and May test, reproduces the mechanics of the Bowstring tests in a seated position.

Prone Knee Bending Test

The prone knee bending (PKB) test stretches the femoral nerve using hip extension and knee flexion to stretch the nerve termination in the quadriceps muscle.[72] Some clinicians prefer using the femoral slump test in place of the PKB to remove the effect of gravity (see Slump Test earlier). Both tests have been used to indicate the presence of upper lumbar disk herniations,[95] particularly when the hip extension is added.[96] The femoral nerve travels anteriorly to both the hip and the knee (as does the rectus femoris). Therefore, the nerve roots and the rectus femoris are stretched with a combination of knee flexion and hip extension. The lateral cutaneous nerve of the thigh and the hip flexors travel anterior to the thigh and may be stressed with the hip extension component of this maneuver.

Some clinicians recommend performing a PKB test before executing a sacroiliac "upslip" correction because there is a small potential to avulse the L2–3 nerve roots with this maneuver.

The PKB test is performed as follows: the patient is positioned prone, and the clinician stabilizes the ischium to prevent an anterior rotation of the pelvis. The clinician then gently moves the lower extremity into knee flexion, bending the knee until the onset of symptoms (Fig. 11-12). This maneuver is likely to produce a stretching sensation on the anterior aspect of the patient's thigh. The zone at which the dura is stretched is 80–100 degrees of knee flexion. Knee flexion greater than 100% introduces both a rectus femoris stretch and lumbar spine motion into the findings. A number of sensitizing maneuvers can be used including hip extension, plantar flexion, dorsiflexion, or head movements.

The test is positive if there is a reproduction of unilateral pain in the lumbar area, buttock, posterior thigh, or a combination in the 80–100 degree range of knee flexion which could indicate an L2, L3, or L4 nerve root impairment although an acute L4–S1 disk protrusion may also produce positive findings.[97]

The reliability and validity of the PKB are not known.[81] Porchet et al.[98] found the test to have a sensitivity of 84%, but the positive findings were associated with severe lateral disk herniations.

FIGURE 11-12 Prone knee bend.

FIGURE 11-13 ULTT 1 (median nerve).

Crossed Prone Knee Bending Test

This is a variation of the PKB test except that the uninvolved lower extremity is moved into knee flexion. A positive test is the reproduction of the patient's symptoms in the untested (opposite) leg. No diagnostic accuracy studies have been performed to determine the sensitivity and specificity of this test.

UPPER LIMB TENSION TESTS

The role of adverse neuromechanics in the upper limb and trunk has received much attention since the 1970s,[48,99,100] and has been linked to chronic neck and arm pain and upper limb disorders.[101,102]

Upton and McComas[34] demonstrated that the peripheral nerve and its cervical roots might manifest irritation at simultaneous sites. A further study, which investigated adverse tension in the neural system in 20 subjects suffering from unilateral symptoms of tennis elbow, appeared to suggest that the adverse tension could be a factor.[103]

The relative mobility of the nerve root and its investing sheath, which occurs in the lumbar spine, also has been demonstrated in the cervical spine.[104] This is mobility is produced with certain movements of the arm and occurs maximally at C5 and C6, to a lesser degree at C7, and to an even lesser degree at C8 and T1.[22]

The ULTTs, or brachial plexus tension tests, involve an ordered sequence of movement of the shoulder girdle, arm, elbow, forearm, wrist, and hand. Because there are a number of tissues in the cervicobrachial region that could be stressed by these maneuvers, cervical side bending or cervical flexion, which are thought to be more selective to the nervous system, are added.[104]

The principles behind the ULTT are the same as those described for the lower extremity tension tests. Therefore, only the procedures themselves are described here. During these procedures, care must be taken to maintain the cervical spine in neutral flexion-extension, side bending, and rotation.

ULTT 1 (MEDIAN NERVE DOMINANT)

The patient is positioned supine. The clinician depresses the shoulder girdle, abducts the humerus to approximately 110 degrees, supinates the forearm, and extends the elbow, wrist, and fingers (Fig. 11-13). The sensitizers for this test are cervical spine side flexions either toward or away from the involved side. The test is repeated on the contralateral extremity, and the results are compared.

Several studies have shown that the longitudinal motion of the median nerve is affected by motion of the fingers and wrist, with digital flexion resulting in a proximal slide into the forearm, and wrist and finger extension both producing a distal slide of the nerve toward the hand.[104–106] Hyperextension of the wrist has been shown to cause the median nerve to slide 10–15 mm distally relative to a fixed bony landmark in the carpal tunnel whereas flexion of the wrist and fingers moves the nerve 4 mm proximally.[105]

ULTT 2 (RADIAL NERVE DOMINANT)

The patient is positioned supine. The clinician depresses, abducts, and internally rotates the shoulder, pronates the forearm, extends the elbow, and flexes the wrist and thumb (Fig. 11-14). The sensitizers for this test are cervical spine side flexions either

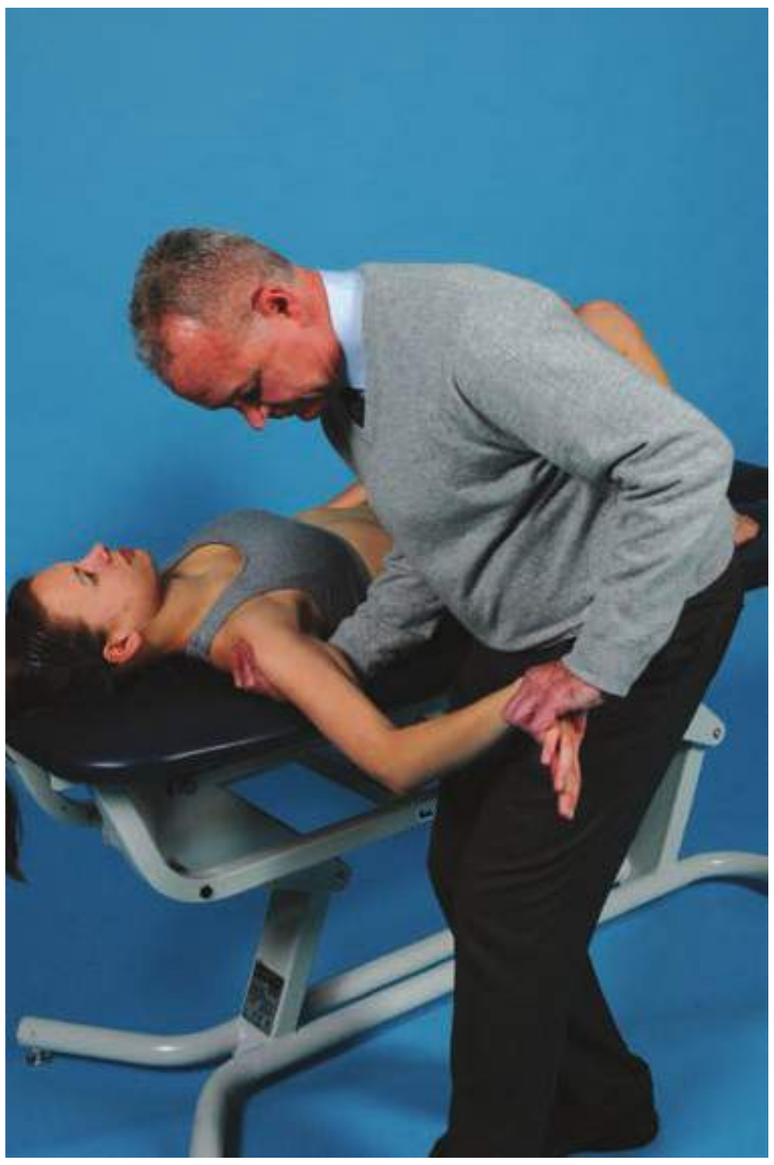

FIGURE 11-14 ULTT 2 (radial nerve).

toward or away from the involved side. T e test is repeated on the contralateral extremity, and the results are compared.

ULTT 3 (ULNAR NERVE DOMINANT)

T e patient is positioned supine. T e clinician extends the wrist, supinates the forearm, fully flexes the elbow, and depresses and abducts the shoulder. T e sensitizers for this test are side flexion of the head and neck, both toward and away from the test side. T e test is repeated on the contralateral extremity, and the results are compared.

Evans[107] described a modification of the basic ULTT 3. T e patient actively abducts the humerus with the elbow straight, stopping just short of the onset of symptoms. T e patient then externally rotates the shoulder just short of symptoms, and the clinician holds this position. Finally, the patient flexes the elbows so that the hand is placed behind the head. Reproduction of the symptoms with elbow flexion is considered a positive test.

Musculocutaneous Nerve

T e patient is positioned supine with the head unsupported by a pillow. T e clinician, facing the patient's feet, supports the patient's arm in about 80 degrees of elbow flexion. T e shoulder is placed in full external rotation and approximately 10 degrees of abduction. Shoulder depression is then applied followed by glenohumeral extension (the "sensitizer"), elbow extension, and wrist ulnar deviation.

Axillary Nerve

T e patient is positioned supine with the head unsupported by a pillow. T e clinician places one hand on top of the patient's shoulder and depresses the shoulder. T e glenohumeral joint is then externally rotated, and the patient side flexes the head away from the tested side. T e shoulder is then abducted to approximately 40 degrees.

Suprascapular Nerve

T e patient is positioned supine with the head unsupported by a pillow. T e clinician places a hand on top of the patient's shoulder. T e patient's arm is placed in internal rotation and shoulder girdle protraction. T e arm is then moved into horizontal adduction followed by the patient side bending the head away from the test side. T e clinician now depresses the shoulder.

NEURODYNAMIC MOBILITY INTERVENTIONS

Adverse neural tension is an abnormal response to mechanical stimuli of neural tissue. T e genesis of this abnormal tissue response can be from a variety of factors to include injuries (compression, vibration, and postsurgical), intraneural, extraneural, and anatomic.[108] A factor that receives a significant amount of attention involves that of repetitive strain injuries specifically with the upper extremities.

T e detrimental effects of immobilization on musculoskeletal structures are well documented as are the benefits of early mobilization protocols. T e rationale behind the use of neural mobilization techniques is to attempt to restore the dynamic balance between the relative movement of neural tissues and surrounding mechanical interfaces, thereby allowing reduced intrinsic pressures on the neural tissue and improving nerve conduction velocity.[109] By applying early mobilization to the neural system, it seems possible that similar benefits should occur. T e benefits from such techniques are though to include facilitation of nerve gliding, a reduction in nerve adherence, the dispersion of noxious fluids, increased neural vascularity, and improvements in the axoplasmic flow.[55,109,110] However, an important distinction needs to be made between techniques that lengthen or stretch the dura and techniques that stretch the anatomic structures that surround the involved neural tissue. T ere is limited evidence reporting favorable outcomes when using neural mobilization to treat specific patient populations, but the appropriate parameters of dosage (i.e., duration, frequency, and amplitude) remain to be confirmed.[111]

Elvey and Hall[23] recommend an initial intervention of passive, gentle, and controlled oscillatory movements to the anatomic structures that surround the neural tissue before progressing to the techniques that stretch both the surrounding tissues and the neural tissues together. Using this approach, the treatment barrier is represented by the onset of muscle activity.[100] For example, in the cervical spine, the sequence of neurodynamic mobilizations is initiated with shoulder depression with the neck in neutral and the arm by the side followed by shoulder depression with fixation of the cervical spine, then shoulder depression, cervical fixation, and arm traction with the arm by the side. Once this progression has been performed without any adverse effects, the more specific movements used to isolate the nerve are employed.

Evidence for the efficacy of this gradual approach has been demonstrated in subjects with low back pain and radiculopathy,[49,61,112] lateral epicondylalgia,[113] and chronic cervicobrachial pain.[23,114] Cleland et al.[115] performed a pilot clinical trial to determine if slump stretching resulted in improvements in pain, centralization of symptoms, and disability in 30 patients with nonradicular low back pain with suspected mild to moderate neural mechanosensitivity. Patients were randomized to receive lumbar spine mobilization and exercise (n = 14) or lumbar spine mobilization, exercise, and slump stretching (n = 16). All patients were treated with physical therapy twice weekly for 3 weeks for a total of six visits. Upon discharge, outcome measures were reassessed. Independent t-tests were used to assess differences between groups at baseline and discharge. No baseline differences existed between the groups ($p > 0.05$). At discharge, patients who received slump stretching demonstrated significantly greater improvements in disability (9.7 points on the Oswestry Disability Index, $p > 0.01$), pain (0.93 points on the numeric pain rating scale, $p > 0.001$), and centralization of symptoms ($p > 0.01$) than patients who did not. The authors suggested that slump stretching is beneficial for improving short-term disability, pain, and centralization of symptoms and also recommended that future studies should examine whether these benefits are maintained at a long-term follow-up.[115]

A recent systematic review of randomized controlled trials with an analysis of the therapeutic efficacy of neural mobilizations found only limited evidence to support its use.[109] However, choosing the right technique for the right patient based on causal mechanism is fraught with difficulty when it comes to heterogeneous groups.[116]

Stretching Program for the Sciatic Nerve

The home stretching exercises to improve tissue mobility, and neural extensibility are performed in three phases or positions as follows:[117]

1. The patient is positioned supine with the hips and knees are flexed at a comfortable range. Using the uninvolved leg, the patient lifts the heel of the involved side up until he or she experiences a stretch (Fig. 11-15). This position is maintained for approximately 1 minute (can be performed up a wall to provide additional support).
2. From the position in step 1, the patient slides the heel further up. If this maneuver provokes any paresthesias, the patient allows the heel back down. Progress is measured by timing the period during which the patient is able to keep the knee straight.
3. The patient performs the same maneuver as in step 2 but with a pillow under the head. This stretch is performed 3–5 times a day for 3–5 minutes at a time.

Stretches for the Upper Extremity Nerves

The recommended home stretching exercise to improve tissue mobility and neural extensibility of the peripheral nerves throughout the upper extremity is performed in four phases or positions as follows:[117]

1. The patient is seated with the cervical spine in neutral sidebending and the arm abducted to 90 degrees. The patient is asked to extend the fingers and to begin flexing the elbow while sidebending toward the elevated arm (Fig. 11-16A).
2. Keeping the upper extremity in the same position, the patient is asked to bend the head away from the elevated arm (Fig. 11-16B). When a gentle stretch is felt, the position is held for 10–15 seconds.
3. When the patient is able to maintain the previous stretch for 30–60 seconds, trunk rotation away from the involved side is added.
4. Once full trunk rotation is achieved, various positions of cervical side bending and elbow flexion/extension can be attempted (Fig. 11-16C). For example, elbow extension combined with contralateral cervical side bending. To increase tension, forearm supination or pronation can be superimposed on the elbow motions.

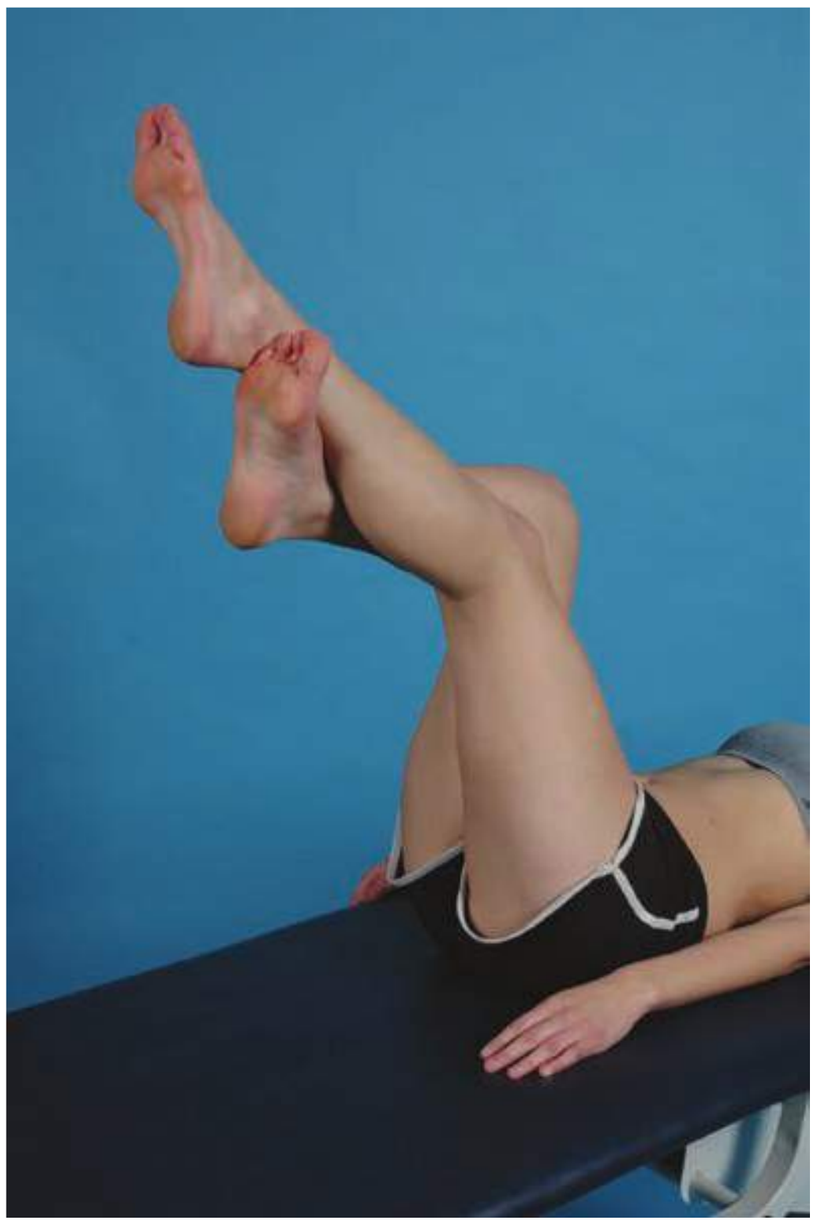

FIGURE 11-15 Sciatic nerve stretch.

Each position is held for 7 seconds and is repeated five times per session.

A series of home stretching exercise to improve tissue mobility and neural extensibility of the median nerve in cases of carpal tunnel syndrome have been advocated. Theoretically, stretching exercises of the median nerve affect symptom resolution in a carpal tunnel syndrome by:[118]

- stretching the adhesions
- broadening the longitudinal area of contact between the median nerve and the transverse carpal ligament
- reducing tenosynovial edema by a milking action
- improving venous return from the nerve bundles
- reducing pressure inside the carpal tunnel

FIGURE 11-16 Upper extremity nerve stretches.

Six positions are used for mobilization of the median nerve at the wrist:

1. The wrist in neutral, with the fingers and thumb in flexion (Fig. 11-17)
2. The wrist in neutral, with the fingers and thumb extended (Fig. 11-18)
3. The wrist and fingers extended, with the thumb in neutral (Fig. 11-19)
4. The wrist, fingers, and thumb extended (Fig. 11-20)
5. The wrist, fingers, and thumb extended, with the forearm supinated (Fig. 11-21)

FIGURE 11-17 The wrist in neutral, with the fingers and thumb in flexion.

CHAPTER 12

Improving Muscle Performance

CHAPTER OBJECTIVES

At the completion of this chapter, the reader will be able to:

1. Outline the various roles of human skeletal muscle.
2. List the various roles of muscle in the human body.
3. Differentiate among muscle strength, endurance, and power.
4. Understand the importance of manual muscle testing
5. Perform a gross muscle screening of a patient's strength
6. Perform specific manual muscle tests to the various muscles of the body
7. Define delayed onset muscle soreness (DOMS) and explain why it occurs.
8. Describe the concept of specificity of training.
9. Describe strategies to increase muscle strength, endurance, and power.
10. List the different types of resistance that can be used to improve muscle performance.
11. Outline the various types of exercise progression and the components of each.
12. Explain the basic principles behind plyometrics.

OVERVIEW

Movement of the body or any of its parts involves considerable activity from those muscles directly responsible. Muscle is the only biological tissue capable of actively generating tension. T is characteristic enables the human skeletal muscle to perform the important functions of maintaining upright body posture, moving body parts, and absorbing shock. For functional body motions to take place, the muscles producing movement must have a stable base from which to work from. If a functional limitation is highlighted during the physical examination of the patient, the clinician must determine the cause of the functional and/or participation restrictions. If the cause is found to be poor muscle performance, a progression of exercises to enhance muscle performance must be initiated. One of the most common ways of improving muscle performance is through the use of graded resistance exercises, which can be applied globally or locally. T e clinician must remember that there are a number of factors that influence a patient's ability to exercise. T ese factors can include fear of pain or reinjury, poor motivation, low compliance, depression, the side effects of medication, and impaired attention or memory.

Muscle Performance

T e ability of a muscle to carry out its various roles is a measure of muscle performance. T e three main types of muscle contraction are isometric, concentric (Fig. 12-1A and B), and eccentric (Fig. 12-2A and B) (see Chapter 1). Muscle performance can be assessed by measuring a number of parameters. T ese include strength, endurance, and power.

- Strength. T e improvement of muscle strength is an integral component of most rehabilitation programs. Strength may be defined as the amount of force that may be exerted by an individual in a single maximum muscular contraction against a specific resistance, or the ability to produce torque at a joint. Strength can be measured in one of three ways: as a maximal force exerted in an isometric contraction, the maximal load that can be lifted once, or the peak torque during isokinetic measurement. In a clinical setting, muscle strength can be measured as follows:
  - Manual muscle testing (MMT): MMT is an acceptable standardized process utilized to find gross strength deficits and to isolate muscle groups and actions (see later).
  - Using a dynamometer: Dynamometry is the process of measuring forces that are doing work. A dynamometer is a device that measures strength by using a load cell or spring-loaded gauge. T ese measurements are more objective than MMT. Examples of a dynamometer include the following:
    - Handheld: T is is used to assess the grip strength of a patient, or to measure muscle group strength by having the patient exert maximal force against the dynamometer.

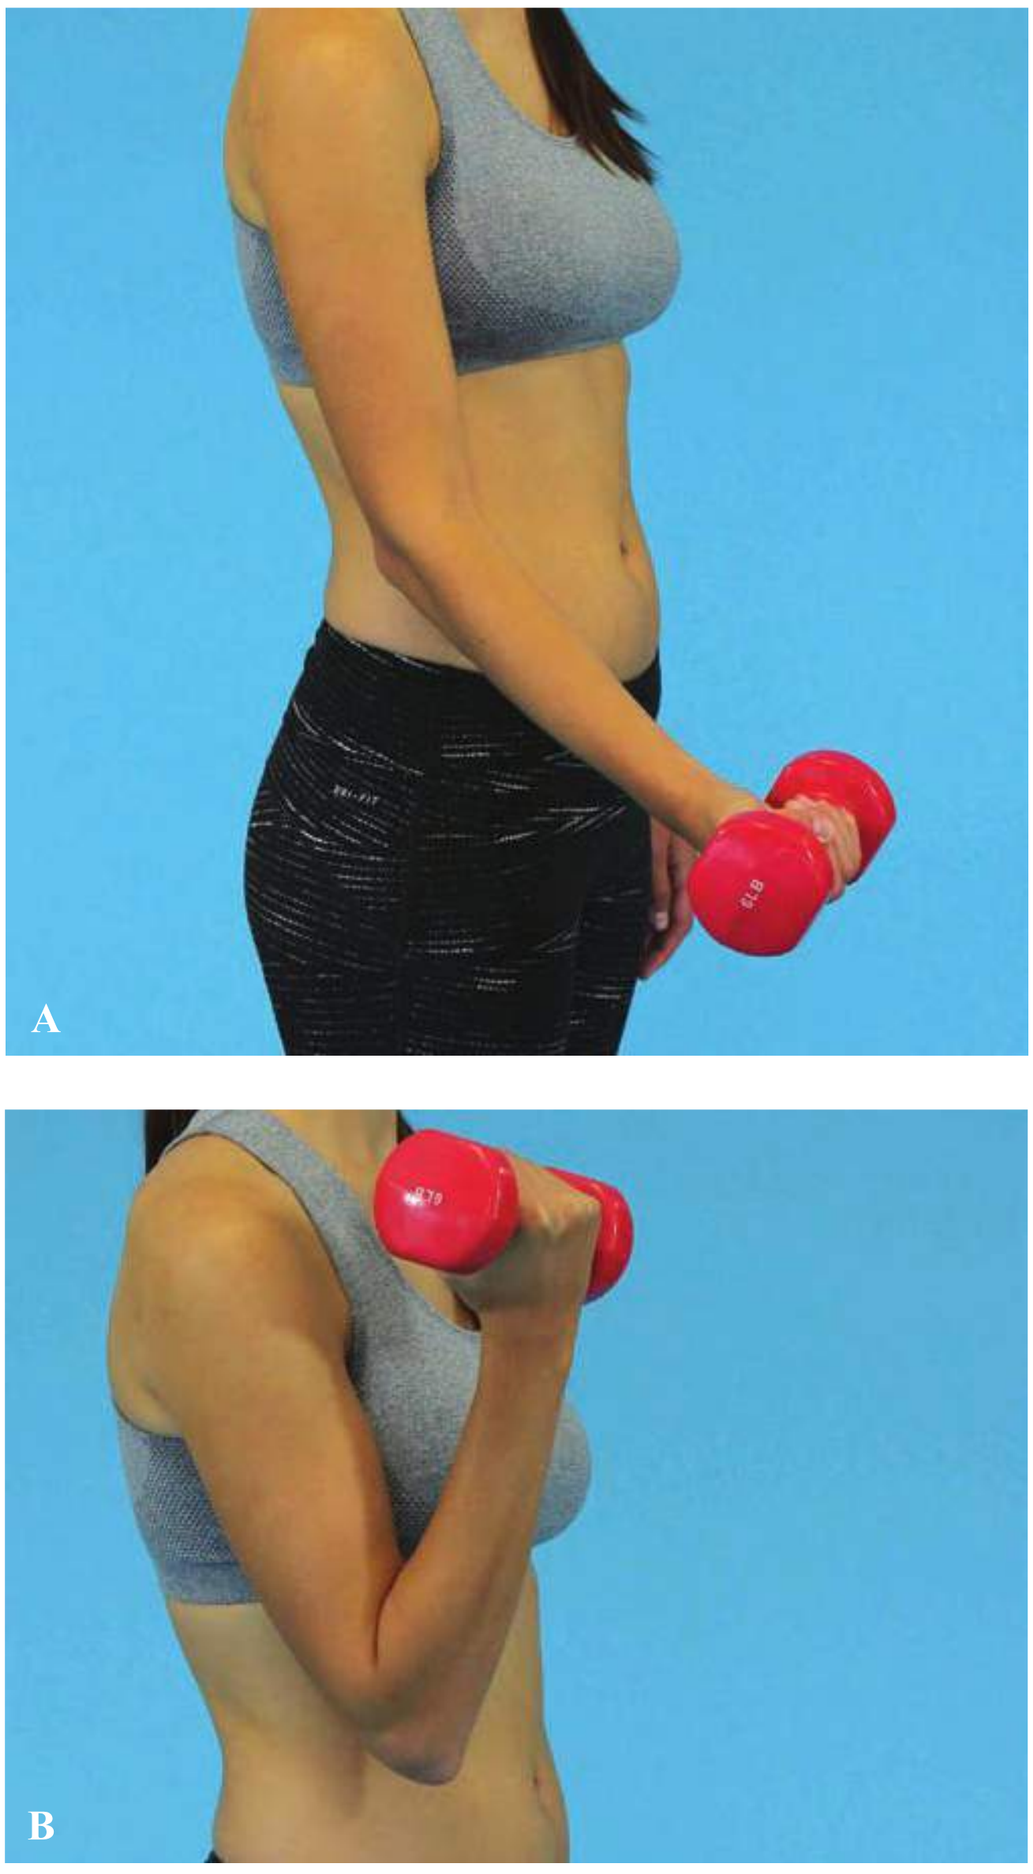

FIGURE 12-1 Concentric contraction. A: Start position. B: End position.

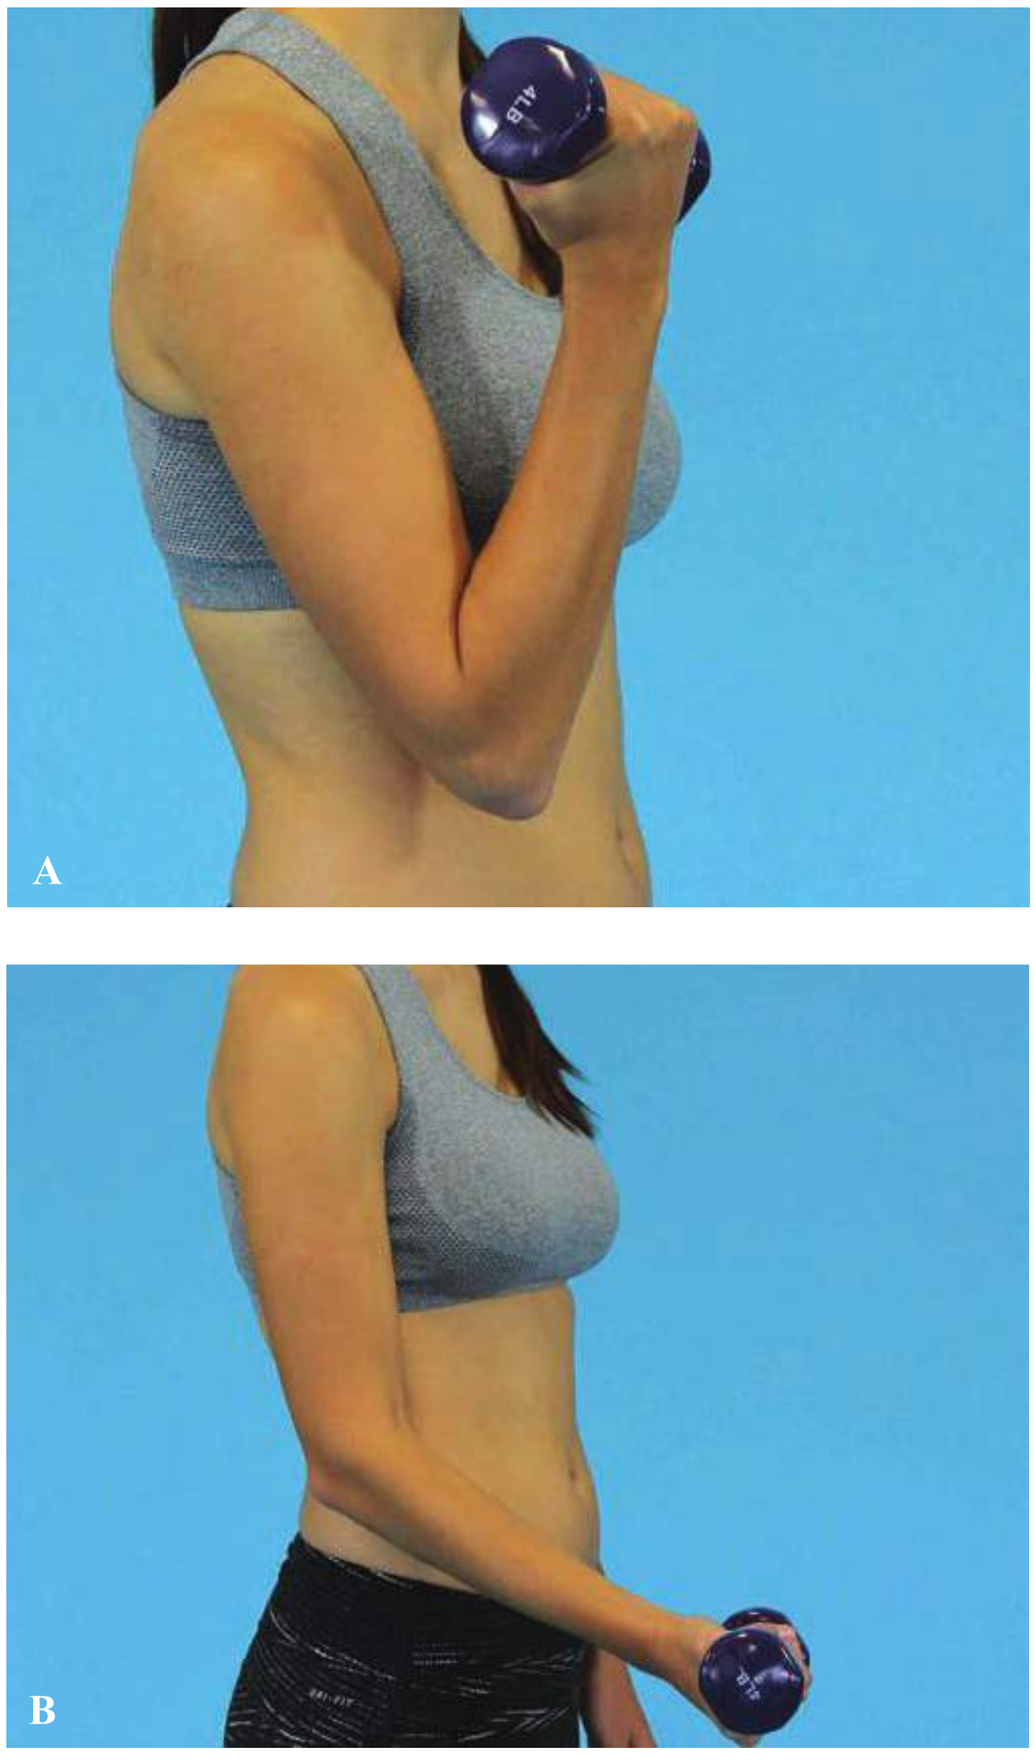

FIGURE 12-2 Eccentric contraction. A: Start position. B: End position.

- Isometric: T is measures the static strength of the muscle group by stabilizing the extremity using stabilization straps or verbal instruction.
- Isokinetic: T is measures the strength of a muscle group during a movement with constant, predetermined speed.

- Power. Mechanical power is the product of strength and speed. More specifically, power is work per unit of time (force × distance/time) or force × velocity (distance × time). T us, time is an essential element when training for power. Muscular power, the maximum amount of work an individual can perform in a given unit of time, is the product of muscular force and velocity of muscle shortening. Muscles with a predominance of fast-twitch fibers generate more power at a given load than those with a high composition of slow-twitch fibers.[1] T e ratio for mean peak power production by type IIb, type IIa, and type I fibers in skeletal tissue (see Chapter 1) is 10:5:1.[2] Greater force development is the rate at which strength increases and is the most important normal adaptation for the majority of athletes, as muscular power is an important contributor to activities requiring both strength and speed. T e assessment of power involves increasing the work a muscle must perform during a specific period of time, or reducing the amount of time required to produce a given force.
- Endurance. Skeletal muscle endurance requires the ability of a muscle, or group of muscles, to continue to perform low-intensity sustained activities without fatigue while maintaining proper alignment of the body segments over an extended period of time with balance and control. T ere are two types of endurance: general endurance, which is a base level of cardiorespiratory ability, and special endurance, which is related to specific activities (metabolic capacity).[3] Endurance can be assessed by having the patient perform many repetitions using low resistance or sustaining a muscle contraction for an extended period of time.

T e above parameters are used in rehabilitation to enhance balance, joint stabilization, coordination, the performance of activities of daily living, and to improve athletic performance. T ese three components of muscle performance are important

Box 12-1 Changes in Muscle Performance Based on Age During Adulthood

Young and Middle Adulthood

Muscle mass in men and women peaks between 18 and 25 years of age.

A decrease in muscle mass begins to occur as early as 25 years of age although muscle mass constitutes approximately 40% of total body weight.

Muscle strength and endurance reach a peak during the second decade of life, earlier for women than men. However, by sometime in the third decade, strength declines between 8% and 10% per decade through the fifth or sixth decade. This decline occurs less rapidly in physically active versus sedentary individuals.

Late Adulthood

The rate of decline of muscle strength accelerates to 15–20% per decade during the sixth and seventh decades and increases to 30% per decade thereafter so that by the eighth decade muscle mass has decreased by 50% compared to peak muscle mass during young adulthood.

While both type I and type II fiber numbers decrease with age, there is preferential atrophy of type II muscle fibers.

There is a significant deterioration in functional abilities by the eighth decade but this deterioration occurs less rapidly in physically active versus sedentary individuals.

Data from Kisner C, Colby L-A, eds. Resistance exercise for impaired muscle performance. In: Therapeutic Exercise: Foundations and Techniques. 6th ed. Philadelphia, PA: F. A. Davis; 2012:157–240.

in functional activities as they can allow the patient to interact with their environment in a more efficient and pain-free way through increased movement control and capacity. It is important to remember that muscle performance changes throughout the lifespan but that improvements in strength and endurance are possible with only a modest increase in physical activity. T e changes that occur in early childhood through adolescence are described in Chapter 30. T e changes that occur throughout adulthood are summarized in Box 12-1.

CLINICAL PEARL

The ultimate source of energy for muscular contraction is the adenosine triphosphate (ATP) molecule. The catabolic breakdown of the chemical bonds of the ATP molecule provides the energy necessary to allow myosin cross bridges to pull the actin filaments across the myosin filaments, which results in muscle contraction (see Chapter 1).

To measure improvement in muscle performance, it is necessary to have a baseline measurement from which to demonstrate gains. Typically the baseline measure used is muscle strength through an assessment of the patient's ability to perform an isometric contraction. Muscle testing requires that the patient be able to voluntarily control the tension developed in the muscles. Muscle strength can be assessed grossly or specifically. Normally, gross strength is assessed first, and specific testing is used when the gross muscle screening highlights an area of muscle weakness.

Gross Muscle Screening

A gross muscle screening is performed on a patient when a quick assessment of the patient's general level of muscle strength is required. If any weakness is found during the gross muscle screening test, a specific muscle test is then performed. It is important to remember that the gross muscle screening does not detail the determination of strength; it only provides the clinician with information as to whether a region of the body is either normal or weak. Regardless of the type of muscle testing used, the procedure is innately subjective and depends on the subject's ability to exert a maximal contraction. T is ability can be negatively affected by such factors as pain, poor comprehension, motivation, cooperation, fatigue, and fear.

T e gross muscle testing procedures for each of the main regions of the body are described in Table 12-1. One of the more common gross muscle testing procedures is the one performed by the clinician before gait training with an assisted device when the clinician is not sure of the patient's capabilities. In this scenario, the clinician must efficiently assess the strength of the major muscle groups that are used when using an assistive device. T e muscle groups tested include the shoulder abductors (Fig. 12-3), the shoulder flexors (Fig. 12-4), the shoulder extensors (Fig. 12-5), the elbow flexors (Fig. 12-6), the elbow extensors (Fig. 12-7), the wrist extensors (Fig. 12-8), the wrist flexors (Fig. 12-9), the hip flexors (Fig. 12-10), the knee extensors (Fig. 12-11), the knee flexors and hip extensors (the hamstrings) (Fig. 12-12), the hip abductors (Fig. 12-13), the ankle dorsiflexors (Fig. 12-14), and the ankle plantarflexors (Fig. 12-15).

Specific Muscle Testing

Specific muscle testing, also called MMT is a procedure for the evaluation of the voluntary function and strength of individual muscles and muscle groups based on effective performance of limb movement in relation to the forces of gravity and manual resistance. T e theoretical concepts and grading methods of MMT are outlined in Chapter 4.

CLINICAL PEARL

Maximum muscular strength is the maximum amount of tension or force that a muscle or muscle group can voluntarily exert in one maximal effort, when the type of muscle contraction, limb velocity, and joint angle is specified.

To accurately perform a specific muscle test, the clinician must have knowledge of the following:

- T e origin and insertion of the muscle being tested.
- T e function of the muscle being tested. Muscles rarely perform one single action; instead they form groups of actions that overlap with the functions of other muscles.

TABLE 12-1 Gross Muscle Screening

Patient Position	Tested Muscle Group	Procedure
Supine	Hip flexors	The patient is instructed to raise both legs off the supporting surface simultaneously while keeping both legs straight. The position is held for 10 seconds. The hip flexors can also be tested in the sitting position.
	Hip abductors	The patient is instructed to abduct the legs to each side then to hold the position while the clinician attempts to bring the legs together.
	Hip adductors	The patient is instructed to keep the legs together while the clinician attempts to separate the legs
	Hip extensors	The patient is instructed to flex the hips and the knees keeping the soles of the feet on the supporting surface and to raise the pelvis from the supporting surface. This position is held for 10 seconds.
	Shoulder flexors and scapular upward rotators	The patient is instructed to flex the shoulder to 90 degrees with the elbow straight and to hold the position while the clinician attempts to push the arms into extension
	Shoulder extensors and scapula downward rotators	The patient is instructed to flex the shoulder to 90 degrees with the elbow straight and to hold the position while the clinician attempts to push the arms into flexion
	Shoulder horizontal abductors	The patient is instructed to flex the shoulder to 90 degrees with the elbow straight and to hold the position while the clinician attempts to push the arms together into horizontal adduction
	Shoulder adductors	The patient is instructed to bring the hands together in front of the chest, keeping the elbow straight and to hold this position. The clinician attempts to separate the arms into horizontal abduction.
	Neck and trunk flexors	The patient is instructed to hold both arms straight in front of the body and then to raise the head and shoulders off the supporting surface, and to hold this position
Supine or sitting	Shoulder abductors	The patient is instructed to abduct the shoulder to the side up to shoulder level with the elbows straight. The clinician attempts to push the arms down to the patient's sides into shoulder adduction.
	Shoulder adductors	The patient is instructed to abduct the shoulder to the side up to shoulder level with the elbows straight. The clinician attempts to push the arms over the patient's head into shoulder abduction.
	Shoulder internal rotators	The patient is instructed to hold the arms at the sides, flex the elbows to approximately 90 degrees and to place the forearms in neutral. The clinician attempts to push the arms outward into external rotation of the shoulder
	Shoulder external rotators	The patient is instructed to hold the arms at the sides, flex the elbows to approximately 90 degrees and to place the forearms in neutral. The clinician attempts to push the arms inward into internal rotation of the shoulder
	Elbow flexors	The patient is instructed to hold the arms at the sides, flex the elbows to approximately 90 degrees and to place the forearms in neutral. The clinician attempts to push the forearms toward the supporting surface into elbow extension
	Elbow extensors	The patient is instructed to hold the arms at the sides, flex the elbows to approximately 90 degrees and to place the forearms in neutral. The clinician attempts to push the forearms toward the shoulders into elbow flexion
	Forearm supinators	The patient is instructed to hold the arms at the sides, flex the elbows to approximately 90 degrees and to place the forearms in neutral. The clinician attempts to turn the palms down into pronation
	Forearm pronators	The patient is instructed to hold the arms at the sides, flex the elbows to approximately 90 degrees and to place the forearms in neutral. The clinician attempts to turn the palms upward into supination
	Wrist flexors	The patient is instructed to hold the arms at the sides, flex the elbows to approximately 90 degrees and to place the forearms in neutral. The clinician attempts to push the palms away from the body into wrist extension
	Wrist extensors	The patient is instructed to hold the arms at the sides, flex the elbows to approximately 90 degrees and to place the forearms in neutral. The clinician attempts to push the palms toward the body into wrist flexion
	Finger flexors	The patient is instructed to hold the arms at the sides, flex the elbows to approximately 90 degrees and to place the forearms in neutral. The clinician places his or her index and middle fingers into the patient's hand and the patient is asked to squeeze the fingers. The clinician then attempts to pull the fingers out.

TABLE 12-1 Gross Muscle Screening (Continued)

Patient Position	Tested Muscle Group	Procedure
	Finger extensors	The patient is instructed to hold the arms at the sides, flex the elbows to approximately 90 degrees and to place the forearms in neutral. The patient is asked to straighten the fingers and then the clinician attempts to push the fingers into flexion
	Anterior interossei	The patient is instructed to hold the arms at the sides, flex the elbows to approximately 90 degrees and to place the forearms in neutral. The patient is asked to adduct the fingers and then the clinician attempts to pull the fingers into abduction
	Posterior interossei	The patient is instructed to hold the arms at the sides, flex the elbows to approximately 90 degrees and to place the forearms in neutral. The patient is asked to abduct the fingers and then the clinician attempts to push the fingers into adduction
	Opponens pollicis	The patient is instructed to hold the arms at the sides, flex the elbows to approximately 90 degrees and to place the forearms in neutral. The clinician places his or her index finger between the patient's thumb and each finger one at a time while asking the patient to pinch the finger
Sitting	Latissimus dorsi and triceps	The patient is instructed to place both hands on the supporting surface next to the hips, keeping the elbows straight and the shoulder shrugged. The patient is then asked to depress the scapular by lifting the buttocks off the supporting surface.
	Upper trapezius and levator scapulae	The patient is instructed to shrug the shoulders toward the ears and to hold the position. The clinician attempts to push the shoulders down into depression
	Internal rotators of the hip and evertors of the feet	The patient is instructed to evert the foot and to hold the position while the clinician pushes on the lateral border of each foot, into inversion and external rotation of the hip
	External rotators of the hip and invertors of the feet	The patient is instructed to invert the foot and to hold the position while the clinician pushes on the medial border of each foot, into eversion and internal rotation of the hip
Prone	Rhomboids, middle trapezius, and posterior deltoid	The patient is instructed to flex the elbows level with the shoulders, pinch or adduct the scapulae together and raise the arms from the supporting surface. The clinician attempts to push the arms downward
	Elbow and shoulder extensors	The patient is instructed to raise the arm off the supporting surface while keeping the arms at the sides and the elbows straight. The clinician attempts to push the arms downward
	Extensors of the hips, back, neck, and shoulders	The patient is instructed to keep the arms at the sides and to raise the head and shoulders and arms and legs of the supporting surface simultaneously by arching the back. The position is held for 10 seconds
Prone or sitting	Hamstrings	The patient is instructed to flex the knees to about 90 degrees. The clinician attempts to pull the knees into extension
	Quadriceps	The patient is instructed to flex the knees to about 90 degrees. The clinician attempts to push the knees into flexion
Standing	Gastrocnemius/soleus	The patient is instructed to stand on one leg with one finger on the supporting surface for balance. The patient is then asked to rise up on tiptoes and to repeat 10 times. The other leg is then tested
	Dorsiflexors	The patient is instructed to walk on the heel for 10 steps
	Hip and knee extensors	The patient is instructed to do five partial deep-knee bends

For that reason, if a component of a muscle's function is lost, other muscles that have duplicate functions can compensate for that loss.

- How to eliminate substitute or trick motions. T is is best accomplished by using standardized testing positions. Where appropriate, these motions are included in each of the test procedures so that the clinician is aware of what to avoid.
- How to skillfully apply resistance. Pressure should be applied slowly, very gently, and gradually before progressing to the maximum resistance tolerable.
- T e standard positions for each muscle test based on the effects of gravity. Typically the patient is positioned in either an antigravity or a gravity-eliminated position (see later).

T e main purposes of specific muscle testing are as follows:

- To help determine a diagnosis. For example, specific muscle testing can aid in precisely localizing a lesion in the peripheral nervous system.
- To establish a baseline for muscle reeducation and exercise.
- To determine a patient's need for supportive apparatus (orthosis, assistive device of ambulation, or splints).
- To help determine a patient's progress.

FIGURE 12-15 Gross muscle testing of the ankle plantarflexors.

The patient is positioned in an antigravity position for grades 3–5 and in a gravity-eliminated position for grades 0–2. If the muscle strength is less than grade 3, then the methods advocated in muscle testing manuals must be used. For the testing methods and positions described in this chapter, it is assumed that the patient has a grade of 3–5. Alternative, gravity eliminated/minimized positions will also be provided.

CLINICAL PEARL

If the clinician is having difficulty differentiating between a grade 4 and a grade 5, the eccentric "break" method of muscle testing may be used. This procedure starts with an isometric contraction, but then the clinician applies sufficient force to cause an eccentric contraction or a "break" in the patient's isometric contraction.

Muscle Testing of the Shoulder Complex

A number of significant muscles control motion at the shoulder and provide dynamic stabilization (see Chapter 16).

Upper Trapezius and Levator Scapulae

It is worth remembering that it is difficult to differentiate the strength of the levator scapulae from that of the upper trapezius. For this reason, the levator scapulae strength is often assessed together with the rhomboids, or with the upper trapezius. The patient is seated with the arm relaxed at the sides. The patient is asked to raise the shoulder as high as possible, and to extend and rotate the occiput toward the elevated shoulder (Fig. 12-16). The clinician stabilizes the top of the shoulders with one hand and applies resistance against the head in the direction of cervical flexion anterolaterally (see Fig. 12-16). The command given to the patient is "Don't let me separate your head and shoulder." Substitution or trick motions can include abduction and upward rotation of the scapula (serratus anterior), elevation and downward rotation of the scapula (rhomboid major and minor), anterior tilting of the scapula (pectoralis minor), and elevation of the first and second ribs (scalenus muscle group). The gravity minimized/eliminated position for this muscle is with the patient

FIGURE 12-14 Gross muscle testing of the ankle dorsiflexors.

FIGURE 12-16 Test position for the upper portion of the trapezius (and levator scapulae).

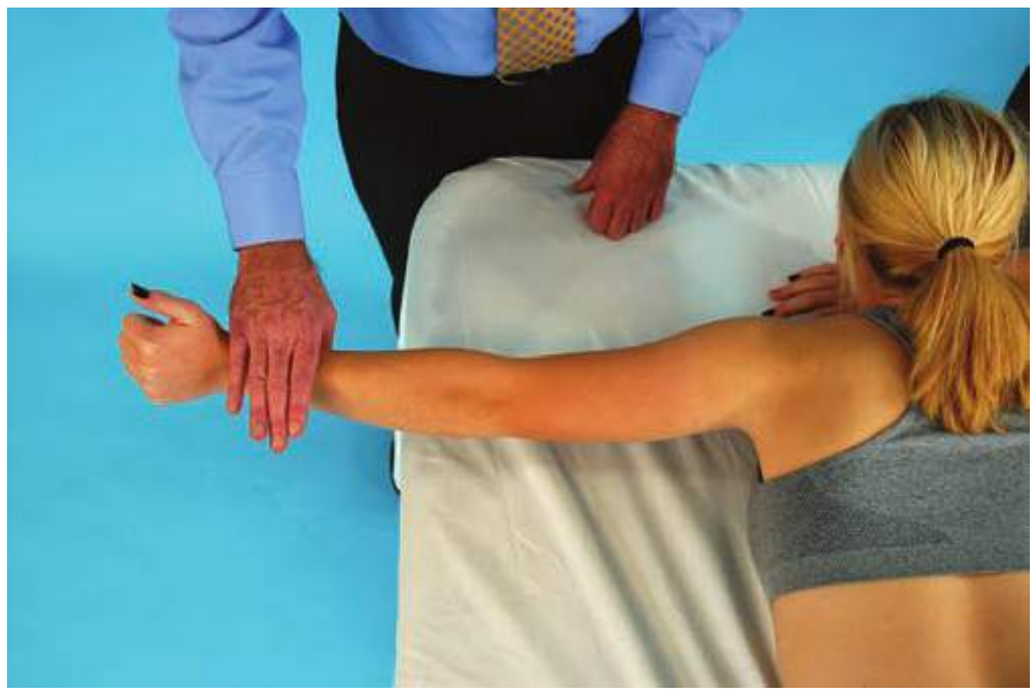

FIGURE 12-17 Test position for the middle trapezius.

positioned in a supine or prone position with the upper limb and shoulder supported.

Middle Trapezius

To specifically test this muscle, the patient is positioned in prone with the shoulder abducted to 90 degrees, the elbow extended, and the upper extremity externally rotated so that the thumb points toward the ceiling (Fig. 12-17). The clinician applies pressure against the forearm in a downward direction toward the table. The command given to the patient is "Don't let me push your arm down while keeping your elbow straight and your thumb pointing upward." Substitution or trick motions can include trunk rotation, horizontal abduction of the shoulder (posterior deltoid) elevation and downward rotation of the scapula (rhomboid major and minor), depression and downward rotation of the scapula (lower trapezius), synergistic contraction of the upper and lower fibers of the trapezius muscle, and synergistic contraction of the lower trapezius and the rhomboids. The gravity minimized/eliminated position for this muscle is with the patient positioned in sitting with the upper limb supported on a friction free surface in a position of 90 degrees of abduction and 90 degrees of elbow flexion.

Lower Trapezius

To specifically test this muscle, the patient is positioned in prone with the arm placed diagonally overhead, and the shoulder is externally rotated (Fig. 12-18). The clinician applies pressure against the forearm downward toward the table. The command given to the patient is "Don't let me push your arm down while keeping your arm diagonally upward and your thumb facing upward." Substitution or trick motions can include assistance from the posterior deltoid, latissimus dorsi, or pectoralis major. The gravity minimized/eliminated position for this muscle is with the patient positioned in prone with the arms by the sides and the upper extremity supported by the clinician. The patient is asked to depress and adduct the scapula through the full range of motion.

Serratus Anterior

To specifically test this muscle, the patient is positioned in supine, standing, or sitting.

- Supine: the patient is asked to flex the shoulder to 90 degrees with slight abduction and with the elbow in extension. From this position, the patient moves the arm upward toward the ceiling by abducting the scapula. The clinician applies resistance by grasping around the forearm and elbow and applying a downward and inward pressure toward the table (Fig. 12-19). The command given to the patient is "Try to lift your arm higher by moving your shoulder forward while I push down on it."
- Standing: the patient places a hand against the wall with the shoulder in forward flexion to 80–90 degrees and the elbows locked in extension. While monitoring the inferior angle of the scapula for any winging, the command given to the patient is "Push against the wall."
- Sitting: this test focuses on the upward rotation action of the serratus in the abducted position. The patient is asked to move the humerus into approximately 120–130

FIGURE 12-18 Test position for the lower trapezius.

FIGURE 12-19 Test position for the serratus anterior—patient supine.

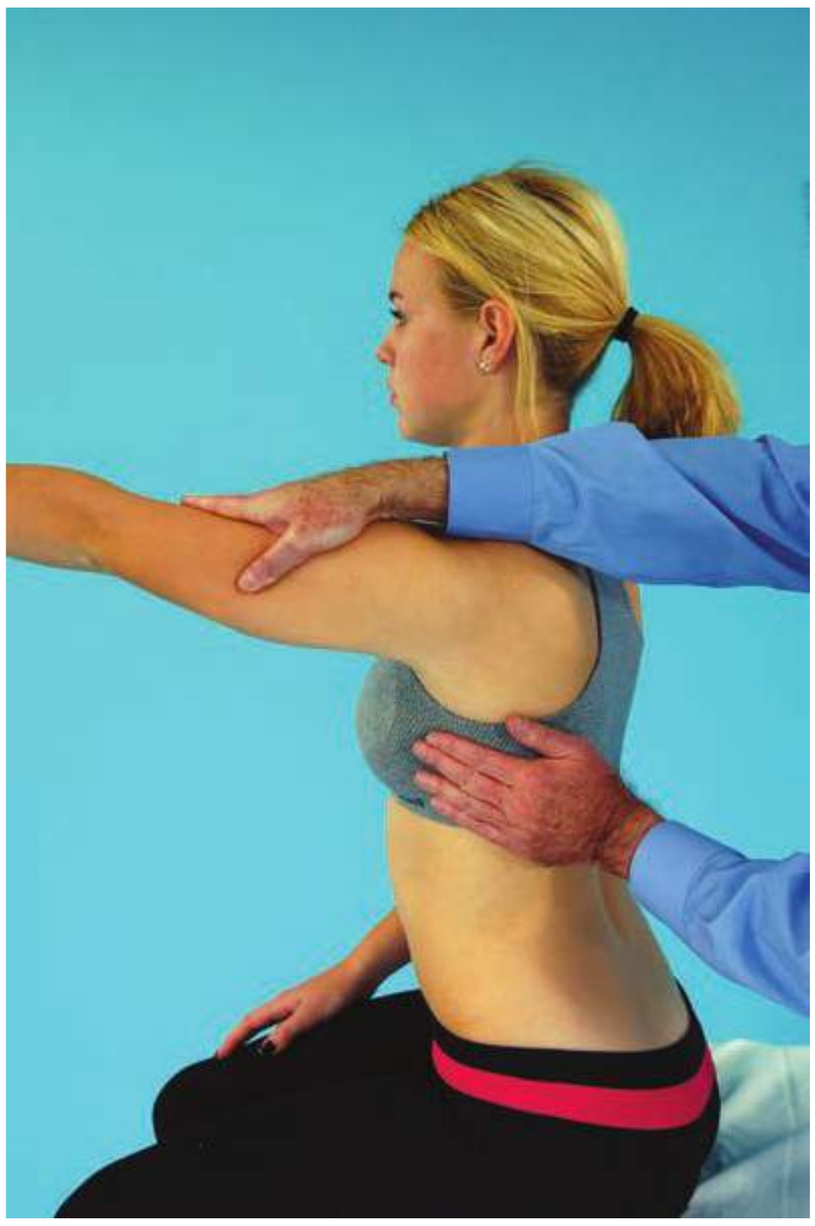

FIGURE 12-20 Test position for the serratus anterior—patient sitting.

degrees of flexion. Using one hand, the clinician stabilizes the inferior aspect of the scapula, and the other hand is placed on the anterior aspect of the arm (Fig. 12-20). The command given to the patient is "Keep your arm still while I try and push it down," as the clinician pushes downwardly on the arm while applying a resistive force with the other hand into medial rotation of the inferior angle of the scapula.

Substitution or trick motions typically occur in sitting and can include flexion of the vertebrae, or rotation of the vertebrae.

The gravity minimized/eliminated position for this muscle is with the patient positioned in sitting with the upper limb resting on a table, with the shoulder positioned in 90 degrees of flexion, and the elbow extended.

Rhomboid Major, Minor, and Levator Scapulae

The patient is positioned in prone with the head turned toward the tested side, the elbow flexed, and the ipsilateral humerus abducted, slightly extended, and externally rotated (Fig. 12-21A). The clinician applies pressure with one hand against the patient's arm in the direction of abducting the scapula and externally rotating the inferior angle, while the other hand is placed on the patient's shoulder in the direction of depression (see Fig. 12-21A). The command given to the patient is "Don't let me push your arm down." Substitution or trick motions can include assistance from the wrist extensors, middle trapezius, posterior deltoid, latissimus dorsi, teres major, and levator scapulae. An alternative test can be performed with the patient positioned in prone with the upper extremity positioned in 90 degrees of abduction and internally rotated so that the thumb is pointing down

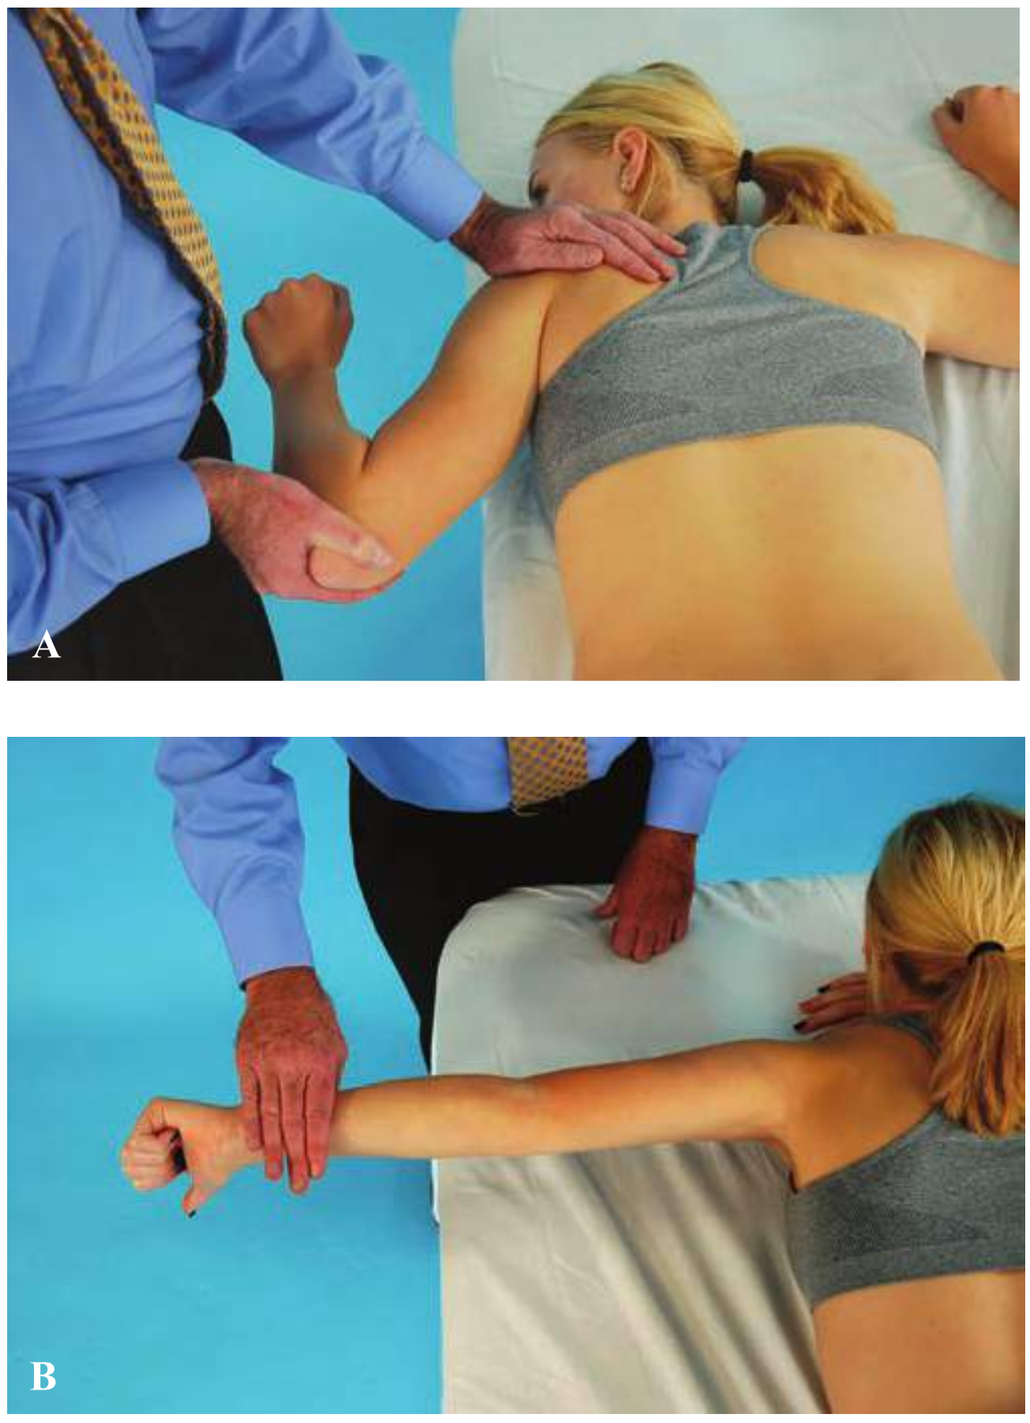

FIGURE 12-21 A: Test position for the rhomboids (and levator scapulae). B: Alternate test position for the rhomboids.

(Fig. 12-21B). The patient is asked to raise the arm toward the ceiling and to hold the position while the clinician applies a downward force to the patient's forearm. The gravity minimized/eliminated position for this muscle is with the patient positioned in sitting with the hand resting on the lumbar spine.

Latissimus Dorsi

To specifically test this muscle, the patient is positioned in prone with the shoulder internally rotated and adducted and the palm facing upward (Fig. 12-22). The patient is asked to

FIGURE 12-22 Test position for the latissimus dorsi.

extend the shoulder while keeping the elbow straight. The command given to the patient is "While keeping your palm facing the ceiling, don't let me push your arm down." The clinician stabilizes the thorax, and resistance is given proximal to the elbow joint using a force that is a combination of shoulder abduction and minimal flexion (see Fig. 12-22). Substitution or trick motions can include scapular adduction with no shoulder motion, anterior tipping and abduction of the scapula, assistance from the teres major, posterior deltoid, or pectoralis major (sternal head). The gravity minimized/eliminated position for this muscle is with the patient positioned in sidelying, with the upper limb supported in 90 degrees of shoulder flexion and internal rotation, and with the elbow flexed.

Teres Major

To specifically test this muscle, the patient is positioned in prone with the upper extremity extended, abducted, and medially rotated and with the back of the hand resting on the small of the back. The clinician places a hand against the arm proximal to the elbow (Fig. 12-23), and the command given to the patient is "Keeping your hand on your back, don't let me move your arm toward the table," while the clinician generates a force into flexion and abduction of the upper extremity. Substitution or trick motions can include scapular adduction without shoulder motion, external rotation of the glenohumeral joint, and assistance from the latissimus dorsi, pectoralis major, and teres minor. In general, the teres major muscle is not tested in a gravity eliminated position, because it will only contract against resistance.

Pectoralis Major

To specifically test this muscle, the patient is positioned in supine. The patient's arm position depends on which portion of the muscle is being tested:

- The clavicular portion (upper fibers): the patient arm is positioned in 60–90 degrees of shoulder abduction and the elbow is slightly flexed. The patient is then asked to horizontally adduct the shoulder as the clinician applies resistance proximal to the wrist (or proximal to the elbow if the elbow flexors are weak) in a downward and outward direction (Fig. 12-24A). The coracobrachialis, a synergist of the upper fibers, can also be assessed (Fig. 12-24B).

FIGURE 12-23 Test position for the teres major.

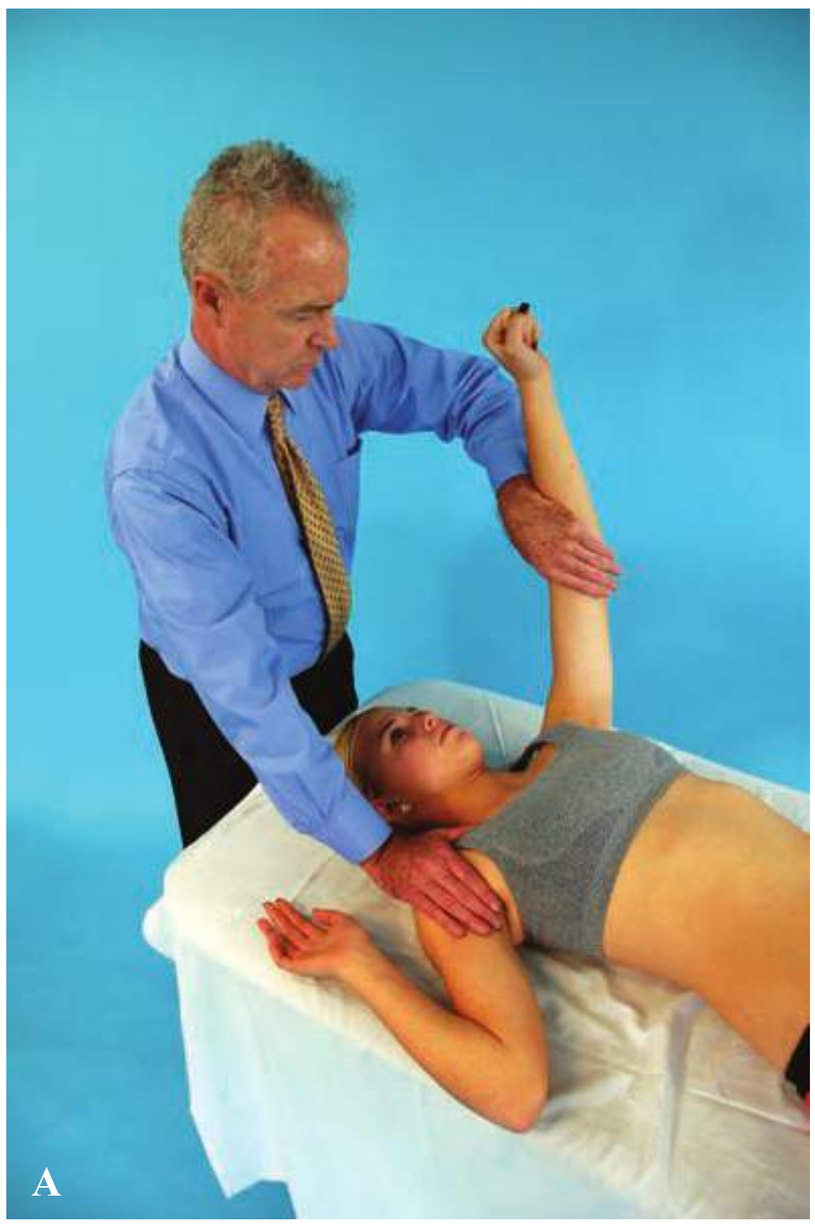

FIGURE 12-24 A: Test position for the pectoralis major—upper fibers. B: Test position for the coracobrachialis.

- The sternal portion (lower fibers): the patient arm is positioned in 120 degrees of shoulder abduction with the elbow slightly flexed. The patient is asked to move the arm down and in across the body as the clinician applies resistance proximal to the elbow in an up and outward direction (Fig. 12-25).

Substitution or trick motions can include trunk rotation, assistance from the anterior deltoid, coracobrachialis, and biceps brachii. The gravity minimized/eliminated position for this muscle is with the patient positioned in sitting with the shoulder positioned in neutral rotation and in 90 degrees of abduction, the elbow flexed to 90 degrees, and the upper limb supported.

Pectoralis Minor

To specifically test this muscle, the patient is positioned in supine with the arms at the sides and the patient is asked to

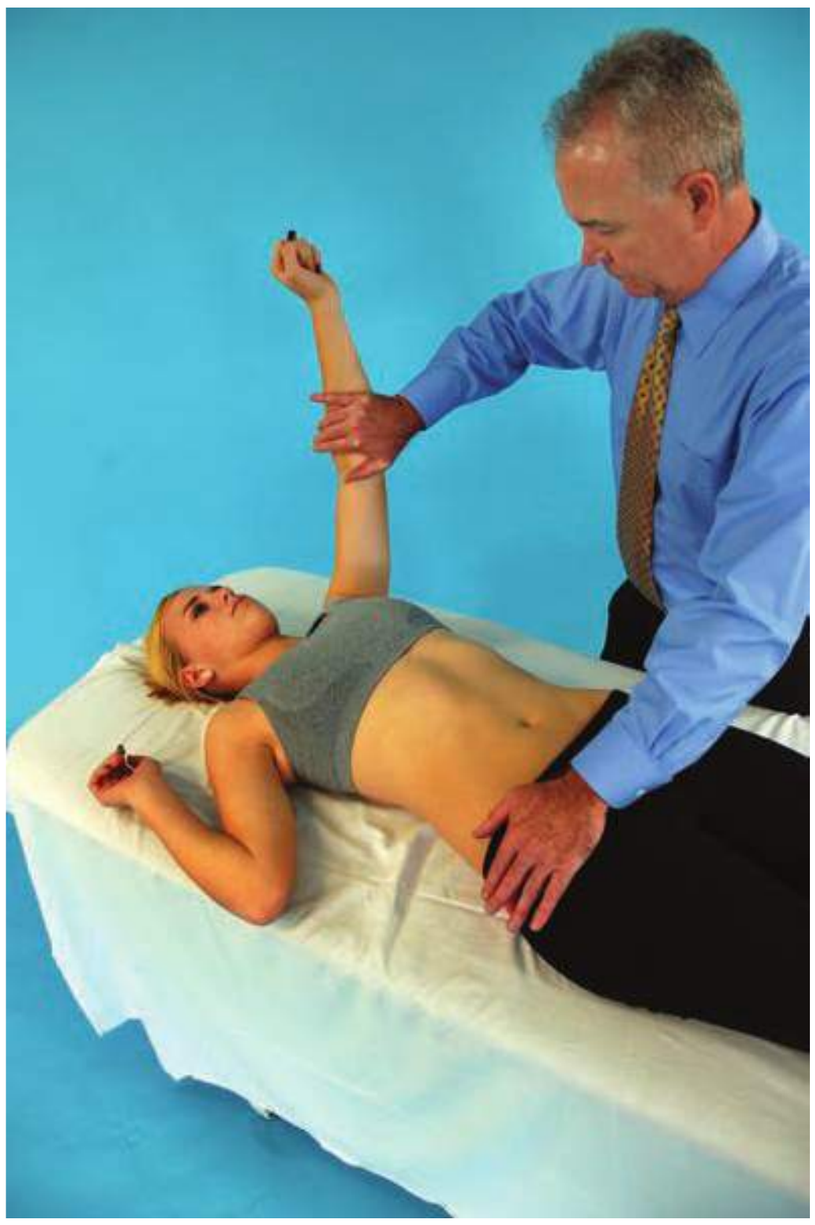

FIGURE 12-25 Test position for the pectoralis major—lower fibers.

lift the shoulder girdle from the table (without using force from the elbow or hand) and to hold the position while the clinician applies resistance against the anterior aspect of the shoulder (Fig. 12-26) in a downward direction toward the table. Substitution or trick motions can include flexion of the wrist or fingers, which can give the appearance of anterior tipping of the scapula. The gravity minimized/eliminated position for this muscle is with the patient positioned in sitting with the hand resting on the small of the back.

Deltoid

To specifically test the various portions of this muscle, the patient's arm position used depends on which portion of the muscle is being tested:

FIGURE 12-26 Test position for pectoralis minor.

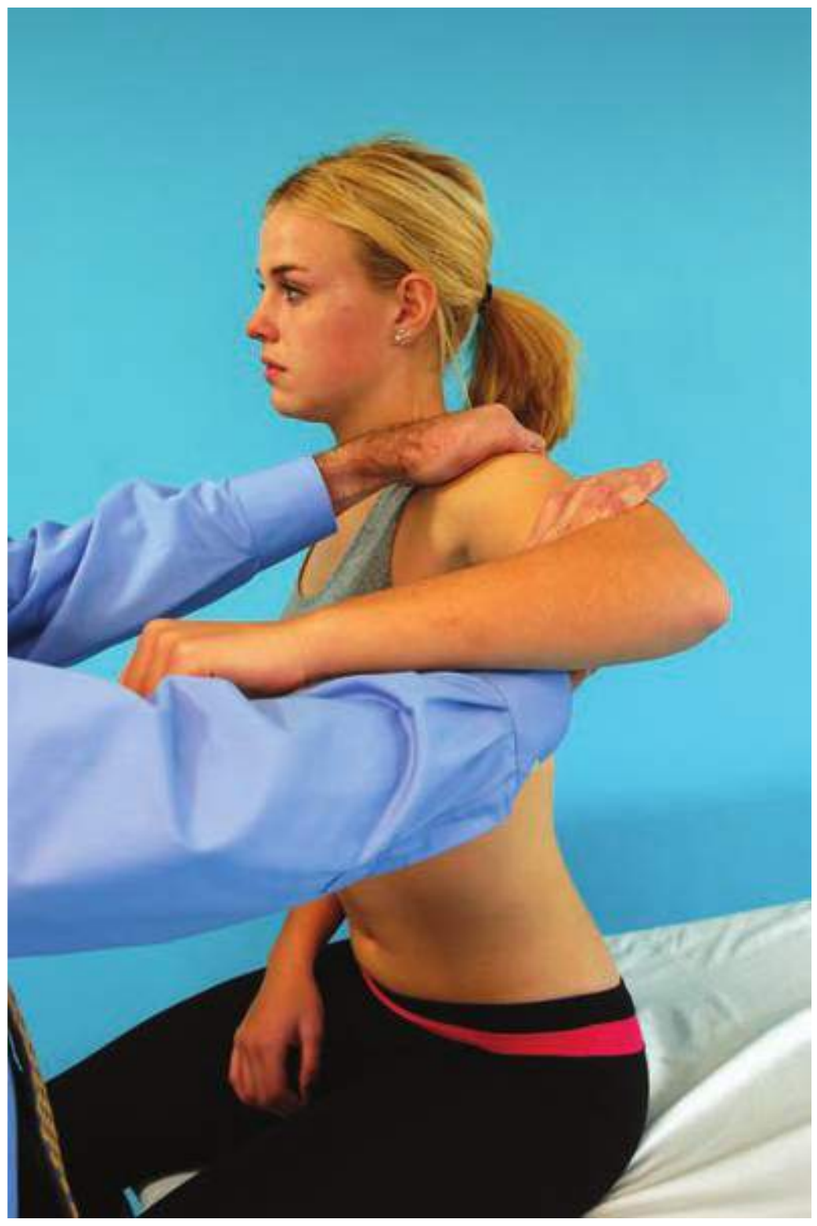

FIGURE 12-27 Test position for the anterior deltoid.

- Anterior deltoid. The patient is positioned in sitting or supine with the shoulder abducted in minimal flexion. The command given to the patient is "Move your arm diagonally forward and toward your body, and hold it against my resistance." While stabilizing the patient's shoulder with one hand, the clinician uses the other hand to apply resistance to the anterior and medial aspect of the arm proximal to the elbow in the direction of abduction and minimal extension (Fig. 12-27). Substitution or trick motions can include elevating the shoulder and leaning backward, assistance from the biceps brachii, coracobrachialis, or pectoralis major (clavicular head), or by moving the scapula. The gravity minimized/eliminated position for this muscle is with the patient positioned in sidelying with the upper extremity supported, and the shoulder positioned in neutral, and the elbow flexed.
- Middle deltoid. The patient is positioned in sitting with the arm abducted to 90 degrees and the elbow flexed to approximately 90 degrees. The patient is asked to hold this position while the clinician applies resistance just proximal to the elbow in a downward direction (Fig. 12-28). Substitution or trick motions can include trunk flexion to the same side, or assistance from the biceps brachii, supraspinatus or serratus anterior. The gravity minimized/eliminated position for this muscle is with the patient positioned in supine with the upper extremity supported and the elbow flexed to 90 degrees.
- Posterior deltoid. The patient positioned in sitting with the shoulder abducted to approximately 90 degrees and positioned in minimal shoulder extension and

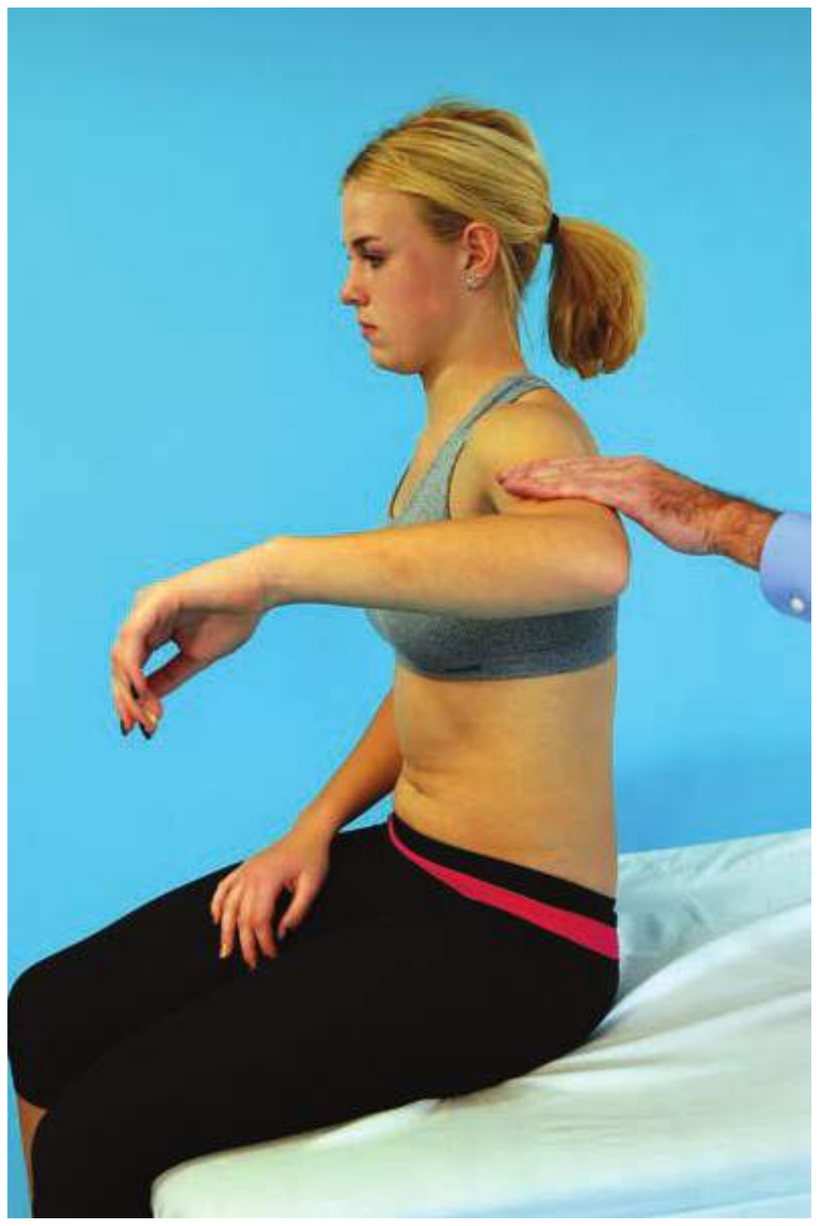

FIGURE 12-28 Test position for the middle deltoid.

internal rotation. The patient is asked to push the arms back toward the clinician as the clinician uses one hand to stabilize the scapula and the other hand to apply resistance to the posterolateral aspect of the arm, proximal to the elbow, in the direction of shoulder abduction and slight flexion (Fig. 12-29). Substitution or trick motions can include assistance from the long head of the triceps or adduction of the scapula without horizontally abducting the shoulder. The gravity minimized/eliminated position for this muscle is with the patient positioned in sitting with the upper extremity supported on a table, and the shoulder and elbow flexed to 90 degrees.

FIGURE 12-29 Test position for the posterior deltoid.

FIGURE 12-30 Test position for the shoulder external rotators—teres minor and infraspinatus—patient prone.

Rotator Cuff

The rotator cuff (RC) muscles consist of the supraspinatus, infraspinatus, teres minor, and the subscapularis. Each of the muscles of the RC can be specifically tested, with the patient setup dependent on which muscle is being tested:

- Teres minor. The patient is positioned in prone with the shoulder abducted to 90 degrees and the arm supported by the table so that the forearm is permitted to move freely (Fig. 12-30). The patient is asked to externally rotate the shoulder so that the forearm moves toward the ceiling. The patient is asked to hold this position while the clinician applies resistance to the patient's wrist in a downward direction with one hand, while using the other hand to support the patient's arm (see Fig. 12-30). The teres minor can also be tested with the patient in supine with the humerus in external rotation and the elbow held at a right angle. Using one hand, the clinician stabilizes the upper arm, while using the other arm to apply pressure in the direction of internal rotation of the humerus (Fig. 12-31).
- Subscapularis. The patient is positioned in prone with the shoulder abducted to 90 degrees and the arm resting on the table so that the forearm is permitted to move freely

FIGURE 12-31 Test position for the shoulder external rotators—teres minor and infraspinatus—patient supine.

FIGURE 12-32 Test position for the shoulder internal rotators—subscapularis—patient prone.

(Fig. 12-32). The patient is asked to internally rotate the shoulder so that the forearm moves toward the ceiling. The patient is asked to hold the position while the clinician applies resistance at the wrist in a downward direction with one hand, while using the other hand to support the patient's arm (see Fig. 12-32). The subscapularis can also be tested with the patient in supine with the upper arm at the side and the elbow held at the right angle (Fig. 12-33). Using one hand to stabilize the patient's upper arm, the clinician uses the other hand to apply force to the inner aspect of the patient's wrist and forearm in a direction of external rotation. Substitution or trick motions can include scapular abduction, pronation of the forearm, and assistance from the pectoralis major, teres major, and latissimus dorsi. The gravity minimized/eliminated position for this muscle is with the patient positioned in prone with the shoulder flexed over the edge of the table.

- Supraspinatus. The patient is positioned in sitting with the arm by the side, and the head rotated ipsilaterally and extended. Using one hand, the clinician palpates the supraspinatus; the other hand applies resistance at the elbow into shoulder adduction while the patient is asked to raise the arm up into shoulder abduction. This is a difficult muscle to isolate as it works in conjunction with the middle deltoid.

FIGURE 12-33 Alternate test position for the internal rotators—subscapularis—patient supine.

- Infraspinatus. The patient is positioned in prone with the shoulder abducted to 90 degrees and the arm supported by the table so that the forearm is permitted to move freely (see Fig. 12-30). The patient is asked to externally rotate the shoulder so that the forearm moves toward the ceiling and to hold that position. Using one hand, the clinician stabilizes the patient's arm while using the other hand to apply resistance in a downward direction at the patient's wrist (see Fig. 12-30). The infraspinatus can also be tested with the patient in supine with the humerus in external rotation and the elbow held at a right angle. Using one hand, the clinician stabilizes the upper arm, while using the other arm to apply pressure in the direction of internal rotation of the humerus (see Fig. 12-31).

Long Head of the Biceps Brachii

The strength of the long head of the biceps is assessed in combination with the short head of the biceps (see Elbow Flexors later).

Muscle Testing of the Elbow

Biceps Brachii

To specifically test this muscle the patient is positioned in sitting with the elbow flexed to approximately 90 degrees and the forearm in supination. Using one hand to stabilize the patient's shoulder, the clinician uses the other hand to apply resistance over the anterior aspect of the patient's forearm while asking the patient to hold the position of elbow flexion against the resistance (Fig. 12-34). As with all of the elbow flexors, the gravity minimized/eliminated position is with the patient positioned in sitting with the arm supported on a table at 90 degrees of abduction, the shoulder in neutral rotation, and the elbow extended. Substitution or trick motions when testing any of the elbow flexors can include shoulder extension, assistance from the pronator teres, or the wrist and finger extensors and flexors.

Brachialis

To specifically test this muscle, the patient is positioned in sitting or supine with the elbow flexed and the forearm pronated

FIGURE 12-34 Test position for the biceps brachii.

FIGURE 12-35 Test position for the brachialis.

FIGURE 12-37 Test position for the pronator teres.

(Fig. 12-35). Using one hand to stabilize the patient's arm, the clinician places the other hand over the posterior surface of the patient's forearm proximal to the wrist and applies a force in the direction of elbow extension while asking the patient to try and prevent the motion (see Fig. 12-35).

Brachioradialis

To specifically test this muscle, the patient is positioned in sitting or supine with the elbow flexed and the forearm placed in a neutral position half way between supination and pronation (Fig. 12-36). Using one hand to stabilize the patient's elbow, the clinician places the other hand proximal to the patient's wrist and applies a force toward elbow extension while asking the patient to resist the movement.

Pronator Teres

To specifically test this muscle, the patient is positioned in sitting or supine with the elbow flexed to approximately 80-90 degrees and the forearm fully pronated (Fig. 12-37). Using one hand, the clinician stabilizes the patient's elbow against the patient's thorax while placing the other hand proximal to the patient's wrist (see Fig. 12-37). T e patient is asked to maintain the position while the clinician generates a force into forearm supination. Substitution or trick motions can include trunk flexion to the contralateral side, and abduction and internal rotation of the shoulder. T e gravity minimized/eliminated position for this muscle is with the patient positioned in sitting with the shoulder supported on a table at 90 degrees of flexion, the elbow flexed to 90 degrees and the forearm perpendicular to the table.

Extensor Carpi Radialis Longus

To specifically test this muscle, the patient is positioned in sitting or supine with the elbow extended and the forearm just short of full pronation. Using one hand, the clinician supports the patient's forearm, and the patient is asked to extend the wrist in a radial direction (Fig. 12-38). Using the other hand, the clinician applies pressure to the posterior aspect of the patient's hand along the second metacarpal bone in an ulnar direction while asking the patient to prevent the movement (Fig. 12-38).

Flexor Carpi Radialis

To specifically test this muscle, the patient is positioned in sitting or supine, with the wrist flexed and ulnarly deviated and the forearm in supination. Using one hand, the clinician supports the patient forearm, while using the index and middle finger of the other hand to apply pressure on the thenar eminence in an ulnar and extension direction (Fig. 12-39). T e patient is asked to prevent this motion.

FIGURE 12-36 Test position for the brachioradialis.

FIGURE 12-38 Test position for the extensor carpi radialis longus and brevis.

FIGURE 12-39 Test position for the flexor carpi radialis.

Flexor Carpi Ulnaris

To specifically test this muscle, the patient is positioned in supine or sitting with the forearms supported, the wrist flexed, and the fingers relaxed. T e patient is asked to flex and ulnarly deviate the wrist. While stabilizing the wrist with one hand, the clinician generates a radial and extension force with the other on the medial aspect of the patient's hand (Fig. 12-40).

Pronator Quadratus

Although located proximal to the wrist, this muscle is tested with the other forearm pronators. To specifically test this muscle the patient is positioned in sitting or supine with the elbow completely flexed, and the forearm pronated. Using one hand to stabilize the patient's elbow, the clinician places the other hand proximal to the patient's wrist and applies a force into supination while asking the patient to prevent the movement (Fig. 12-41).

Supinator

To specifically test this muscle, the patient is positioned in standing or sitting. T e patient's arm can be positioned in one of two ways:

- T e shoulder flexed to 90 degrees, the elbow fully flexed, and the forearm fully supinated (Fig. 12-42).
- T e shoulder and elbow extended behind the patient and the forearm supinated (Fig. 12-43).

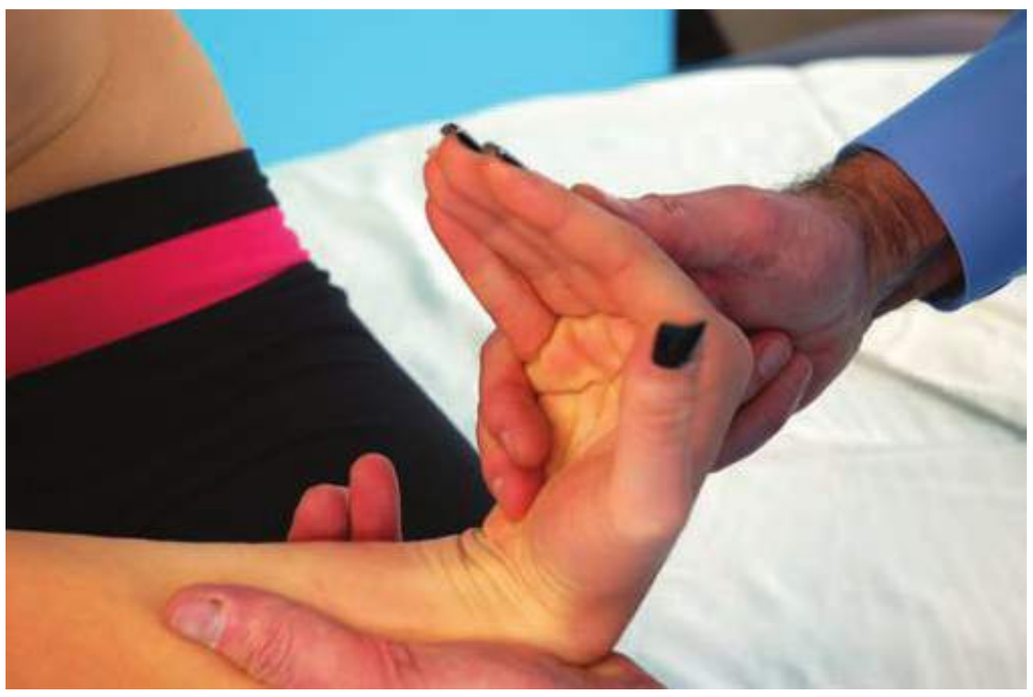

FIGURE 12-40 Test position for the flexor carpi ulnaris.

FIGURE 12-41 Test position for the pronator quadratus.

FIGURE 12-42 Test position for the supinator.

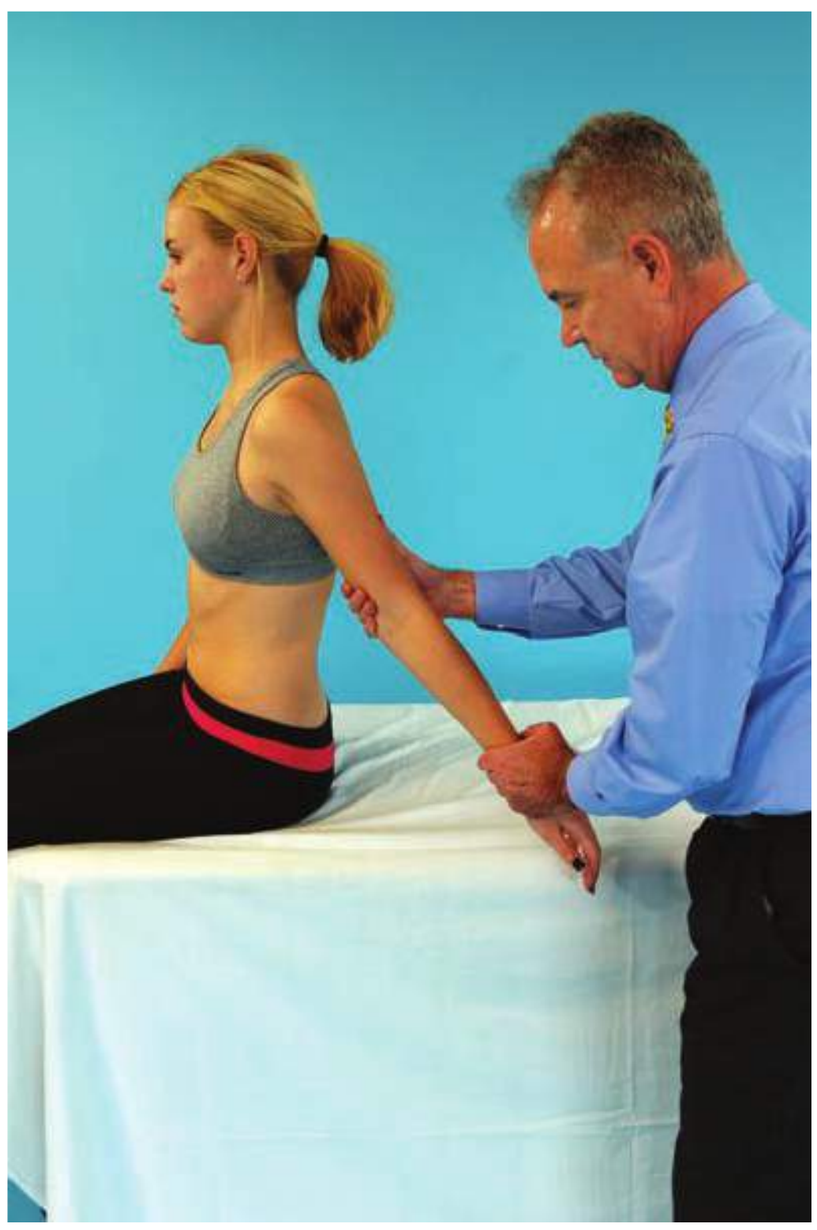

FIGURE 12-43 Alternate test position for the supinator.

FIGURE 12-44 Test position for the triceps brachii—patient prone.

FIGURE 12-45 Test position for the triceps brachii—patient supine.

Using one hand to stabilize the patient's upper arm at the elbow, the clinician places the other hand just proximal to the patient's wrist and applies a force into pronation while asking the patient to prevent the motion.

Triceps Brachii and Anconeus

To specifically test the triceps brachii and anconeus, three different positions can be used:

- Patient prone. The patient abducts the shoulder to 90 degrees, extends the elbow fully, and then unlocks it slightly (Fig. 12-44).
- Patient supine. The patient flexes the shoulder to 90 degrees, extends the elbow fully, and then unlocks it slightly (Fig. 12-45).
- Patient is sitting. The patient abducts the shoulder to 160 degrees, extends the elbow fully, and then unlocks it slightly (Fig. 12-46). This is position is the one used most commonly.

With each of the foregoing positions, the clinician uses one hand to stabilize the upper arm and places the other hand proximal to the patient's wrist. The patient is asked to hold the arm position while the clinician applies a force into elbow flexion.

Substitution or trick motions can include flexion of the shoulder. The gravity minimized/eliminated position for this muscle is with the patient positioned in sitting with the shoulder supported in 90 degrees of abduction and internal rotation and with the elbow flexed and the forearm in neutral.

Muscle Testing of the Wrist and Forearm

The muscles of the forearm are contained within three major fascial compartments, the anterior forearm, the posterior forearm, and the compartment referred to as the mobile wad, and can be subdivided into the 19 intrinsic muscles that arise and insert within the hand and the 24 extrinsic muscles that originate in the forearm and insert within the hand (see Chapter 18).

Palmaris Longus

To specifically test this muscle, the patient is positioned in sitting or supine with the forearm supinated and is asked to flex the wrist and cup the palm (Fig. 12-47). While supporting the patient's forearm with one hand, the clinician uses the

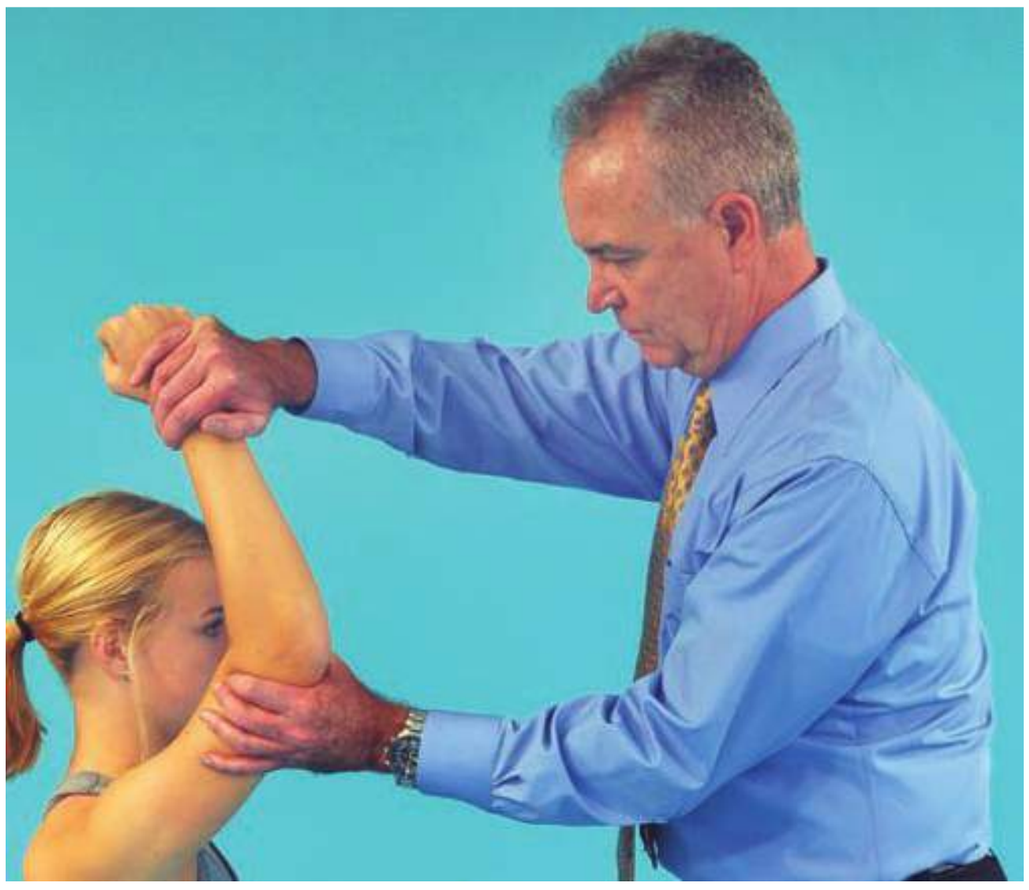

FIGURE 12-46 Test position for the triceps brachii—patient sitting.

FIGURE 12-47 Test position for the palmaris longus.

other hand to apply an uncupping and wrist extension force to the thenar and hypothenar eminences of the patient's hand (see Fig. 12-47).

Flexor Digitorum Superf cialis

To specifically test this muscle, the patient is positioned in sitting or supine with the forearm supported in supination and the metacarpophalangeal (MCP) joint stabilized by the clinician. T e patient is asked to bend the middle phalanx of the finger (Fig. 12-48). If necessary, the clinician can stabilize the three fingers that are not being tested in extension and prevent the wrist from flexing. T e clinician tests each finger individually by applying an extension force to the anterior aspect of the middle phalanx while asking the patient to prevent the movement.

FIGURE 12-48 Test position for the flexor digitorum superficialis.

FIGURE 12-49 Test position for flexor pollicis longus.

Flexor Pollicis Longus

To specifically test this muscle, the patient is positioned in sitting or supine with the hand supported and the forearm in supination. Using one hand, the clinician stabilizes the MCP joint of the thumb into extension (Fig. 12-49) and uses the other hand to generate an extension force to the anterior aspect of the distal phalanx of the thumb (see Fig. 12-49).

Flexor Digitorum Profundus

To specifically test this muscle, the patient is positioned in sitting or supine with the wrist in a neutral position or slightly extended. Using one hand, the clinician stabilizes the proximal and middle phalanges of the finger to be tested. T e patient is asked to flex the DIP joint of the finger while the clinician applies an extension force to the anterior aspect of the DIP (Fig. 12-50).

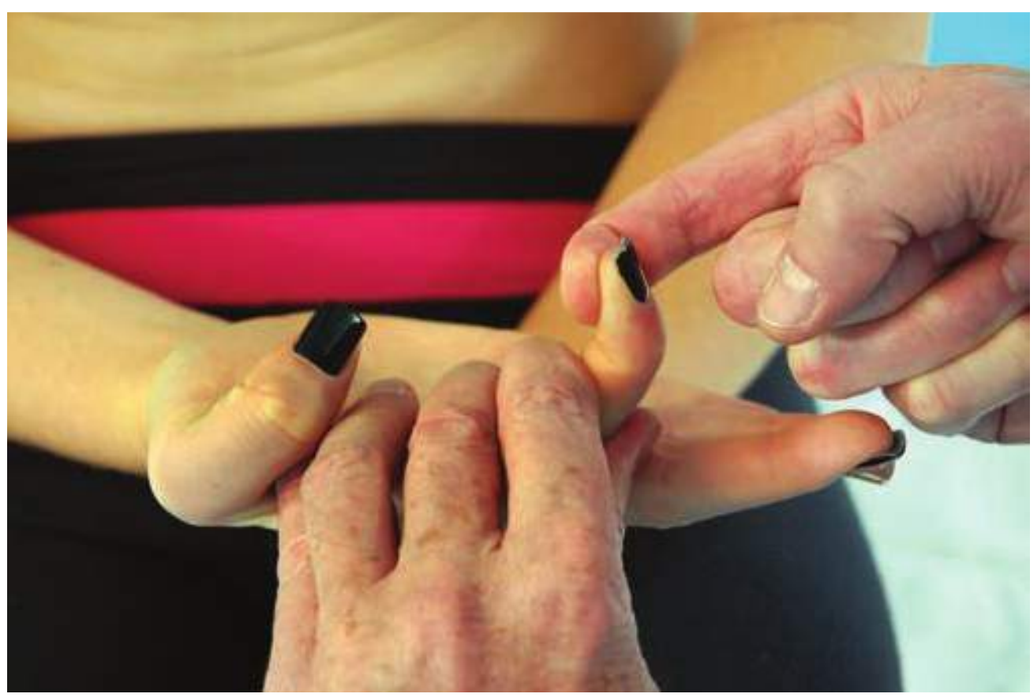

FIGURE 12-50 Test position for flexor digitorum profundus muscle.

FIGURE 12-51 Test position for the extensor carpi radialis brevis.

Extensor Carpi Radialis Brevis

To specifically test this muscle, the patient is positioned in sitting or supine with the elbow fully flexed (to place the ECRL in a position of mechanical insufficiency), and the forearm just short of full pronation supported by the examiner or the table (Fig. 12-51). The patient is asked to extend the wrist in a radial direction and to hold that position while the clinician applies pressure to the posterior aspect of the hand along the second and third metacarpal bones.

Extensor Digitorum Communis

To specifically test this muscle the patient is positioned supine or sitting with the forearm pronated, the wrist positioned in neutral—halfway between flexion and extension—and the MCP and proximal interphalangeal (PIP) joints slightly flexed. The patient is asked to extend the MCP of the finger to be tested and to hold that position. The clinician uses one hand to stabilize the wrist and, using two fingers of the other hand, applies pressure against the posterior surfaces of the patient's proximal phalanges (Fig. 12-52).

Extensor Digiti Minimi

To specifically test this muscle the patient is positioned supine or sitting with the forearm pronated, the wrist positioned in neutral—halfway between flexion and extension—

FIGURE 12-52 Test position for the extensor digitorum communis.

FIGURE 12-53 Test position for the extensor digiti minimi.

and the MCP and PIP joints slightly flexed. The patient is asked to extend the MCP of the fifth digit and to hold that position. The clinician uses one hand to stabilize the wrist and, using two fingers of the other hand, applies pressure against the posterior surface of the patient's proximal phalange (Fig. 12-53).

Extensor Carpi Ulnaris

To specifically test this muscle, the patient is positioned sitting or supine with the forearm positioned in complete pronation. The patient is asked to extend the wrist in an ulnar direction and to hold this position. Using one hand to stabilize the patient's forearm, the clinician uses the other hand to apply pressure to the posterior aspect of the patient's hand along the fifth metacarpal bone in a radial direction (Fig. 12-54).

FIGURE 12-54 Test position for the extensor carpi ulnaris.

FIGURE 12-55 Test position for the abductor pollicis longus.

FIGURE 12-56 Test position for the extensor pollicis brevis.

Abductor Pollicis Longus

To specifically test this muscle, the patient is positioned sitting or supine. The patient is asked to abduct and slightly extend the thumb and to hold that position. Using one hand, the clinician stabilizes the patient's wrist and uses the other hand to apply an adduction and flexion force against the lateral aspect of the distal first metacarpal (Fig. 12-55).

Extensor Pollicis Brevis

To specifically test this muscle, the patient is positioned sitting or supine with the MCP joint of the thumb extended. Using one hand, the clinician stabilizes the patient's wrist, while using a finger from the other hand to apply a flexion force against the proximal phalanx of the thumb (Fig. 12-56).

Extensor Pollicis Longus

To specifically test this muscle, the patient is positioned in sitting or supine with the thumb extended. The clinician uses one hand to stabilize the patient's hand and uses the other to apply a flexion force to the distal phalanx of the posterior surface of the patient's thumb (Fig. 12-57).

Extensor Indicis

To specifically test this muscle, the patient is positioned in sitting or supine and is asked to extend the index finger. The clinician uses one hand to stabilize the patient's wrist and uses the other hand to generate a flexion force to the posterior aspect of the proximal phalanx of the index finger (see Fig. 12-58).

Muscle Testing of the Hand

The muscles of the hand are those that originate and insert within the hand and are responsible for the fine finger movements (see Chapter 18).

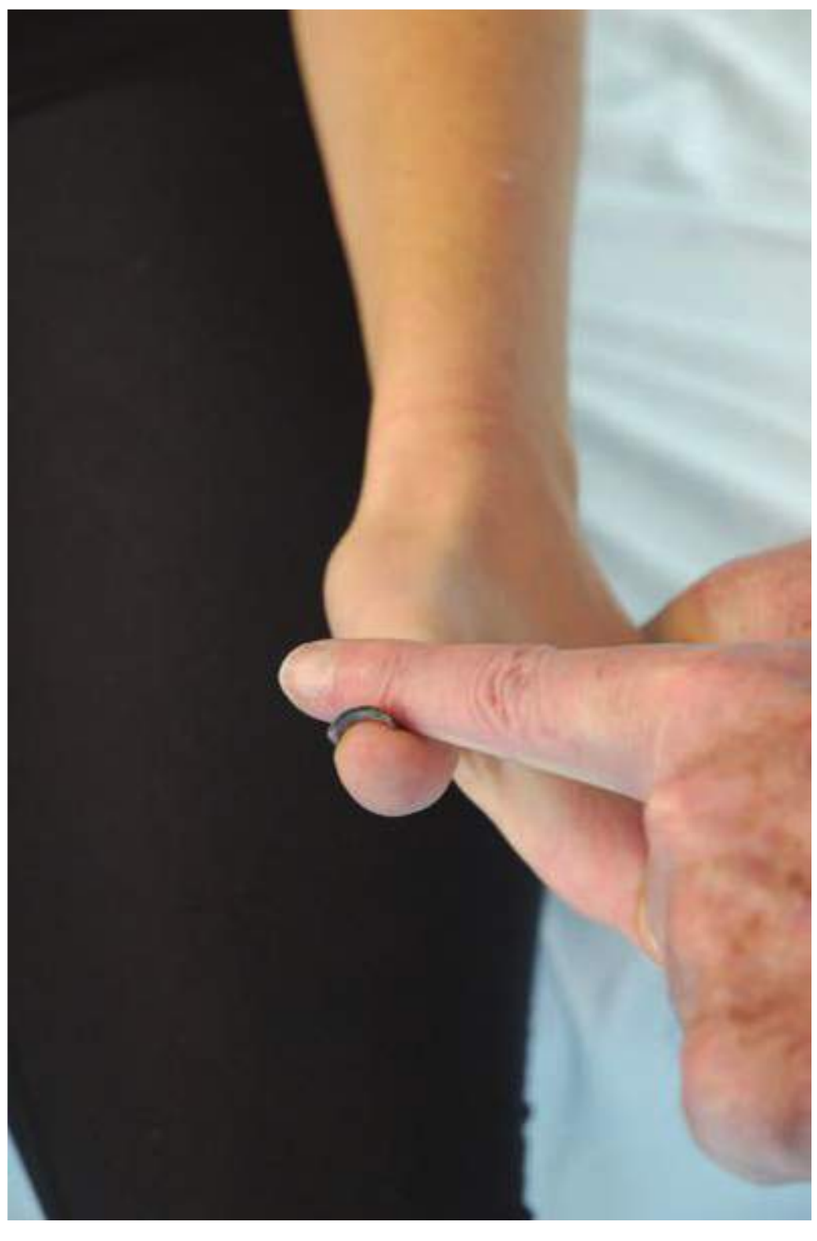

FIGURE 12-57 Test position for the extensor pollicis longus.

FIGURE 12-58 Test position for the extensor indicis.

Abductor Pollicis Brevis

To specifically test this muscle, the patient is positioned in sitting or supine and is asked to abduct the thumb. Using one hand, the clinician stabilizes the patient's wrist and hand and uses the other hand to generate a downward force against the proximal phalanx of the patient's thumb (Fig. 12-59).

Flexor Pollicis Brevis

To specifically test this muscle, the patient is positioned in sitting or supine and is asked to flex the thumb. Using one hand, the clinician stabilizes the patient's wrist and hand and uses the other hand to apply an extension force to the anterior surface of the proximal phalanx of the patient's thumb (Fig. 12-60).

FIGURE 12-59 Test position for the abductor pollicis brevis.

FIGURE 12-60 Test position for the flexor pollicis brevis.

Opponens Pollicis

To specifically test this muscle, the patient is positioned in sitting or supine and is asked to touch his or her thumb to the little finger (a combination of flexion, abduction, and slight internal rotation). T e clinician uses one hand to stabilize the patient's wrist and hand, and the other hand to generate pressure to the metacarpal bone of the thumb in an adduction and external rotation and extension direction (Fig. 12-61).

Adductor Pollicis

To specifically test this muscle, the patient is positioned in sitting or supine and is asked to move the thumb toward the palm. Using one hand, the clinician stabilizes the patient's

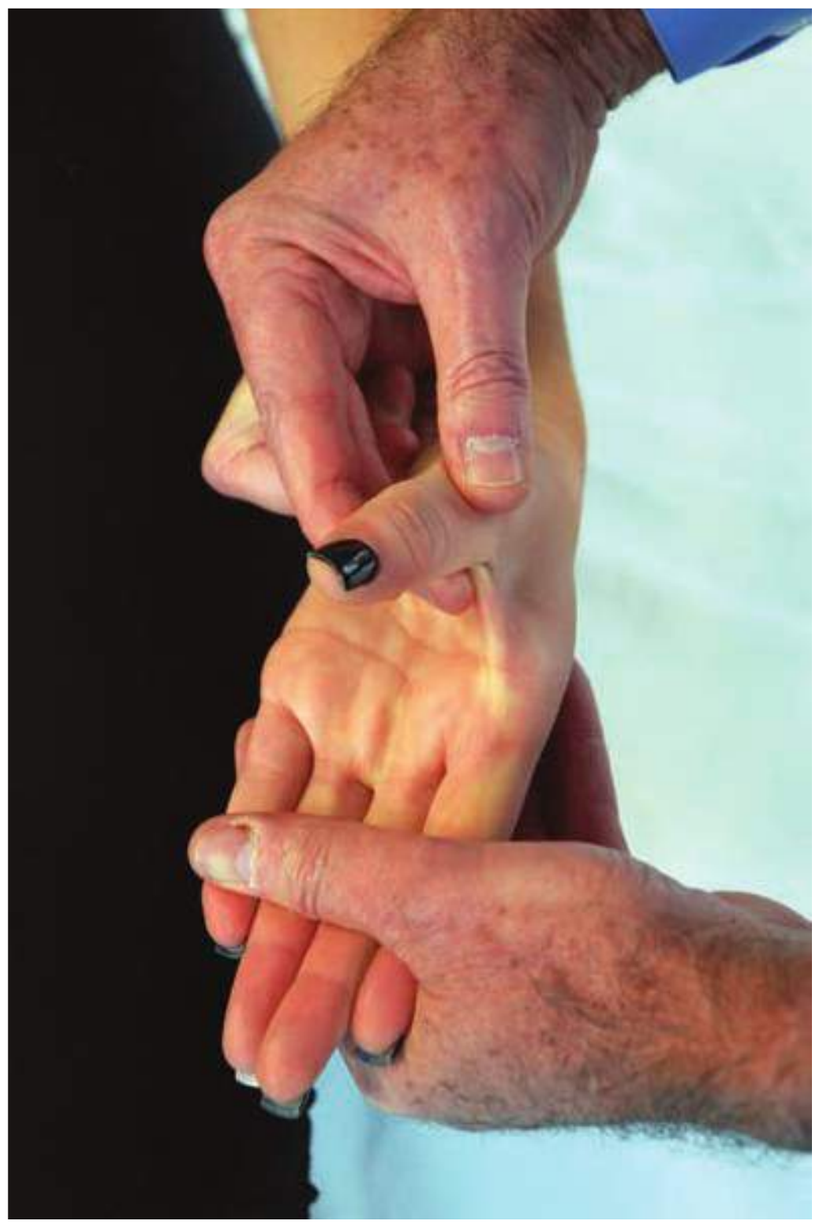

FIGURE 12-61 Test position for the opponens pollicis.

FIGURE 12-62 Test position for the adductor pollicis.

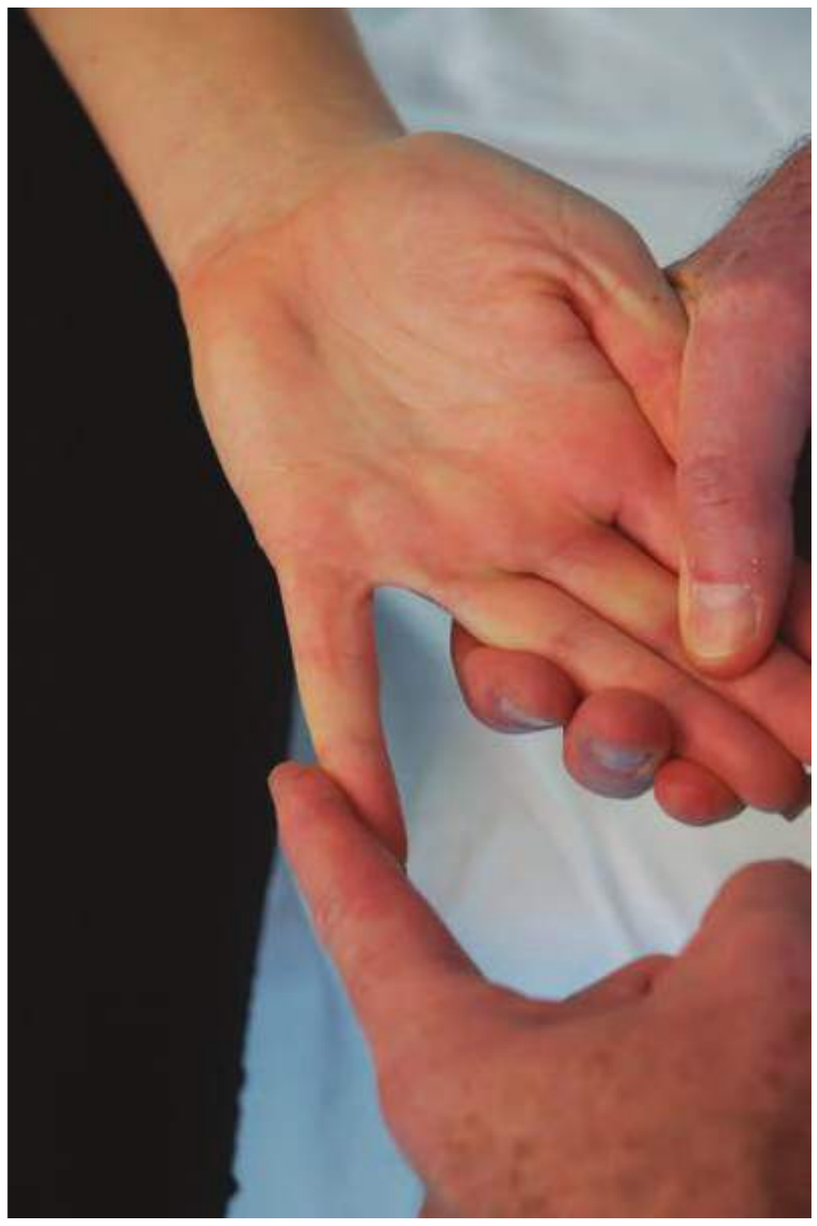

FIGURE 12-63 Test position for the abductor digiti minimi.

wrist and hand, while using the other to apply an abduction force to the inner aspect of the thumb (Fig. 12-62).

Abductor Digiti Minimi

To specifically test this muscle, the patient is positioned sitting or supine and is asked to abduct the little finger. T e clinician uses one hand to stabilize the patient's wrist and hand, and the other to apply an adduction force against the ulnar aspect of the middle phalanx of the patient's fifth digit (Fig. 12-63).

Flexor Digiti Minimi

To specifically test this muscle, the patient is positioned sitting or supine and is asked to flex the little finger at the MCP joint while maintaining the interphalangeal joint in extension. Using one hand, the clinician stabilizes the patient's wrist and hand, while using the other to apply an extension force against the flexed proximal phalanx of the patient's fifth digit (Fig. 12-64).

Opponens Digiti Minimi

To specifically test this muscle, the patient is positioned in sitting or supine and is asked to try to cup the fifth metacarpal toward the thumb. Using one hand, the clinician stabilizes the patient's wrist and hand, while using the other hand to grasp the first metacarpal of the fifth digit and apply a downward force (Fig. 12-65).

Anterior Interossei

To specifically test this muscle group, the patient is positioned sitting or supine with the digits not being tested stabilized, and the finger being tested brought toward the midline. One by one, the clinician applies pressure in an abduction direction against the appropriate side of the distal phalanx of the thumb, index, ring, and little finger (Fig. 12-66).

Posterior Interossei

To specifically test this muscle group, the patient is positioned sitting or supine with the digits not being tested stabilized, and the finger being tested moved away from the midline. One by one, the clinician applies pressure in the direction of

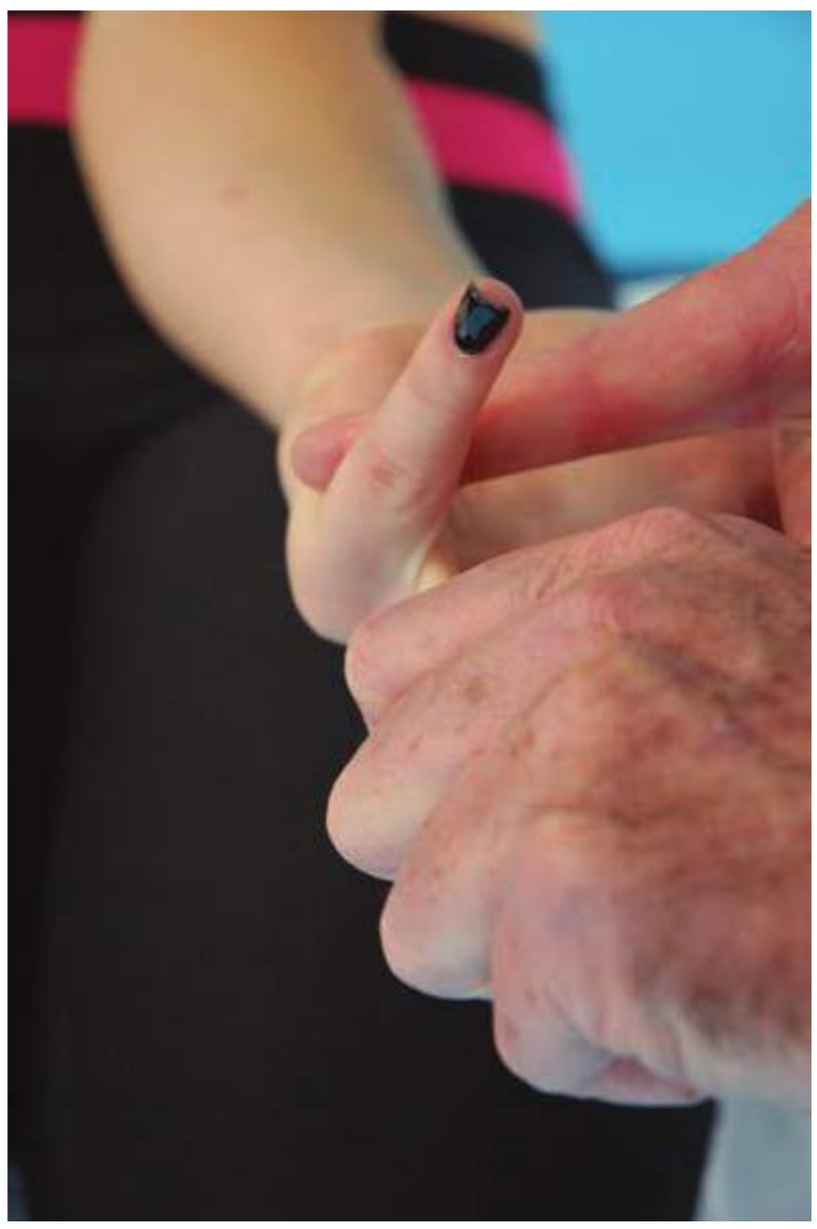

FIGURE 12-64 Test position for the flexor digiti minimi.

FIGURE 12-65 Test position for the opponens digit minimi.

FIGURE 12-67 Test position for the posterior interossei.

adduction against the appropriate side of the distal phalanx of the thumb, index, ring, and little finger (Fig. 12-67).

Lumbricals

To specifically test this muscle group, the patient is positioned in sitting or supine and is asked to place the hand into an intrinsic plus position (Fig. 12-68) and to hold the position. Using one hand, the clinician stabilizes the patient's wrist in minimal extension, and pressure is then applied in two distinct phases:

1. A flexion force is applied to the posterior surfaces of the distal and middle phalanges.
2. An extension force is applied to the anterior surfaces of the proximal phalanges.

Muscle Testing of the Hip

The hip joint is surrounded by a large number of muscles that accelerate, decelerate, and stabilize the hip joint. Indeed, 21 muscles cross the hip, providing both triplanar movement and stability between the femur and acetabulum (see Chapter 19).

Iliopsoas

To specifically test this muscle, the patient is positioned in supine or sitting:

- Supine. The patient's lower extremity is positioned in knee extension, slight hip abduction, and flexion of the hip (Fig. 12-69).

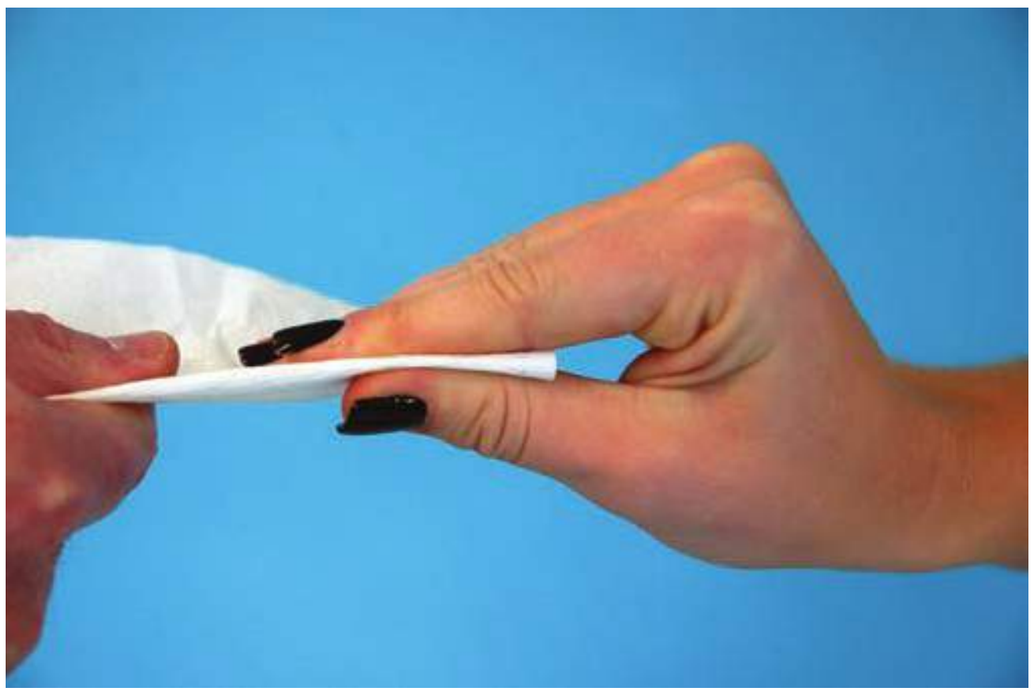

FIGURE 12-68 Test position for the lumbricals.

FIGURE 12-69 Test position for iliopsoas—patient supine.

FIGURE 12-66 Test position for the anterior interossei.

FIGURE 12-70 Test position for iliopsoas—patient sitting.

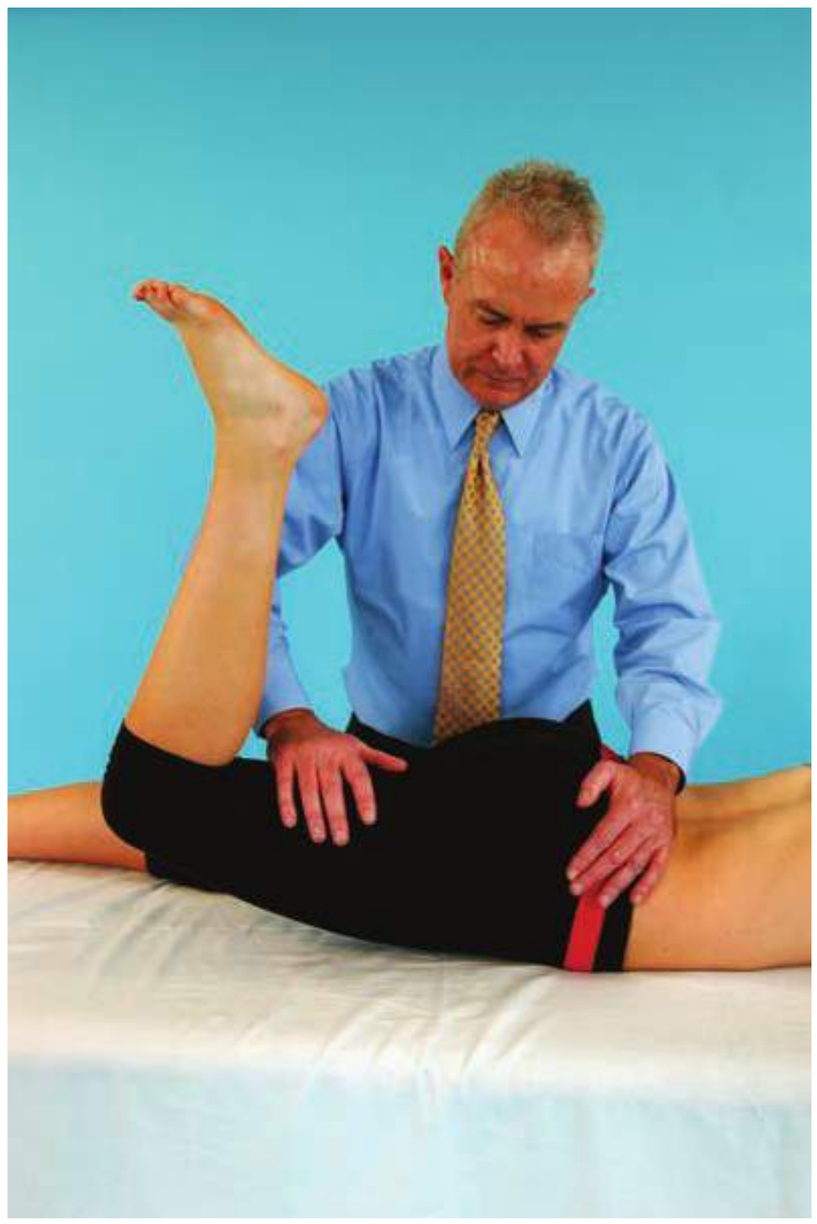

FIGURE 12-71 Test position for gluteus maximus.

- Sitting. With the knee flexed, the patient flexes the hip (Fig. 12-70).

With both positions, the clinician applies pressure on the distal femur in the direction of hip extension while the patient attempts to prevent the motion. Caution should be taken to ensure that the patient does not externally rotate the femur, as this will cause the hip adductors to contract. Substitution or trick motions can include hip abduction and external rotation, hip abduction, and internal rotation, or assistance from the rectus femoris. T e gravity minimized/eliminated position for this muscle is with the patient positioned in sidelying with the extremity supported on a friction-free surface and the hip positioned in neutral rotation with the knee flexed to 90 degrees.

Gluteus Maximus

To specifically test this muscle, the patient is positioned in prone with the knee flexed to at least 90 degrees (to eliminate hamstring activation) and the hip extended (Fig. 12-71). T e clinician applies a force over the distal femur in a direction of hip flexion while the patient attempts to prevent the motion. Substitution or trick motions can include assistance from the hamstrings or an increase in the lumbar lordosis. T e gravity minimized/eliminated position for this muscle is with the patient positioned in sidelying with the extremity supported; the hip flexed to 90 degrees, and the knee flexed.

Gluteus Medius

To specifically test this muscle, the patient is positioned in sidelying with the tested leg uppermost. T e patient hip is positioned in abduction, slight extension, and external rotation (Fig. 12-72). While stabilizing the pelvis with one hand, the clinician applies a force of abduction and minimal flexion to the hip at the distal femur while the patient attempts to prevent the motion. Substitution or trick motions can include assistance from the quadratus lumborum and the lateral abdominals which can tilt the pelvis laterally giving the appearance

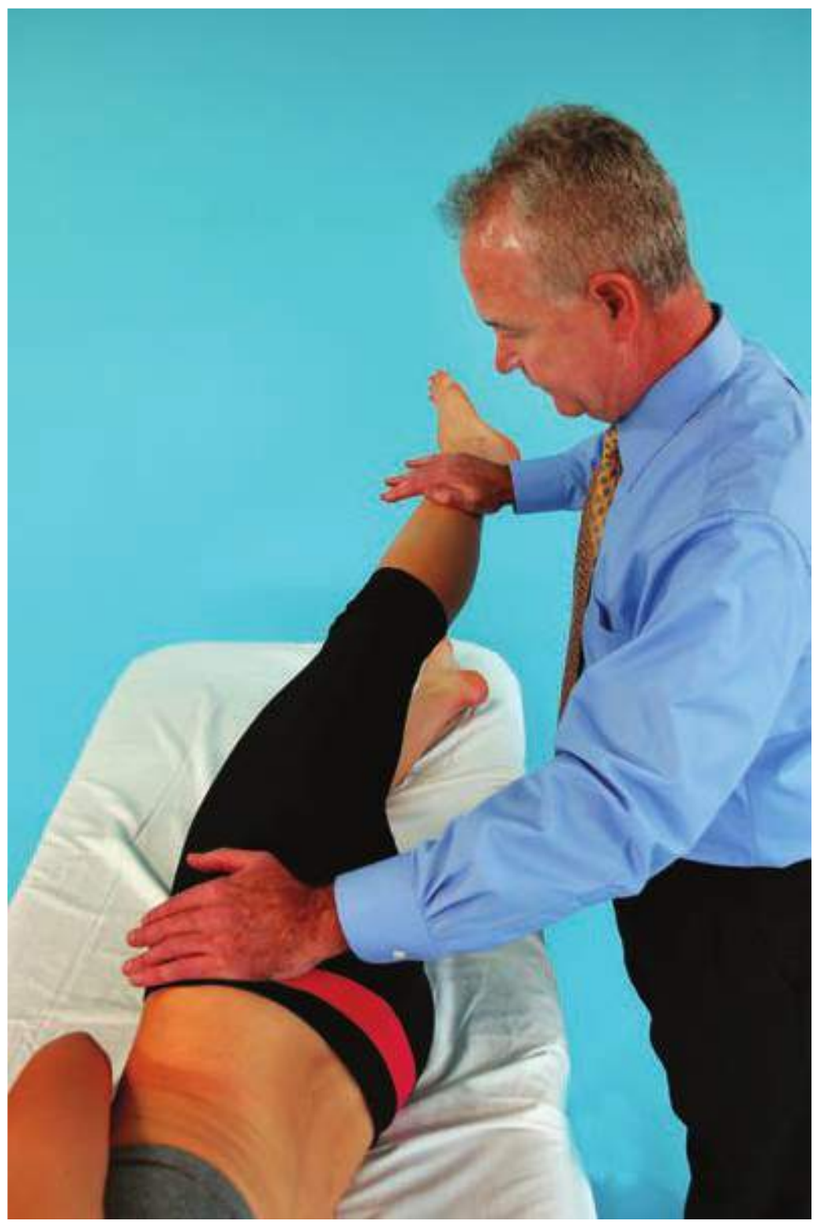

FIGURE 12-72 Test position for gluteus medius.

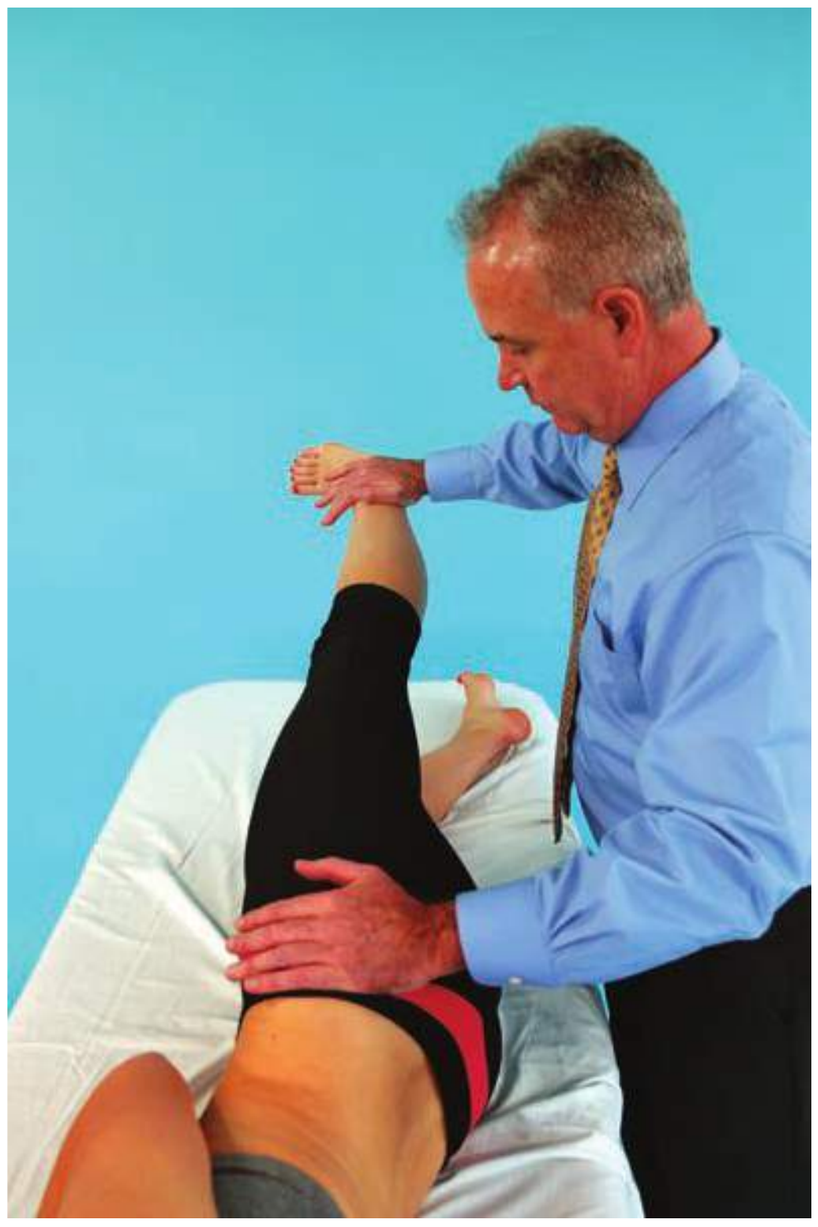

FIGURE 12-73 Test position for gluteus minimus.

FIGURE 12-74 Test position for tensor fasciae latae.

of abduction, assistance from the gluteus maximus (superior fibers), or allowing the patient to roll slightly toward the supine position, which places the tensor fasciae latae (TFL) in a more favorable position for hip abduction. The gravity minimized/eliminated position for this muscle is with the patient positioned in supine with the extremity on a friction-free surface.

Gluteus Minimus

To specifically test this muscle, the patient is positioned in sidelying with the tested side uppermost. The patient is asked to abduct the hip while avoiding any rotation, flexion, or extension of the hip (Fig. 12-73). While stabilizing the pelvis with one hand, the clinician applies an adduction and minimal extension force to the hip at the distal femur while the patient attempts to prevent the motion from occurring.

Tensor Fasciae Latae

To specifically test this muscle, the patient is positioned in supine with the knee extended. The patient is asked to abduct, flex, and internally rotate the hip and to hold the position (Fig. 12-74) while the clinician applies resistance in a direction of hip extension and hip abduction (the rotational component is not resisted) on the distal tibia. Substitution or trick motions can include assistance from the hip flexors. The gravity minimized/eliminated position for this muscle is with the patient positioned in long-sitting with the hips supported on the table, flexed to 45 degrees and in neutral rotation, and the upper extremities supporting the trunk.

Rectus Femoris

The specific test for this muscle is described in the section Muscle Testing of the Knee.

Hip External Rotators

The hip external rotators include the piriformis, quadratus femoris, obturator internus, obturator externus, gemellus superior, and gemellus inferior. The external rotators of the hip are tested as a group. The patient is positioned in sitting with the thigh supported on the table and the lower leg over the end of the table. The patient rotates the hip externally such that the foot moves toward the contralateral side (Fig. 12-75). Using one hand, the clinician stabilizes the patient's thigh while with the other hand generating a force of internal rotation of the hip by applying pressure to the inner aspect of the leg (see Fig. 12-75).

Hip Internal Rotators

The internal rotators of the hip consist of the TFL, gluteus minimus, and gluteus medius (anterior fibers). These muscles are tested as a group. The patient is positioned in sitting with the thigh supported on the table and the lower leg over the end of the table. The patient rotates the hip internally such that the foot moves away from the contralateral side. Using one hand, the clinician stabilizes the patient's thigh while with the other hand generating a force of external rotation of the hip by applying pressure to the outer aspect of the leg (Fig. 12-76).

Hip Adductors

The hip adductors are tested as a group. The patient is positioned in sidelying with the tested side closest to the table. The clinician supports the uppermost leg in hip abduction, and the patient is asked to adduct the lower leg off the table (Fig. 12-77). The gravity minimized/eliminated position for this muscle group is with the patient positioned in supine.

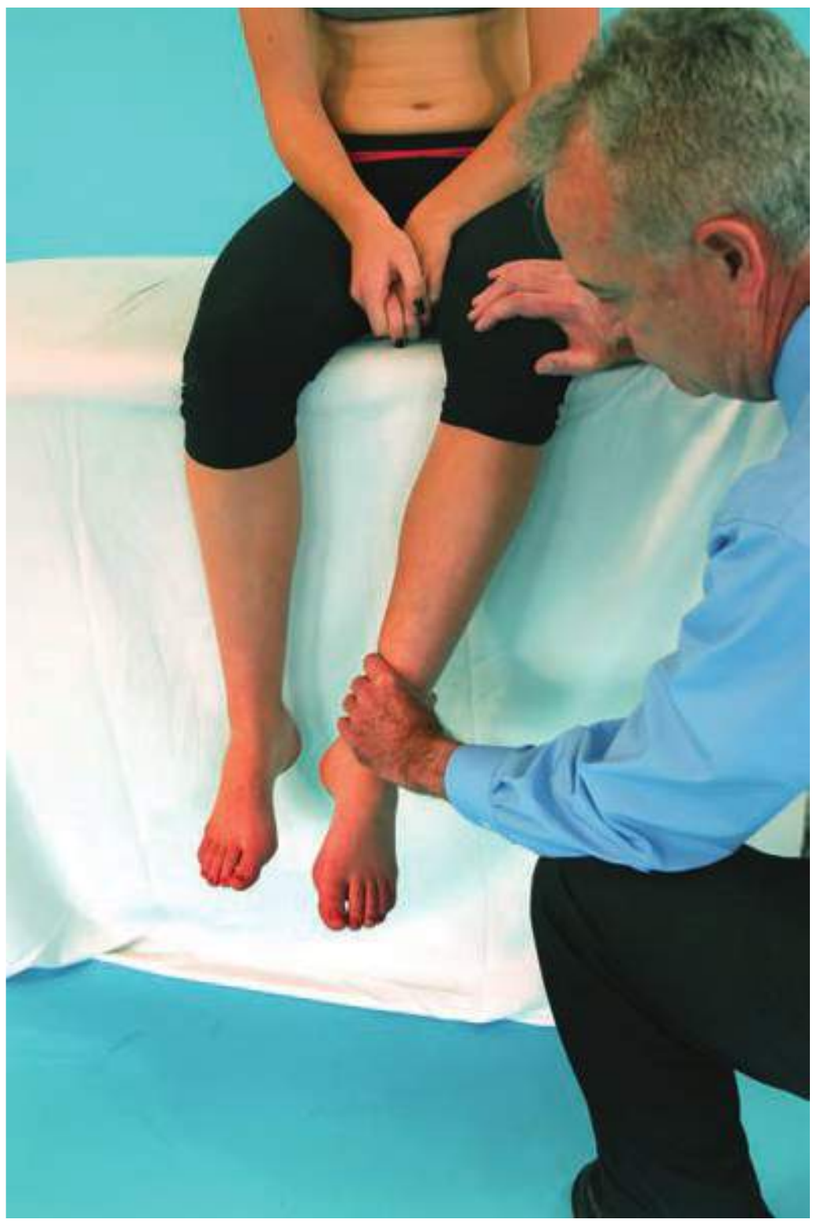

FIGURE 12-75 Test position for external rotators of the hip.

FIGURE 12-76 Test position for internal rotators of the hip.

FIGURE 12-77 Test position for hip adductor muscle group.

FIGURE 12-78 Test position for sartorius.

Sartorius

To specifically test this muscle, the patient is positioned in supine. The patient is asked to externally rotate, abduct, and flex the hip while also flexing the knee. The clinician places one hand on the outer aspect of the patient's knee and uses the other hand to cup the patient's heel. The patient is asked to prevent any motion as the clinician applies an extension, internal rotation, and adduction force to the hip while also applying an extension force to the knee (Fig. 12-78).

Hamstrings

The hamstrings muscle group consists of the biceps femoris, the semimembranosus, and the semitendinosus. The specific tests for these muscles are described in the section Muscle Testing of the Knee.

Muscle Testing of the Knee

The major muscles that act on the knee joint complex are the quadriceps, the hamstrings (semimembranosus, semitendinosus, and biceps femoris), the gastrocnemius, the popliteus, and the hip adductors (see Chapter 20).

Quadriceps

To specifically test this muscle group, the patient is positioned sitting at the edge of the table with the thigh supported and the leg hanging over the edge (Fig. 12-79). The patient is

FIGURE 12-79 Test position for the quadriceps femoris group.

FIGURE 12-80 Test position for the biceps femoris.

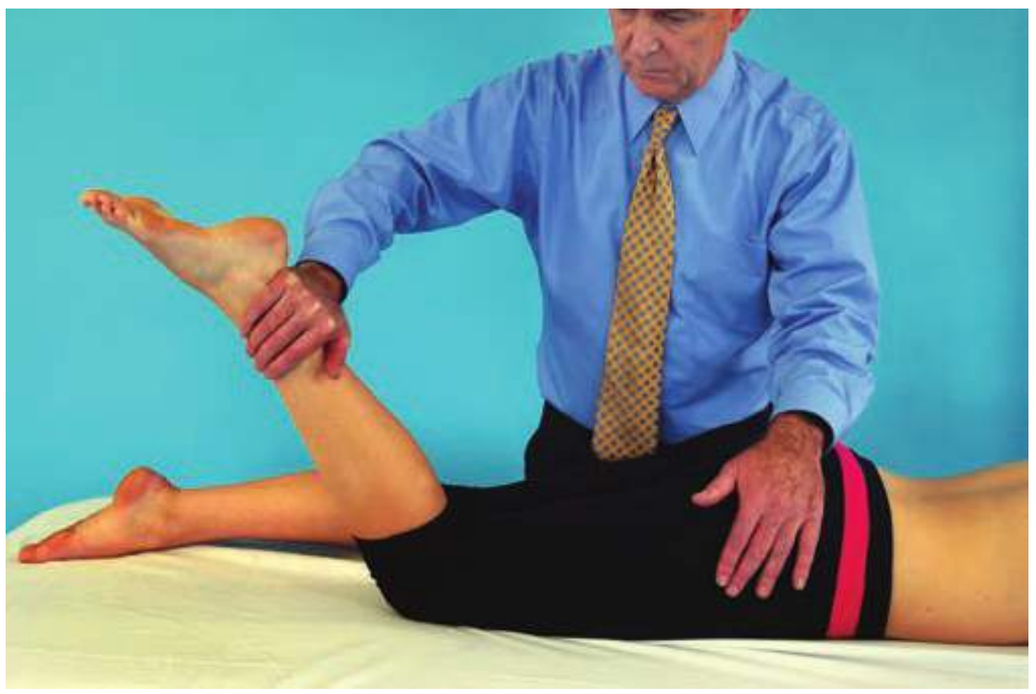

FIGURE 12-81 Test position for the semitendinosus and semimembranosus.

asked to lean backward to relax the hamstrings and then to straighten the knee to just short of full extension. Using one hand, the clinician stabilizes the patient's thigh and places the other hand over the anterior surface of the distal leg just proximal to the ankle. The clinician applies a force into knee flexion with the hand just proximal to the ankle while asking the patient to resist the movement.

Hamstrings

The hamstrings are specifically tested based on their anatomy—the semimembranosus and semitendinosus are tested together, and the biceps femoris is tested separately. The gravity minimized/eliminated position for this muscle group is with the patient positioned in sidelying with the tested leg on a friction free surface.

- To specifically test the semimembranosus and semitendinosus, the patient is positioned in prone with the knee flexed to approximate 45 degrees and the tibia internally rotated so that the toes are pointing inward (Fig. 12-80). Using one hand to stabilize the patient's thigh, the clinician places the other hand just proximal to the ankle on the posterior aspect of the patient's leg and applies a force toward knee extension while asking the patient to prevent the motion (see Fig. 12-80).
- To specifically test the biceps femoris, the patient is positioned in prone with the knee flexed to approximately 45 degrees and the tibia in slight external rotation so that the toes are pointing outward (Fig. 12-81). Using one hand to stabilize the patient's thigh, the clinician places the other hand just proximal to the ankle on the posterior aspect of the patient's leg and applies a force toward knee extension while asking the patient to prevent the motion (see Fig. 12-81).

Gastrocnemius

The specific test for this muscle is described in the Muscles of the Leg and Foot section later.

Popliteus

To specifically test this muscle, the patient is positioned in sitting with the knee flexed to 90 degrees. The patient is asked to internally rotate the tibia (Fig. 12-82). There is no resistance applied for this test—the test is used to determine whether the muscle is active and capable of internally rotating the tibia.

Muscle Testing of the Leg and Foot

Twenty-three muscles are involved with motion at the foot and ankle, 12 of which originate on the tibia or fibula, and 11 on the foot itself (see Chapter 21).

Tibialis Anterior

To specifically test this muscle, the patient is positioned in supine or sitting, and the patient's foot is positioned in dorsiflexion and inversion, with the great toe pointing downward

FIGURE 12-82 Testing the function of the popliteus.

FIGURE 12-83 Testing position for tibialis anterior.

FIGURE 12-84 Test position for extensor digitorum longus.

(to minimize activation of the extensor hallucis longus). The knee must remain flexed during the test to allow complete dorsiflexion. Using one hand, the leg is stabilized by the clinician, while resistance is applied to the medial posterior aspect of the forefoot in an inferior/lateral direction into plantarflexion and eversion (Fig. 12-83).

Extensor Digitorum Longus

To specifically test this muscle, the patient is positioned sitting or supine, and the patient is asked to extend the toes. Using one hand to stabilize the ankle and keeping the foot in slight plantarflexion, the clinician uses the other hand to apply force against the proximal phalanges of toes 2 through 5 in the direction of toe flexion (Fig. 12-84).

Extensor Hallucis Longus

To specifically test this muscle, the patient is positioned in supine or sitting, and the ankle is positioned in a neutral position. The patient is asked to extend the MTP and interphalangeal joints of the great toe and to hold a position while the clinician applies pressure on the distal phalanx in a plantarflexion direction (Fig. 12-85).

Fibularis (Peroneus) Tertius

To specifically test this muscle, the patient is positioned sitting, or supine and the patient is asked to dorsiflex and then evert the foot (Fig. 12-86). While using one hand to stabilize the patient's lower leg, the clinician uses the other hand to apply pressure on the dorsal and lateral aspects of the foot into a plantarflexion and inversion direction while asking the patient to prevent the motion.

Gastrocnemius

To specifically test the gastrocnemius, the patient is positioned in standing on one leg holding onto something for balance. Keeping the knee straight, the patient is asked to raise

FIGURE 12-85 Test position for the extensor hallucis longus.

FIGURE 12-86 Test position for the peroneus tertius.

up on the toes (Fig. 12-87). For a normal grading, the patient should be able to repeat this 10 times.

Soleus

To specifically test this muscle, the patient is positioned in prone with the knee flexed to 90 degrees. Using one hand, the clinician

FIGURE 12-87 Test position for the gastrocnemius.

FIGURE 12-88 Test position for the soleus.

stabilizes the distal leg of the patient by holding the proximal ankle. T e patient is asked to plantarflex the ankle without inversion or eversion of the foot, and the clinician applies a dorsiflexion force to the posterior calcaneus (Fig. 12-88).

Plantaris

T e plantaris muscle is tested using the specific test of the gastrocnemius.

Tibialis Posterior

To specifically test this muscle, the patient is positioned supine or sitting with the foot and ankle plantarflexed and inverted. T e patient is asked to sustain this position throughout the test. Using one hand, the clinician stabilizes the proximal to the patient's ankle, while using the other hand to apply an eversion and dorsiflexion force to the patient's foot and ankle (Fig. 12-89).

FIGURE 12-89 Test position for the tibialis posterior.

FIGURE 12-90 Test position for the flexor digitorum longus.

Flexor Digitorum Longus

To specifically test this muscle, the patient is positioned supine or sitting. T e patient is asked to flex the toes and to sustain the position throughout the test. Using one hand to stabilize the midfoot, the clinician applies an extension force to the toes (Fig. 12-90).

Flexor Hallucis Longus

To specifically test this muscle, the patient is positioned in supine or sitting and is asked to flex the great toe. It is important to note that the patient may have difficulty isolating the motion of this toe from the other toes. Using one hand to stabilize the patient's ankle, the clinician uses the other hand to stabilize the metatarsals while applying an extension force of the great toe (Fig. 12-91).

FIGURE 12-91 Test position for the flexor hallucis longus.

FIGURE 12-92 Test position for the peroneus longus and brevis.

Fibularis (Peroneus) Longus and Brevis

Both of these muscles are tested together. T e patient is positioned in sitting or supine and is asked to plantarflex and evert the foot (Fig. 12-92). Using one hand, the clinician stabilizes the distal leg and, using the other hand, applies a force on the lateral aspect of the foot into inversion and dorsiflexion.

Abductor Hallucis

To specifically test this muscle, the patient is positioned in supine or sitting. Using one hand, the clinician stabilizes the patient's foot while using the other hand to apply adduction force to the great toe and while asking the patient to prevent the motion (Fig. 12-93). It is important to remember that this muscle is difficult for many people to isolate.

FIGURE 12-93 Test position for the abductor hallucis.

FIGURE 12-94 Test position for the flexor digitorum brevis.

- Abductor digiti minimi. This muscle arises from the lateral process of the calcaneal tuberosity as well as the plantar aponeurosis and inserts into the lateral side of the base of the proximal phalanx of the little toe. The muscle functions to assist in flexion of the interphalangeal joint of the fifth digit and to stabilize the forefoot. The synergists of this muscle include the flexor digitorum longus and the fourth lumbrical. The antagonist to this muscle is the fifth anterior interossei. There is no specific test for this muscle.
- Flexor digitorum brevis. To specifically test this muscle, the patient is positioned in sitting or supine. Using one hand to stabilize the patient's midfoot, the clinician uses the other hand to apply pressure against the plantar surface of the PIP joints of the second through fifth digits (Fig. 12-94).

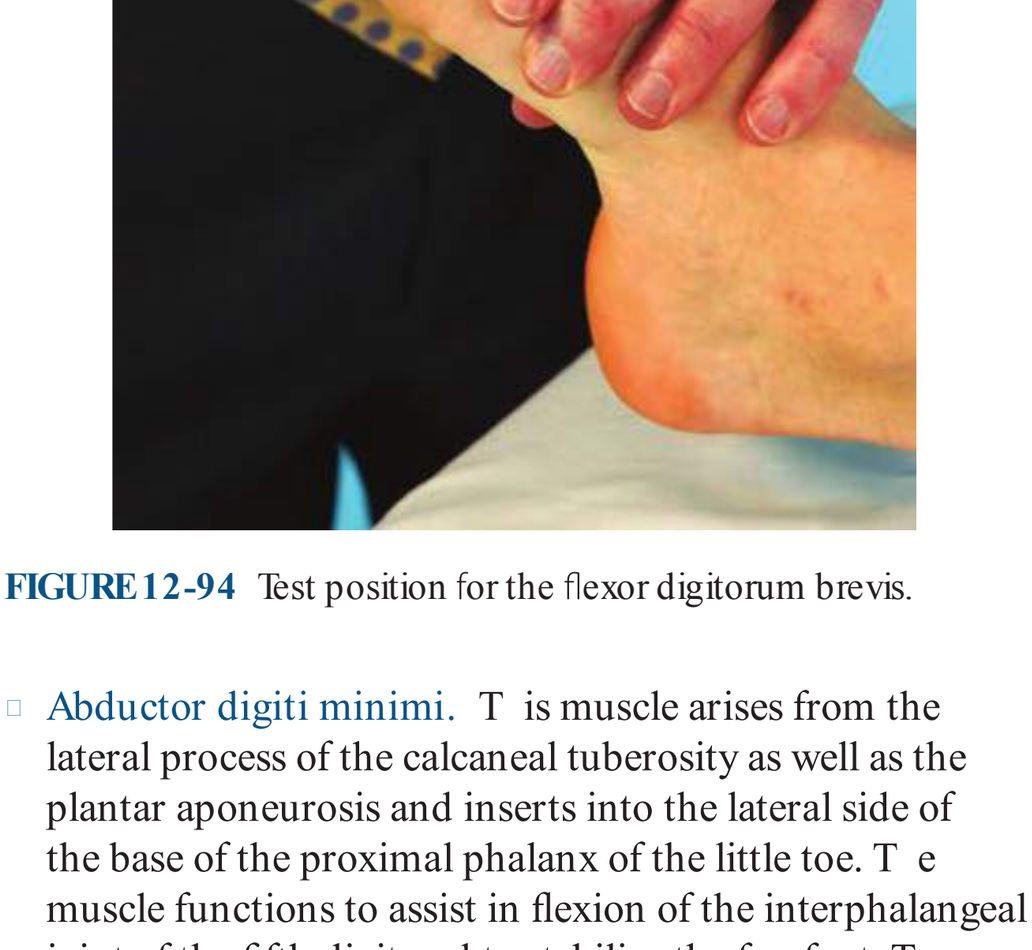

FIGURE 12-95 Test position for the lumbricals.

FIGURE 12-96 Test position for the flexor hallucis brevis.

- Flexor digitorum accessories. There is no specific test for this muscle.
- Lumbricals. To specifically test these muscles, the patient is positioned supine or sitting and is asked to flex the MTP joints of the feet. While using one hand to stabilize the patient's foot, the clinician uses the other hand to apply an extension force under the MTP joints of toes 2 through 4 (Fig. 12-95).
- Flexor hallucis brevis. To specifically test this muscle, the patient is positioned in supine or sitting. Using one hand to stabilize the foot proximal to the MTP joint and maintaining a neutral position of the foot and ankle, the clinician uses the other hand to apply an extension force at the MTP joints of the great toe (Fig. 12-96).
- Adductor hallucis. There is no specific test for this muscle.
- Posterior (dorsal) and anterior (plantar) interossei. To specifically test these muscle groups, the patient is positioned in supine or sitting and is asked to extend the interphalangeal joints of the four lateral toes. The clinician stabilizes the MTP joints and places a finger on the posterior surface of the distal phalanges of each toe in the direction of flexion (Fig. 12-97).

FIGURE 12-97 Test position for the interossei muscles.

Contraindications to Strengthening, Endurance, and Power Exercises

Absolute contraindications include unstable angina, uncontrolled hypertension, uncontrolled dysrhythmias, hypertrophic cardiomyopathy, and certain stages of retinopathy. Patients with congestive heart failure, myocardial ischemia, poor left ventricular function, or autonomic neuropathies must be carefully evaluated before initiating an exercise program. Typically, the presence of pain and inflammation are contraindications to resistance exercises until both are controlled.

A number of precautions need to be taken when exercising patients who have a compromised cardiovascular or pulmonary system (see Chapter 15):

- An appropriate level of intensity must be chosen. Too high a level can overload the cardiorespiratory system causing it to work anaerobically, not aerobically. Too high an intensity can overstress the muscular system, which can potentially cause injuries.
- A sufficient period of time should be allowed for warm-up and cool-down to permit adequate cardiorespiratory and muscular adaptation.

CLINICAL PEARL

Contraindications to muscle performance training:

- Inflammation. Exercise can increase swelling and cause damage to muscles or joints.
- Pain. Severe joint or muscle pain during exercise, or for more than 24 hours after exercise, requires an elimination or reduction of the exercise.

Overtraining

While the goal of any rehabilitation program is to get the patient better as quickly as possible, safety must never be sacrificed for efficiency. Overtraining occurs because of an insufficient amount of rest, recovery, and unloading. Overtraining results in a loss of the body's adaptive capability after chronic high-volume loading, or in response to an excessive increase in either duration or intensity of training. Two types of fatigue are recognized: muscle fatigue (see Chapter 1), and cardiopulmonary fatigue (see Chapter 15). The signs and symptoms of overtraining include an inability to recover from exercise, a lowered resistance to injury, a decline in performance, chronic fatigue or exhaustion, loss of appetite, inability to sleep, lethargy, muscle soreness, and an altered metabolism.[4–6] Overtraining should not be confused with overloading which is discussed in the Specificity of Training section.

Other potential indicators of overtraining include delayed onset muscle soreness (DOMS), stress fracture (see Chapter 2), pathological fracture, and a prolonged increase in symptoms.

Delayed Onset Muscle Soreness

Familiar to most individuals at some time, muscular soreness is one of the drawbacks to participating in an exercise program involving activity beyond what one usually experiences. The purpose of the recovery phase is to restore the muscles in the body to pre-exercise levels through promotion of venous turn and removal of metabolites from muscle, reestablishment of fluid balance, replacement of depleted fuel energy reserves, and relaxation in muscles that were active.[7] The recovery period is also necessary to replenish muscle glycogen following prolonged exercise of the continuous or integral nature. If the recovery period is insufficient, DOMS can result. Acute soreness is apparent during the later stages of an exercise bout and during the immediate recovery period.[8] This results from an accumulation of end products that occurs with exercise, specifically H^+ ions, and lactate, but generally disappears in between 2 minutes and 1 hour after cessation of exercise.[8] DOMS, on the other hand, appears 24–56 hours after the exercise bout,[9] and can exhibit as anything, from minor muscle soreness to debilitating pain and swelling, but is most commonly described as causing a reduction in joint range of motion, shock attenuation, and peak torque.[10] A recent review of DOMS confirms that the mechanisms, treatment strategies, and impact on athletic performance remain uncertain.[11] Recognized mechanisms include lactic acid and potassium accumulation, muscle spasms, mechanical damage to the connective tissues, inflammation, enzyme efflux secondary to muscle cell damage, and edema.[11] DOMS is also associated with structural damage to the subcellular components of muscle fibers, including the sarcolemma, membranes in the sarcoplasmic reticulum, the T-tubule, and the myofibrils.[12] This damage can result in muscle weakness up to 46% immediately after exercise, and for up to 72 hours after exercise.[12]

There is a marked increase in the proportion of disrupted muscle fibers after eccentric exercise as compared with concentric exercise, which has been roughly correlated to the degree of DOMS.[13] Eccentric exercise is also linked to morphologic and metabolic signs of muscle alteration: myofibrillar damage along the Z-band,[14, 15] mitochondrial swelling,[14, 15] increased intramuscular pressure,[14, 15] and impaired glycogen resynthesis.

Given the role of eccentric exercise in DOMS, prevention of DOMS involves the careful design of any eccentric program, which should include preparatory techniques, accurate training variables, and appropriate aftercare, including a cool-down period of low-intensity exercise to facilitate the return of oxygen to the muscle. It is a widely held belief among athletes and coaches that massage is an effective therapeutic modality that can enhance muscle recovery and reduce soreness following intense physical activity.[16] However, the actual scientific literature does not tend to support the positive efficacy of manual massage as a postexercise therapeutic modality in the athletic setting.[16–18]

To help prevent DOMS, there is some controversy as to whether a cool-down or warm-up should be used. A number of studies advocate a short (5–10 minutes) low-intensity warm-up (30–65% of VO_2 max) to assist in maintaining venous return and removal of metabolites above levels during passive rest.[19, 20] However, one randomized controlled trial found that whereas a 10-minute warm-up reduced perceived muscle soreness (measured on a 100-mm visual analogue scale) 48 hours after exercise (mean effect of 13 mm, 95% CI 2–24 mm), a 10-minute cool-down had no apparent effect (mean effect of 0 mm, 95% CI 1–11 mm).[21]

If the prevention of DOMS is unsuccessful, the intervention should include, as appropriate, rest, local measures to reduce edema (e.g., cryotherapy, elevation of the involved limb(s)), drug therapy (typically nonsteroidal anti-inflammatory agents), or further exercise (aerobic submaximal exercise with

no eccentric component, e.g., swimming, biking, or stepper machine, pain-free flexibility exercises, and high-speed [300 degrees per second] concentric-only isokinetic training).[22, 23]

Pathological Fracture

A pathologic fracture occurs when a bone breaks in an area that is weakened by another disease process. Causes of weakened bone include tumors, infection, osteoporosis or osteopenia, and certain inherited bone disorders (see Chapter 5). If there is no known history of osteoporosis, the clinician must recognize those factors that place a patient at risk for osteoporosis. For example, postmenopausal women are at high risk as are those who are associated with prolonged immobilization or disuse, restricted weight bearing, or extended use of certain medications, such as systemic corticosteroids or immunosuppressants. Somewhat ironically, weight-bearing and resistance exercises are an essential element of the rehabilitation for individuals with, or at risk for, osteoporosis. However, high impact activities such as jumping or hopping, excessive trunk flexion with rotation, and activities that cause torsional movements of the hips should be avoided.

Physiological Changes with Resistance Exercise

To increase muscle strength most effectively, a muscle must work with increasing effort against progressively increasing resistance.[24] In a strength training program, the term load refers to the amount of weight used in a specific exercise. Most strength and conditioning programs describe the load as a percentage of a repetition maximum (RM). The RM can be expressed as the greatest amount of load lifted one time (1 RM). As the load becomes heavier, the number of times an individual can lift the load (perform a rep) decreases, whereas if the load becomes lighter, more reps can be accomplished. If resistance is applied to a muscle as it contracts so that the metabolic capabilities of the muscle are progressively overloaded, adaptive changes occur within the muscle, which make it stronger over time.[25, 26] These adaptive changes include the following[27–33]:

- An increase in the efficiency of the neuromuscular system. Neural adaptations are attributed to motor learning and improved coordination. In normal individuals, an increase in strength after a resisted exercise program is thought to initially occur as a result of neural adaptation. This is increased efficiency results in
  - an increase in the number of motor units recruited, with an increase in the firing rate of each motor unit,
  - an increase in the synchronization of motor unit firing, and
  - an improvement in the endurance of the muscle.
- An increase in the size of the muscle (hypertrophy). If the exercise is continued for a longer period, the initial adaptation of the neuromuscular system is followed by hypertrophy (and possible hyperplasia)[34,35] of muscle fibers. Hypertrophy is an increase in the bulk of an individual muscle fiber caused by an increase in myofibrillar volume (see Chapter 1). The greatest amount of hypertrophy occurs in the type IIb fibers. Mitochondria are the main subcellular structures that determine the oxygen demand of muscle. There is a consensus that there is a dilution of mitochondrial volume density through an increase in myofibrillar (i.e., contractile protein) volume density as a consequence of strength-type exercise training.[36, 37] This is increase in myofibrillar volume density, or hypertrophy that occurs with strength training is regarded as the main cause of the overall increase in the anatomical cross-sectional area (CSA) of an entire muscle group. The fiber hypertrophy is typically greater for fast- than for slow-twitch muscle fibers,[38] although there is remodeling of type IIb to type IIa, there is no change in the distribution/ratio of type I and type II fibers.
- Changes in the metabolic system and enzymatic activity (see Chapter 1). Overall there is an increase in ATP, and phosphocreatine (PCr) and myoglobin storage, and rises in creatine phosphokinase and myokinase.
- An increase in the force per unit area. Strength training has also been shown to lead to an increase in the force per unit CSA of the muscle. This effect has been attributed either to an increase in neural drive[39] or to an actual increase in muscle-specific tension due to a denser packing of muscle filaments.[40] A denser packing of contractile tissue along the tendon could theoretically increase the angle of pennation of muscle fibers.[41]
- A reduction in the time to peak force.[42] This is can be defined as the time from the onset of muscle activation until peak force is attained.
- Stimulation of slow-twitch fibers (when performing workloads of low intensity) and stimulation of fast-twitch IIa fibers (when performing workloads of high intensity and short duration).
- Rhythmic activities increase blood flow to the exercising muscles via contraction and relaxation.
- The power of the muscle improves.
- Improved bone mass (Wolf's law).
- An increase in metabolism/calorie burning/weight control.
- Increased intramuscular pressure results from a muscle contraction of about 60% of its force generating capacity.
- Cardiovascular benefits when using large muscle groups. Strength training of specific muscles has a brief activation period and uses a relatively small muscle mass, producing less cardiovascular metabolic demands than vigorous walking, swimming, etc.
- Changes in body composition. Over a period of time, there is an increase in lean (fat-free) body mass and a decrease in the percentage of body fat.
- Adaptive changes in the connective tissue. The tensile strength of ligaments, tendons, and the connective tissue in muscle increases. There is also an increase in bone mineral density (BMD).
- An increase in the rate of force development.[42]

Conversely, a muscle can become weak or atrophied through:

- Disease.
- Neurologic compromise.

- Immobilization. Continuous immobilization of skeletal muscle tissues can cause some undesirable consequences (see Chapter 2). T ese include weakness or atrophy of muscles. Type I (slow twitch) muscle fibers atrophy at a faster rate than type II (fast twitch) fibers.[43] Muscle atrophy is an imbalance between protein synthesis and degradation. After modest trauma, there is a decrease in whole-body protein synthesis rather than increased breakdown. With more severe trauma, major surgery, or multiple organ failures, both synthesis and degradation increase, the latter being more enhanced.
- Disuse.

Specificity of Training

It appears that the muscle response to resistance training for people who have a broad range of conditions and who might consult a physical therapist is similar to muscle responses reported in young people without impairment.[44] Resistance training can have a beneficial effect in populations where pain is a particular problem, such as people with low back pain and people with osteoarthritis. In addition, resistance training can have a beneficial effect on conditions such as high blood pressure, fracture rehabilitation, and cardiovascular disease. T e effect of resistance training on other impairment parameters, such as BMD, fat mass, and aerobic capacity, remains inconclusive.[44] T ere is also evidence to suggest that improvements in the ability to generate muscle force can carry over into an improved ability to do everyday tasks. T is phenomena, referred to as transfer of training or cross-training, can provide improvements in various parameters of strength in not only the muscles used, but even in a nonexercised, contralateral limb[45–47] However, the effects are generally quite modest, and there are a number of examples in the literature where significant improvements in activity were not demonstrated after resistance training.[44] Part of the problem with drawing conclusions from the literature is the lack of details provided as to the specifics of the exercises prescribed. Specificity of training is an accepted concept in physical therapy rehabilitation. T is concept involves the principle of the specific adaptation to imposed demand (SAID). T us, the focus of the exercise prescription should be to improve the strength and coordination of functional- or sports-specific movements with exercises that approximate the demands of the desired activity (speed, agility, strength, power, endurance, etc.). In addition, exercise protocols should mimic the work:rest ratios of a particular sport.[48] For example, as a wrestler competes in 3-minute periods of varying intensity, the exercise progressions should be made by increasing the intensity or the number of 3-minute intervals.

CLINICAL PEARL

The principle of overload states that a greater than normal stress or load on the body is required for training adaptation to take place. To increase strength, the muscle must be challenged at a greater level than it is accustomed to. High levels of tension will produce adaptations in the form of hypertrophy and recruitment of more muscle fibers.

Three important concepts are related to the SAID principle[7]:

- Overload. When cells, tissues, and organs are loaded beyond what they normally are required to do, they will adapt to permit them to deal with these new loads more effectively. T ese training effects are specific to the energy supply systems that have been utilized, the locale of the stimulus, the specific muscle groups, the joint action(s), the type of contraction, and the speed of contraction. When loads are applied, they should be specific to the desired effect (SAID), and be appropriate to the individual in terms of frequency, intensity, and duration. It is important to remember that once an adaptation has taken place to a specific load, this load is no longer an "overload," and the load must be progressively increased to get further improvements.
- Underload. When cells, tissues, and organs are loaded at a level below what is normally performed, the body will adapt by decreasing its ability in the underloaded component (detraining). Detraining, or reversibility, occurs quickly after the cessation of training—a reduction in the VO_2 max can be detected within a week or two of detraining and continues until training effects are lost. T erefore, it is important that patients are prescribed maintenance programs to continue exercising once their physical therapy sessions have ended.

CLINICAL PEARL

An overprescription of resistance training exercise may result in overstress injuries, whereas underprescription will result in a failure to achieve the necessary or desired strength improvement.

T e SAID principle can be applied by exercising the muscles along each extremity and within the trunk in functional patterns.[49] T e exercise component of the intervention should be as specific as the manual technique used in the clinic. Muscles can be classified into tonic and phasic groups according to how muscles develop from the myotomes[50] (Table 12-2) (see Chapter 1).

CLINICAL PEARL

In general, tonic muscles function as endurance (postural) muscles, whereas phasic muscles function as the power muscles.[51, 52]

Speed–strength training applies the principles of specificity of training and is typically used with highly conditioned athletes who want to take their performance to the next level. Speed–strength training involves taking some of the basic movements of a task and increasing the resistance. For sports, such as baseball and golf, athletes can use devices, such as an oversized ball or weighted golf club, to train the arms and trunk to work against a greater resistance. Sprinters have long benefited from the use of a small parachute to increase

TABLE 12-2	The Various Muscle Types and Their Primary Innervation		
Muscle Type	**Characteristics**	**Primary Innervation**	**Examples**
Type I	Tonic Slow twitch Small neuron	Type 1a phasic nerve endings	Extensors External rotators Abductors
Types IIa and IIb	Phasic Fast twitch Large neuron	Anterior divisions of the nerve plexus	Flexors Adductors Two-joint muscles

wind resistance, or by dragging a tire fastened by a rope. Since the two components of speed production are stride length and stride frequency, exercise protocols can be designed to increase both of these components:[48]

- Stride length can be improved by running uphill, bounding drills, or power skips.[53,54]
- Stride frequency can be improved with fast leg drills into flexion and extension (Fig. 12-98) and adduction and abduction (Fig. 12-99) where the patient attempts to swing the leg as fast as possible while using a support for balance. Other ways to increase stride frequency include resisted sprints (pulling a weighted sled, or parachute), or assisted sprints (the individual is attached to an athlete who pulls the individual, forcing the individual to move his or her legs faster).[54]

T e theory behind speed–strength training is that once the higher resistance is removed the athlete's speed is improved when they perform the activity under normal resistance. Wherever possible, strength testing by the clinician should assess the function of muscle. If a power muscle is assessed, its ability to produce power should be assessed. In contrast, an endurance muscle should be tested for its ability to sustain a contraction for a prolonged period, such as occurs with sustained postures.

In addition to speed–strength training, agility drills, rapid reflex, and specific skill training should form the core of many sports-specific exercise programs.

CLINICAL PEARL

The principles of resistance training can be easily remembered by the acronym PROS—progression, regularity, overload, and specificity.

Mode of Exercise

T e type of exercise performed is referred to as the mode. T is typically describes the manner in which the exercise is carried out, the type of resistance used, and the type of muscle contraction that is used. T e various manners in which exercise can be carried out, including weight-bearing or nonweight bearing, and closed-chain versus open-chain exercises, are covered later in the chapter. As outlined in Chapter 1, a muscle can contract in a variety of ways. Each type of contraction has its advantages and disadvantages.

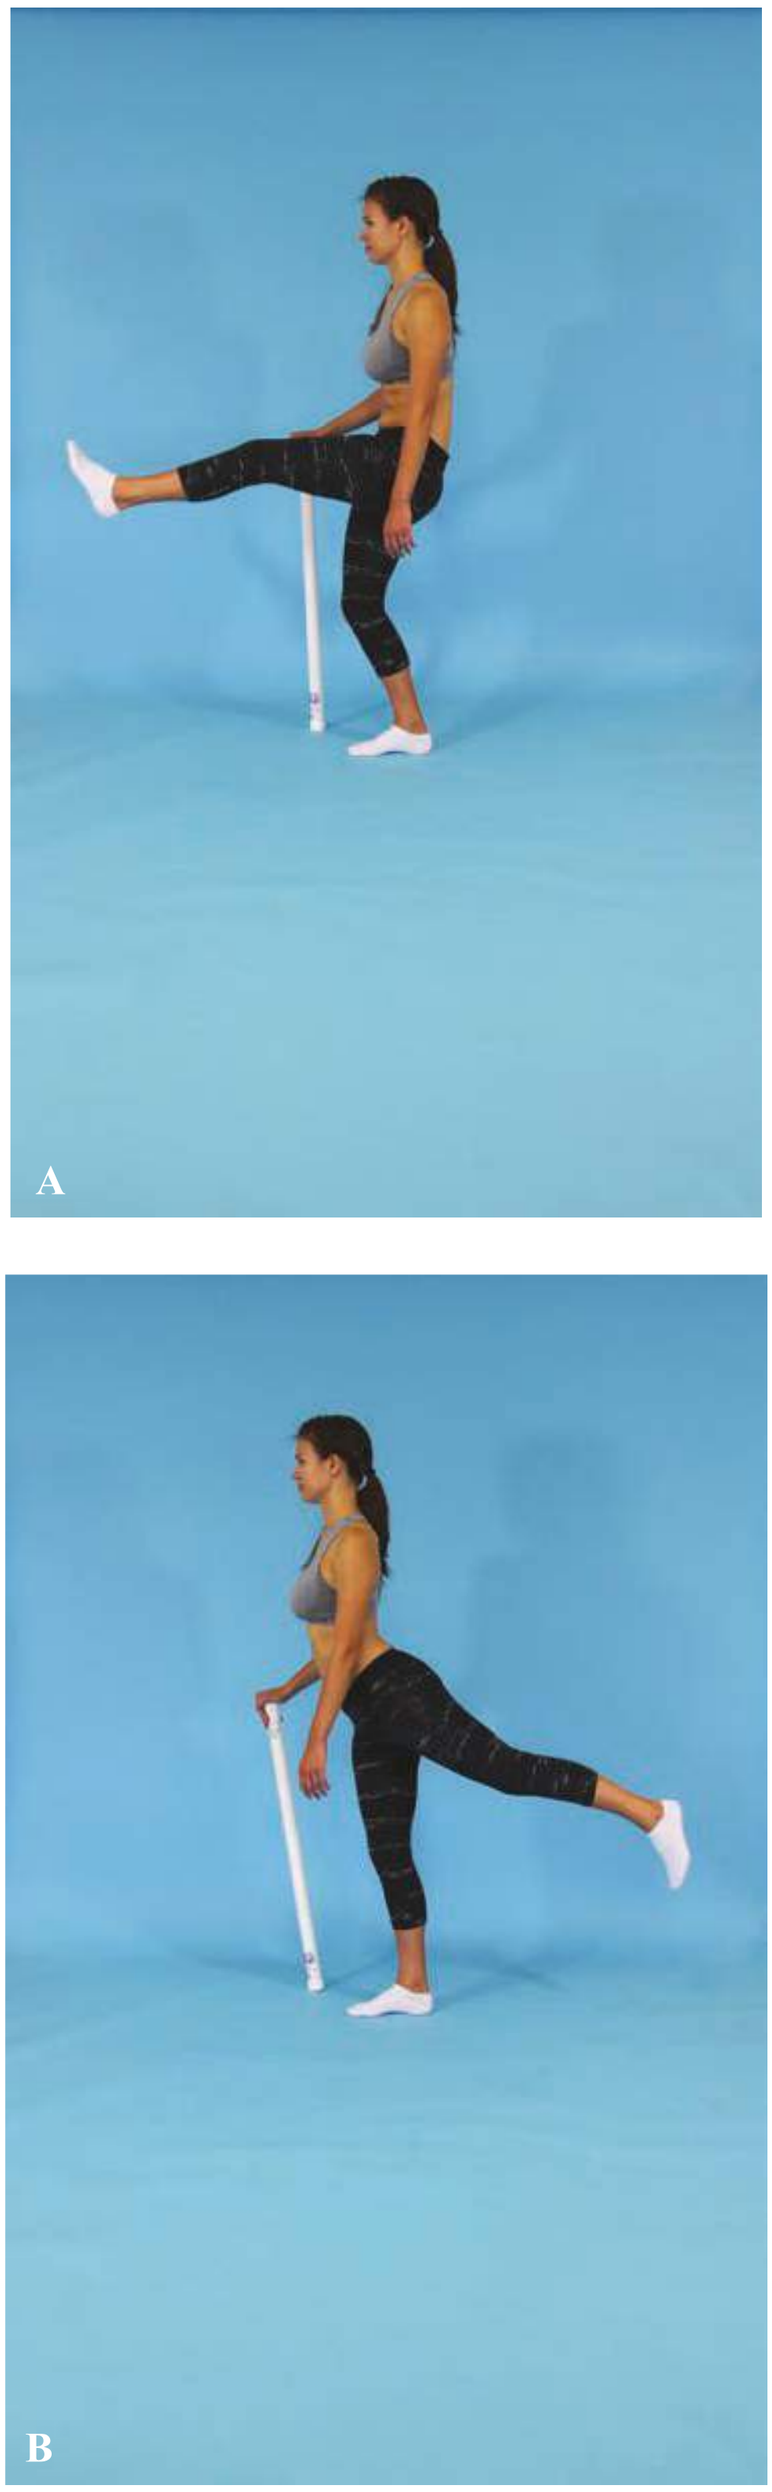

FIGURE 12-98 Fast leg drills into (A) flexion and (B) extension.

FIGURE 12-99 Fast leg drills into abduction and adduction.

Type of Contraction Used

Isometric Exercises

Studies have demonstrated that a 6-second hold of 75% of maximal resistance is sufficient to increase strength when performed repetitively.[55, 56] Isometric exercises have an obvious role when joint movement is restricted, either by pain or by bracing and casting. The primary role in this regard is to prevent atrophy and a subsequent decrease of the ligament, bone, and muscle strength. Isometric exercises have the following disadvantages:

- Strength gains are not increased throughout the range (unless performed at multiple angles).
- They do not activate all of the muscle fibers (primary activation is of slow-twitch fibers).
- There are no flexibility or cardiovascular fitness benefits.
- Peak effort can be injurious to the tissues because of vasoconstriction and joint compression forces.
- There is limited functional carryover.[57]
- Considerable internal pressure can be generated, especially if the breath is held during contraction. During exertional effort, a deep inspiration is followed by closure of the glottis and contraction of the abdominal muscles, which in turn increases intra-abdominal and intrathoracic pressures, and cause an abrupt, temporary increase in arterial blood pressure.[58] This can prove injurious to patients with weakness in the abdominal wall (hernia) or cardiovascular impairment (increase in blood pressure) through the maneuver/phenomenon, even if performed correctly.[59–62]

CLINICAL PEARL

The Valsalva phenomenon has traditionally been associated as occurring with high effort isometric exercises. However, the clinician must remember that this phenomenon can also occur during high effort dynamic muscle contractions.

Concentric Exercises

These contractions are commonly used in the rehabilitation process and in activities of daily living. The biceps curl and the lifting of a cup to the mouth are examples, respectively. Concentric exercises are dynamic and allow the clinician to vary the load from constant, using free weights, to variable, using an exercise machine. The speed of contraction can also be manipulated depending on the goal of the intervention. As outlined in Chapter 1, a maximum concentric contraction produces less force than a maximum eccentric contraction under the same conditions.

A number of programs have been designed for the progression of concentric exercise programs. Some of these PRE programs are summarized in Tables 12-3 and 12-4. An RM is the maximum number of repetitions an individual can perform through the full, available range of motion with control at a given weight. For example, a 1-RM is the weight the patient can lift a maximum of one time. Determining the RM is dependent upon the goals of the individual and his or her functional demands. Since determining a 1-RM to use as a baseline measurement of dynamic strength is not appropriate for many patients, a 5–10-RM testing load is often recommended to estimate the 1 RM. Using this method, the clinician selects a specific amount of resistance (weight) and then notes how many repetitions can be completed to the full range before the muscle begins to fatigue. For example, if the patient was able to perform eight repetitions before becoming fatigued, the 1-RM can be calculated based on the 8-RM. The rehabilitation program designed by DeLorme is based on an RM of 10 (10 RM).[29] The Oxford technique[63] reverses the percentage of the maximum in the three sets (Table 12-3). Both of these programs should only be used with healthy young adults, athletes, and active older adults. The MacQueen technique[64, 65] differentiates between beginning, intermediate, and advanced levels. In contrast, the program designed by Sanders is based on a formula that uses a percentage of body weight to determine starting weights.[66] The daily adjusted progressive resistive exercise (DAPRE) program, designed by Knight, allows for individual differences in the rates at which patients progress in their rehabilitation programs[67] (Table 12-4). Finally, the Berger technique[68] selects an amount of weight that is sufficient to allow 6–8 RM in each of the three sets (the initial selection of a starting weight typically requires some trial and error), with a recovery period of 60–90 seconds between sets. If at least three sets of 6 RM cannot be completed, the weight is considered too heavy and is reduced. Conversely, if it is possible to do more than three sets of 8 RM, the weight is considered too light and is increased. To achieve training-induced adaptations in strength at the beginning of an exercise program is low (30–40% of the RM) for sedentary, untrained individuals

TABLE 12-3 Exercise Progressions

	Set(s) of 10	Amount of Weight	Repetitions
DeLorme program	1	50% of 10 RM	10
	2	75% of 10 RM	10
	3	100% of 10 RM	10
Oxford technique	1	100% of 10 RM	10
	2	75% of 10 RM	10
	3	50% of 10 RM	10
MacQueen technique	3 (beginning/intermediate)	100% of 10 RM	10
	4–5 (advanced)	100% of 2–3 RM	2–3
Sander program	Total of 4 sets (3 times per week)	100% of 5 RM	5
	Day 1: 4 sets	100% of 5 RM	5
	Day 2: 4 sets	100% of 3 RM	5
	Day 3: 1 set	100% of 5 RM	5
	2 sets	100% of 3 RM	5
	2 sets	100% of 2 RM	5
Knight DAPRE program	1	50% of RM	10
	2	75% of RM	6
	3	100% of RM	Maximum
	4	Adjusted working weight	Maximum
Berger's adjustment technique	3	100% of 10 RM	6–8

DAPRE, daily adjustable progressive resistive exercise; RM, repetition maximum.

or very high (>80% of RM) for those already highly trained.[69] For healthy but untrained adults, a typical training zone usually falls between 40% and 70% of the baseline RM.[69]

CLINICAL PEARL

The 1 RM equivalent is a formula that takes into account the weight lifted and reps multiplied by a numeric equivalent.

1 RM = (weight lifted × number of reps × 0.03) + weight lifted.

For example, a patient who has lifted 100 lb for a bench press a total of 12 reps, his or her RM equivalent will be equal to (100 × 12 × 0.03) + 100 = 136.

A typical exercise prescription for high school, collegiate, and professional athletes includes three or more sets of a 6–12 RM per exercise performed 3 days/week.[70] For others, a 10–15 RM is generally recommended.[71] For children and the elderly, a low-to-moderate percentage of the established RM is recommended.[69] Initially, the strengthening exercises are performed on a daily basis, with the variables dependent on the patient's response to the exercise. T is is progressed to every other day, and then to at least three times per week, but no more than four times per week.

TABLE 12-4 Adjustment Sequence for DAPRE Program

Number of Repetitions Performed During Set	Adjusted Working Weight for Fourth Set (lb)	Next Exercise Session (lb)
0–2	− 5–10	− 5–10
3–4	0–5	Same weight
5–6	Same weight	+ 5–10
7–10	+ 5–10	+ 5–15
11	+ 10–20	+ 10–20

DAPRE, daily adjustable progressive resistive exercise.

CLINICAL PEARL

To determine how much weight should be increased for a particular exercise the 2 for 2 rule method is recommended as it is relatively conservative. The rule states that the load should increase if the individual can perform two or more reps over the assigned reps for that particular exercise over two consecutive workouts.

Eccentric Exercises

T e clinical indications for the use of eccentric exercise are numerous[22] (Table 12-5). Eccentric training produces more force than concentric training. A 1987 meta-analysis comparing eccentric to concentric training found that eccentric training is more effective at increasing total and eccentric strength, as well as muscle mass, and that it is superior to concentric training for rate of force development.[72] Since the force–velocity relationship is different during concentric and eccentric muscle contractions (see Chapter 1), an eccentric contraction generates greater tension than a concentric contraction at slow velocities with a maximum load. Clinically this means

TABLE 12-5	Clinical Indications for Eccentric-Biased Exercise

a greater load or weight can be lowered with control than can be lifted. Contrary to popular belief However, a slow eccentric contraction using a constant load does not always generate greater tension than a concentric one. In fact, less tension is often generated, so to increase the tension during an eccentric exercise a greater load has to be used. Since greater loads can be used for eccentric training, there is greater stress on the cardiovascular system during eccentric exercise than during concentric exercise.[73] Somewhat paradoxically, using similar exercise loads, eccentric exercises are more efficient at the metabolic level than concentric exercise—eccentric muscle contractions consume less oxygen and energy stores than concentric contractions.[74] The clinical relevance of this is that muscular endurance can be improved more efficiently using eccentric activities than similar concentric activities because muscle fatigue occurs less quickly with eccentric exercise.[73] Eccentric exercise can be applied by completing the concentric portion of the lift with both extremities (i.e., leg press) and by using only the involved limb for the eccentric portion.

CLINICAL PEARL

Functional strength is the ability of the neuromuscular system to perform combinations of concentric and eccentric contractions in the performance of activities that relate to a patient's needs and requirements in a multiplanar environment (see section "Specificity of Training").[75] There is some evidence to suggest that exercising eccentrically or concentrically can lead to strength gains in the other (eccentric training can improve concentric strength and vice versa).[76] Effective rehabilitation targets specific muscles with regard to functional muscle activity patterns and overall conditioning and uses a progression of increased activity while preventing further trauma.[77] Incremental gains in function should be seen as strength increases.

Isokinetic Exercises

An isokinetic exercise, which can be used throughout all stages of rehabilitation for exercise and testing, is one in which the length of the muscle is changing while the contraction is performed at a constant velocity.[78] Thus, isokinetic exercise is also referred to as accommodating resistance exercise. Early phases of rehabilitation are especially amenable to the accommodative resistance offered since the resistance is never more than the muscle can generate.[79] The main principle behind isokinetic exercise is that peak torque (the maximum force generated through the range of motion) is inversely related to angular velocity, the speed that a body segment moves through its range of motion. Put more simply, the resistance provided by an isokinetic machine moves at some pre-set speed, regardless of the torque applied to it by the individual, thus, the key to isokinetic exercise is not the resistance but the speed at which the resistance can be moved.[80] Fundamental to the concept of isokinetic exercise is that the velocity of muscle lengthening or shortening is both preset and controlled by the unit and remains constant throughout the range of motion of the exercise.

Advantages for this type of exercise include:

- Both high-speed/low-resistance and low-speed/high-resistance regimens result in excellent strength gains.[81–84] High speeds are considered to be between 240 and 360 degrees per second, medium speeds are considered to be between 60 and 240 degrees per second, and slow speeds between 30 and 60 degrees per second.
- Both concentric and eccentric resistance exercises can be performed on the machines.
- Accommodation to fatigue. As the contracting muscle fatigues, a patient is still able to perform repetitions because the resistance encountered is directly proportional to the force applied.
- Provides objective and quantifiable measurements of muscular strength.
- Allows for reciprocal training of agonist and antagonist muscles.
- The machines provide maximum resistance at all points in the range of motion. In addition, the range can be set so that the exercise is only performed in a specific range. This can be advantageous if the patient has a painful arc of motion.
- The gravity-produced torque created by the machine adds to the force generated by the muscle when it contracts resulting in a higher-torque output than it actually created by the muscle.

Disadvantages of this type of exercise:

- Expense. Isokinetic machines, which rely on hydraulic, pneumatic, and mechanical pressure systems, are very expensive, with purchase prices ranging between $45,000 and $80,000.
- Requires maximal effort to work effectively.
- The increased potential for impact loading and incorrect joint axis alignment.[85] During concentric exercise, as the force output decreases, the compressive forces across the moving joint are less at faster angular velocities than at slow velocities.
- Questionable functional carryover.

Types of Resistance Used

Resistance-training programs have the potential for many positive benefits provided the training is appropriately progressed to meet the needs of a person as his or her strength increases. Resistance can be applied to a muscle by any external force or mass, including any of the following.

Gravity

Gravity alone can supply sufficient resistance for a weakened muscle. With respect to gravity, muscle actions may occur

- in the same direction as gravity (downward);
- in the opposite direction to gravity (upward);
- in a direction perpendicular to gravity (horizontal); and
- in the same or opposite direction of gravity, but at an angle.

The direction in which the muscle is working determines the role that gravity plays and the role that the muscle must play in order to counteract the forces of gravity. For example, if an arm muscle is working to lower a book to a table, the biceps muscle works eccentrically against the force of gravity to control the speed of the lowering. If the muscle works to lift the book from the table, the biceps muscle must work concentrically against the force of gravity.

CLINICAL PEARL

An active range of motion exercise is designed to work against gravity, whereas an active assisted exercise is typically performed perpendicular to gravity.

Constant versus Variable Load

This refers to how consistent the resistance is applied. For example, performing a biceps curl while holding a dumbbell provides a constant load. However, the contracting muscle is challenged maximally at only one point in the range of motion in which the maximum torque of the resistance matches the maximum torque output of the muscle. The training premise for a variable load is twofold:[86]

1. The load increases where the muscle has more leverage in the early phases of the lift.
2. The load decreases where the muscle has little leverage in the later phases of the lift.

The load can be made variable by using a specially designed piece of resistance equipment that manipulates the load using a weight cable system that moves over an asymmetrically shaped cam (see Exercise Machines). In addition, variable resistance training using elastic bands or heavy chains has gained popularity. For example, when using elastic bands during a seated overhead dumbbell press, the elastic band is attached to the dumbbell and to the chair. As the patient lifts the dumbbell from the shoulder height position toward the elbow extended position (Fig. 12-100), a concentric contraction is used; whereas as the patient lowers the dumbbells (Fig. 12-101), the eccentric contraction can be enhanced by the pull of the elastic band. The use of chains works by a slightly different mechanism. For example, when a heavy chain is attached to the ends

FIGURE 12-100 Seated dumbell press with elastic band—concentric contraction.

of a bar during a squat, the eccentric load increases early in the lift because the chain links are added at the beginning of the descent, and it decreases as the links accumulate on the ground as the patient moves from the stand position into the

FIGURE 12-101 Seated dumbell press with elastic band—eccentric contraction.

squat position.[48] Conversely, the concentric load increases as the chain-links lift off of the floor.

Body Weight

A wide variety of exercises have been developed that do not require any equipment but rely solely on the patient's body weight for the resistance (e.g., push-up). T ese exercises are commonly referred to as closed-chain exercises, whereas in a non–weight-bearing position where the distal segment moves freely are commonly referred to as an open-chain exercise. Both of these types of exercise are discussed later.

Accommodating Resistance

Isokinetic machines are able to control the velocity of an active movement during exercise.

Small Weights

Cuff weights, dumbbells, and surgical tubing (elastic resistance) are economical ways of applying resistance. Small weights are typically used to strengthen the smaller muscles or to increase the endurance of larger muscles by increasing the number of reps. Free weights also provide more versatility than exercise machines, especially for three-dimensional exercises, as the movements do not occur in a straight line or plane. T e disadvantage of free weights is that they offer no variable resistance throughout the range of motion and so the weakest point along the length–tension curve of each muscle limits the amount of weight lifted. According to a recent study, 96% of rehabilitation professionals use elastic resistance with their patients, and 85% of home exercise programs prescribed by rehabilitation professionals require elastic-resistance bands or tubing.[83,87–92] Elastic resistance offers a unique type of resistance that cannot be classified into the traditional subcategories of strengthening. T e amount of variable resistance offered by elastic bands or tubing is a factor of the internal tension produced by the material. T is internal tension is a factor of the elastic material's coefficient of elasticity, the surface area of the elastic material, and how much the elastic material is stretched.[92] It is commonly believed that the resistance provided by these bands or tubing increases exponentially at the end range of motion. However, the forces produced by the elastic resistance are linear until approximately 500% elongation, at which point the forces increase exponentially.[92] As the elastic resistance is not stretched more than 300% in prescribed exercises, this exponential increase should not be attained. In addition, the torque production of elastic-resistance exercises is similar to that produced by a concentric/eccentric dumbbell exercise: a bell-shaped curve.[93]

Medicine Balls

Medicine balls provide the opportunities to improve strength, balance, and coordination through dynamic movements by training the body as a functional unit and strengthening the core and trunk musculature. Both upper- and lower-body medicine ball exercises can be performed using a variety of speeds, and medicine ball weights and sizes.

Exercise Machines

In situations where the larger muscle groups require strengthening, and where exercises need to be performed in straight and supported lines, a multitude of specific exercise machines can be used. T ese machines are most often used in the more advanced stages of a rehabilitation program when more resistance can be tolerated, but can also be used in the earlier stages depending on the size of the muscle undergoing rehabilitation. Examples of these machines include the multi-hip, the lat pull-down, the leg extension, and the leg curl machine. Exercise machines are often fitted with an oval-shaped cam or wheel that mimics the length of tension curve of the muscle (Nautilus, Cybex). Although these machines are a more expensive alternative to dumbbell or elastic resistance, they do offer some advantages:

- T ey provide adequate resistance for the large muscle groups that cannot be achieved with free weights/cuff weights, or manual resistance.
- T ey are typically safer than free weights as control/support throughout the range is provided.
- T ey provide the clinician with the ability to quantify and measure the amount of resistance that the patient can tolerate over time (as compared with elastic resistance).

T e disadvantages of exercise machines are as follows:

- the inability to modify the exercise to be more functional or three-dimensional
- the inability to modify the amount of resistance at particular points of the range

Manual Resistance

Manual resistance is a type of active exercise in which another person provides resistance manually. An example of manual resistance is proprioceptive neuromuscular facilitation (PNF) (see Chapter 10). T e advantages of manual resistance, when applied by a skilled clinician, are as follows:[94]

- Control of the extremity position and force applied. T is is especially useful in the early stages of an exercise program when the muscle is weak.
- More effective reeducation of the muscle or extremity, using diagonal or functional patterns of movement.
- T e critical sensory input to the patient through tactile stimulation and appropriate facilitation techniques (e.g., quick stretch).
- Accurate accommodation and alterations in the resistance applied throughout the range. For example, the resistance can be modified to avoid a painful arc in the range.
- Ability to limit the range. T is is particularly important when the amount of range of motion needs to be carefully controlled (postsurgical restrictions).

The disadvantages of manual resistance include the following:

- T e amount of resistance applied cannot be measured quantitatively.
- T e amount of resistance is limited by the strength of the clinician/caregiver or family member.
- A difficulty with the consistency of the applied force throughout the range, and with each rep.

Exercise Prescriptions

Before initiating an exercise program, it is necessary to conduct a needs analysis to evaluate the physical requirements and physical attributes of the patient. Determining the selection of exercise is dependent upon the goals and objectives and the needs analysis. Progression is defined as "the act of moving forward or advancing toward a specific goal over time until the target goal has been achieved."[71] A progressive exercise program is recommended to condition the patient for a return to activity and to prevent overload injuries. Such a program should address the following areas:[95–99]

- Flexibility. Attempts should be made to improve general body flexibility, with an emphasis on the specific activity or exercise. T e general flexibility exercises should address the entire kinematic chain and not just the joint in question (e.g., shoulder rotation and elbow motion in the arm, low back, hip rotation, and hamstrings in the legs).
- Strengthening. T e exercises to improve strength should be applied in appropriate amounts and locations to address sports- or functional-specific activities.
- Power. Power is incorporated through the use of rapid movements in appropriate planes with weights and ballistic activities.
- Endurance. Endurance can be built up with aerobic exercises.

Optimal resistance training progressions should always be based on sound rationale and should always be individualized to meet specific training goals. Each progression is made more challenging by altering one of the parameters of exercise, including the intensity, duration, and frequency which are modified according to patient response.

As with prescriptions for medications, a successful exercise prescription requires the correct balance between the dose (exercise variables) and the response (specific health or fitness adaptations).[100] T e dosage of an exercise refers to each particular patient's exercise capability and is determined by a number of variables (Table 12-6).[22] For these variables to be effective, the patient must be compliant and be able to train without exacerbating the condition.[101]

CLINICAL PEARL

The training volume describes the total amount of resistance lifted during a strength training session and is, therefore, dependent upon the weight lifted, the reps, and sets. The training volume is calculated by multiplying the resistance (force × distance) by the total number of repetitions performed in a specified period of time (Training volume = number of sets × number of reps × weight lifted per rep). The volume may also be calculated by adding the frequency and duration of rehabilitation or training sessions.

TABLE 12-6 Resistive Exercise Variables

Resistance (load or weight)
Duration
Training frequency (weekly, daily)
Point of application
Bouts (timed sessions of exercise)
Sets and repetitions
Training volume
Mode (type of contraction)
Rests

Depending on the specific program design, resistance training is known to enhance muscular strength, power, or endurance and can provide a potent stimulus to the neuromuscular system. Other variables such as speed, balance, coordination, jumping ability, flexibility, and other measures of motor performance have also been positively enhanced by resistance training.[71]

CLINICAL PEARL

- If the pain is present before resistance or the end-feel, the patient's symptoms are considered irritable. The intervention in the presence of irritability should not be aggressive, particularly inclusive of exercise.[102]
- If pain occurs after resistance, then the patient's symptoms are not considered irritable and exercise, particularly stretching, can be more aggressive.

It is worth remembering that when the individual trains for two different types of adaptations (e.g., aerobic fitness versus strength), the training stimuli can interfere with one another and result in less improvement in one or both of the effects. For example, when strength loads are combined with aerobic training, the aerobic adaptation is not detrimentally affected, but there is a negative impact on strength development.[7,103]

Each exercise session should include a 5–15-minute warm-up and a 5–15-minute cool-down period.

- Warm-up
  - includes low-intensity cardiorespiratory activities.
  - prevents the heart and circulatory system from being suddenly overloaded.
- Cool-down
  - includes low-intensity cardiorespiratory activities and flexibility exercises.
  - helps prevent abrupt physiological alterations that can occur with sudden cessation of strenuous exercise.

T e length of the warm-up and cool-down sessions may need to be longer for deconditioned or older individuals. T e type of exercise prescribed determines the type of warm-up.[104] T e possible benefits of a warm-up prior to physical activity are listed in Table 12-7. T e most effective warm-up consists of both general (walking, biking, jogging, and gentle resistive exercises) and specific (movements that are appropriate for the particular activity to be undertaken) exercises.[104]

Once the warm-up is completed, it is recommended that a flexibility program be incorporated to increase joint movement and muscle extensibility (see Chapter 13).

TABLE 12-7 Possible Benefits of a Warm-Up Prior to Physical Activity

Increased blood flow to muscles.
Increased oxyhemoglobin breakdown, with increased oxygen delivery to muscles.
Increased circulation leading to decreased vascular resistance.
Increased release of oxygen from myoglobin.
Enhanced cellular metabolism.
Reduced muscle viscosity leading to smoother muscle contraction and increased mechanical ef ciency.
Increased speed of nerve impulses.
Increased sensitivity of nerve receptors.
Decreased activity of alpha fibers and sensitivity of muscles to stretch.
Decreased number of injuries due to increased range of motion.
Decreased stiffness of connective tissue leading to decreased likelihood of tears.
Increased cardiovascular response to sudden strenuous exercise.
Increased relaxation and concentration.

T e initial exercise is prescribed at a level that the patient can perform, before progressing in difficulty. T is will be determined by a number of factors, including the goals of the treatment, the extent of impairment, the patient's age, general health and fitness level, and the stage of healing of the injured tissues. As with any treatment, the prescribed exercises must be performed correctly so that the movement replicates the action of the muscle or muscle groups, and prevents any substitute motions (see Chapter 4). T e early goals of exercise are concerned with increasing circulation, preventing atrophy, increasing protein synthesis, and reducing the level of metabolites.[101]

CLINICAL PEARL

Resistance training, particularly when incorporated into a comprehensive fitness program, reduces the risk factors associated with coronary heart disease, noninsulin-dependent diabetes, and colon cancer; prevents osteoporosis; promotes weight loss and maintenance; improves dynamic stability and preserves functional capacity; and fosters psychological well-being.[71]

Increasing Muscle Strength

Strengthening of a muscle occurs when the muscle is forced to work at a higher level than that to which it is accustomed. A muscle becomes stronger from a resistance training program via hypertrophy or an increase in CSA of the muscle. Functional strength relates to the ability of the neuromuscular system to perform functional activities in a smooth, and coordinated manner. Since all muscles function eccentrically, isometrically, and concentrically in the sagittal, frontal, and transverse planes, an integrated training program should utilize a multiplanar training approach using the entire muscle and velocity contraction spectrum.[48] T e following factors should be considered when designing an exercise program to increase strength.

Repetitions and Sets

T e initial selection of a starting weight may require some trial and error to find the correct number of reps. Despite many studies, no optimal number of repetitions or sets have been established. However, for any given exercise, the recommendations are that the amount of weight selected should be sufficient to allow 8–12 reps per exercise for 3–5 sets with a recovery period between sets of 60–90 seconds to elicit improvements in muscular strength and endurance as well as muscle hypertrophy.[69]

Exercise order. Resistance exercises can be performed in different orders to allow for the most efficient session. Typically, if several muscle groups are exercised in a single session, a few guidelines are recommended[105]:

- Large muscle groups are exercised before small muscle groups
- Multi-joint exercises are performed before single joint exercises
- High-intensity exercises should be performed before low-intensity exercises.

CLINICAL PEARL

Three terms are commonly used with resistance training prescriptions:

- Repetitions. The number of times a specific movement or exercise is repeated.
- Repetition maximum (RM). The RM is the maximum number of repetitions an individual can perform at a given weight. For example, a 10 RM is the weight the patient can lift a maximum of 10 times (see "Type of Contraction Used").
- Set. A particular number of repetitions. Whatever exercise progression is used to achieve an increase in the total number of repetitions while maintaining a suf - cient effort, the number of sets must also be increased. This increase in sets must occur in conjunction with a reduction in the number of repetitions per set by 10–20%[101] or a reduction in the amount of resistance. Generally speaking, no more than three to five sets are used. After each set, there is a brief interval of rest.

Intensity

Intensity is the rate of performing work, or the load or resistance under which the patient exercises. Intensity refers to the power output or how much effort is required to perform the exercise. In clinical terms, intensity refers to the weight or resistance lifted by the patient, or exercise load. In addition, the intensity of exercise is also dependent on the frequency, volume, length of rest periods, and order of exercises. T e

amount of intensity will vary based on the intent—high intensity using the overload principle to increase muscle strength and power, and low intensity to increase endurance. Low-intensity levels are also used in the early stages of soft-tissue healing, after prolonged immobilization, and when the patient is initially learning an exercise to emphasize the correct form. It is now recognized that an individual's perception of effort (rated perceived exertion, or RPE) is closely related to the level of physiological effort.[106, 107] The Borg Scale is commonly used to help determine a patient's RPE, as an individual's perception of effort is closely related to the level of physiological effort—a high correlation exists between a person's RPE multiplied by 10, and their actual heart rate.[106, 107] For example, if a person's RPE is 15, then 15 × 10 = 150; so the heart rate should be approximately 150 beats per minute. A cardiorespiratory training effect can be achieved at a rating of "somewhat hard" or "hard" (13–16). Note that this calculation is only an approximation of heart rate, and the actual heart rate can vary quite a bit depending on age and physical condition. The original scale introduced by Borg[107] rated exertion on a scale of 6–20, but a more recent one designed by Borg included a category (C) ratio (R) scale, the Borg CR10 Scale®(Table 12-8). To determine how much resistance the patient should use during the exercise program, the RM can be calculated.

Patient responses that can modify the intensity include an increase in pain level, muscle fatigue, the time taken to recover from fatigue, cardiovascular response, compensatory movements, the level of motivation, and degree of comprehension. The clinician must be aware that if the load used is too high, the patient may attempt to carry out the desired movement by using substitute motions. This is obviously counterproductive and must be avoided by using an appropriate amount of resistance.

TABLE 12-8 Rating of Perceived Exertion[a]

Traditional Scale	Verbal Rating	Revised 10-Grade Scale	Verbal Rating
6		0	Nothing at all
7	Very, very light	0.5	Very, very weak
8		1.0	Very weak
9	Very light	2.0	Weak (light)
10		3.0	Moderate
11	Fairly light	4.0	Somewhat strong
12		5.0	Strong (heavy)
13	Somewhat hard	6.0	
14		7.0	Very strong
15	Hard	8.0	
16		9.0	
17	Very hard	10.0	Very, very strong (almost maximum) maximal
18			
19	Very, very hard

Frequency

Training frequency refers to the number of times strength-training sessions are completed in a given period (e.g., the number of work-outs per week). Optimal training frequency depends on several factors such as experience, training volume and status, intensity, exercise selection, the level of conditioning, recovery ability, and the number of muscle groups trained per workout session. Those exercises that require greater recovery time should be performed less frequently than others. Based on the studies of isokinetic and eccentric/concentric exercise, muscle strength recovery follows a steady, nonlinear, and predictable increase over time.[22,108,109] The optimal frequency per week has not been established, although a frequency of two to three times per week, every other day, or up to five exercise sessions per week are commonly cited for healthy individuals.[105] In rehabilitation, it is recommended that short sessions of exercises be performed on a daily basis several times a day while keeping both the intensity and repetitions low. As healing progresses, evidenced by a decrease in pain and swelling and an increase in the range of motion, the exercises should be performed every other day. If the training load is near the maximum capacity, more time for recovery will be required to minimize soreness and provide the adequate rest. Once sufficient strength is attained, even if the patient only performs the strength training at a minimum of once per week, the strength can be fairly well maintained over a 3-month period.[110]

Strength is most effectively enhanced by a program featuring high resistance and few reps. More training sessions can be accomplished and provide adequate rest if a split routine is used. A split routine divides the training session into groupings, split between the upper-body and lower-body exercises using a rest interval of 48 hours. Another alternative is to perform a push and pull exercise program, in which the strength training is divided into exercises in which the individual pushes a weight (e.g., triceps extension, bench press), then pulls a weight (e.g., biceps curl, latissimus dorsi pull down).

Duration

Duration refers to the length of the exercise session. It can also refer to the total number of weeks or months during which an exercise program is carried out. Within a particular exercise session, physical conditioning occurs over a period of 15–60 minutes depending on the level of intensity. Average conditioning time is 20–30 minutes for moderate intensity exercise. However, individuals who are severely compromised are more likely to benefit from a series of short exercise sessions (3–10 minutes) spaced throughout the day.

Rest Periods

In most exercises prescriptions, fatigue of the muscle being exercised is the goal. However, fatigue may also occur due to lack of coordination, insufficient balance, poor motivation, or the addition of compensatory movements. In addition, fatigue may also be associated with specific clinical diseases,

for example, multiple sclerosis, cardiac disease, peripheral vascular dysfunction, and pulmonary diseases. Because fatigue is detrimental to performance, rest is an important component of any exercise progression. T e rest period must be sufficient to allow for muscular recuperation and development while alleviating the potential for overtraining.[92] In general, the heavier loads lifted, the longer the rest period between sets. T e rest period between sets can be determined by the time the breathing rate, or pulse of the patient returns to the steady state, or by using the following guidelines:

- muscular endurance: less than 30 seconds rest
- muscular hypertrophy: 60–90 seconds
- muscular strength: 2–5 minutes
- muscle power: 2–5 minutes

A 48-hour rest period between concurrent training sessions is generally recommended.[71]

CLINICAL PEARL

In the rehabilitation population, fatigue should be achieved without exceeding the patient's tolerance and while protecting the injury site. It is now clear that the development of fatigue probably involves several factors that influence force production in a manner dependent on muscle fiber type and activation pattern, and that one of these factors may be the regulation of Ca^{2+} by the sarcoplasmic reticulum.[111] Characteristics of muscle fatigue include reduction in muscle force production capability and shortening velocity, a reduction in the release and uptake of intracellular calcium by the sarcoplasmic reticulum, as well as prolonged relaxation of motor units between recruitment.[111,112]

One of the biggest challenges for a clinician is to find a balance between achieving a maximum training effect while alleviating fatigue. Fortunately, fatigue has a much faster decay time than the training effect. T us, to remove the fatigue, the volume of training should be reduced while maintaining the training effect by holding the intensity of the training load constant.[113]

The Speed of Exercise

T e speed of the exercise should depend on the imposed demands of an individual. Since many functional activities involve reasonably fast velocities of limb movement, increasing the speed of an exercise following the initial phase of learning a particular exercise and developing proficiency in the performance of the exercise is beneficial.[8] In addition, higher-velocity training appears to improve peak power measures.[71] T e speed of an exercise can be controlled more specifically using an isokinetic dynamometer or machine.

Variation

It has been shown that systematically varying volume and intensity is most effective for long-term progression.[71,114] Variation in training, or periodization, is a fundamental principle that supports the need for alterations in one or more program variables over time to allow for the training stimulus to remain optimal (Table 12-9).[71] T e concept of periodization has been rooted in program design universally for many years. Periodization is the systematic process of planned variations in a resistance-training program over a specified training cycle to prevent overtraining and to perform at peak or optimum levels at the right time.[114] Two models of periodization are the classic (linear) and the undulating (nonlinear) protocols:[71]

- **Classic.** T is model is characterized by high initial training volume and low intensity. As training progresses, volume decreases and intensity increases in order to maximize strength, power, or both.
- **Undulating.** T e nonlinear program enables variation in intensity and volume within each 7- to 10-day cycle by rotating different protocols over the course of the training program. Nonlinear methods attempt to train the various components of the neuromuscular system within the same 7- to 10-day cycle. During a single workout, only one characteristic is trained on a given day (e.g., strength, power, or muscular endurance).

Periodization consists of several phases, including the macrocycle, mesocycle, and microcycle. T e macrocycle for an athlete can, for example, last for 1 year ending with the end of a competitive season. T e macrocycle is divided into several mesocycles. A mesocycle defines distinct variations in the resistance and exercise program. For example, a mesocycle for an athlete can be divided into three distinct phases:[104]

- **Conditioning.** T is phase emphasizes developing aerobic and anaerobic fitness, strength, and power.
- **Precompetition.** T is phase emphasizes correct technique.
- **Competition.** During this phase, the emphasis is on competitive performance while maintaining basic conditioning.

T e final breakdown of periodization is the microcycle, which involves changes in training parameters such as intensity,

TABLE 12-9 Types of Training That Incorporate Variation

Circuit training	Circuit training or cross-training incorporates a wide variety of modes of training and uses high repetitions and low weight to provide a more general conditioning program aimed at improving body composition, muscular strength, and some cardiovascular fitness.
Interval training	Interval training includes an exercise period followed by a prescribed rest interval. It is perceived to be less demanding than continuous training and tends to improve strength and power more than endurance. With appropriate spacing of work and rest intervals, a significant amount of high-intensity work can be achieved and is greater than the amount of work accomplished with continuous training. The longer the work interval, the more the anaerobic system is stressed and the duration of the rest period is not more important. In a short work interval, a work recovery ratio of 1:1 or 1:5 is appropriate to stress the aerobic system.

work–rest ratios, sets, reps, exercise order, and specific exercises, and generally lasts for 1–2 weeks. A common format is a 4-week mesocycle that consists of three microcycles of 1 week each, in which the load is progressively increased, followed by a 1-week microcycle of reduced volume and intensity.

Increasing Muscle Endurance

It is well established that endurance training results in enhanced performance and a delayed onset of fatigue during endurance exercise. More specifically, endurance sports improvement is accomplished by increasing aerobic sources of energy by delaying the onset the blood lactate accumulation.[3] Endurance exercise training also leads to a shift of skeletal muscle mitochondria toward an increased use of lipids as a substrate source both at the same absolute and at the same relative exercise intensity.[37,115] T e nature of endurance exercise encourages the body to work aerobically, which is referred to as cardiopulmonary endurance. T is phenomenon, called steady state, occurs after some 5–6 minutes of exercise at a constant intensity level.[37] During steady state, the rate of mitochondrial ATP production is closely matched to the rate of ATP hydrolysis and demonstrates the existence of efficient cellular mechanisms to control mitochondrial ATP synthesis in a wide dynamic range.[116] Endurance exercise training produces an increase in mitochondrial volume density in all three muscle fiber types[117] and thus muscle aerobic power. With a higher mitochondrial density in trained muscle, the rate of substrate flux per individual mitochondrion will be less at any given rate of ATP hydrolysis.[116] T erefore, the required activation of mitochondrial respiration by adenosine diphosphate (ADP) to achieve a given rate of ATP formation will be less, resulting in increased ADP sensitivity of muscle oxidative phosphorylation.[116] To develop endurance, muscles must oxidize lactate during work and decrease dependence on glycolysis to supply energy.[48]

Muscular endurance training is typically prescribed during the general preparation phase of training to prepare the body for the increased work demands that will be required, and to program the body's neuromuscular coordination systems.

To increase muscle endurance, exercises are performed against light resistance for many reps (no fewer than 20 per set) so that the amount of energy expended is equal to the amount of energy supplied. T e amount of weight used during muscular endurance training can be determined by using an RPE scale, in which 1 is very light exertion, and 10 is intense exertion. General endurance is trained by using low loads (30% of 1 RM), short rest periods (10–30 seconds), and repetitions between 20 and 150.[3]

Specialized endurance training may include speed endurance generating tension over a long period of time without a decrease in efficiency.[3] Strength endurance is developed with 25–50% of 1 RM, with a moderate tempo of repetition performance (60–120 repetitions per minute). Using the example of a bench press, if an athlete's maximum weight for the bench press is 220 lb, he or she could reduce the workout weight by 50% (110 lb) and increase the number of reps to approximately 90 per minute.

T e number of reps used is a factor of the speed of one rep, and how many reps the athlete can complete in 60 seconds. For example, if under normal training conditions the athlete takes 3 seconds to raise the weight during a biceps curl and 3 seconds to lower it, the muscle is under tension for 6 seconds and the athlete is working at a speed of 10 reps per minute. By increasing the speed of the rep to 4 seconds (the time the muscle is under tension), the athlete must achieve at least 15 reps in order to build muscular endurance. A mixed intensity interval training program can be used to facilitate sports-specific endurance using 30- to 90-second intervals of varying intensity over the course of 6 minutes, with progression involving increasing the number of 6-minute intervals.[118]

T e major drawback of muscular endurance training is the increased potential for overuse injuries. T is can be offset by manipulating one or more of the training variables, such as sets, loads, tempo, rest periods between sets, the number of exercises, hand position, and grip width. It is also worth remembering that working at a level to which the muscle is accustomed improves the endurance of that muscle but does not increase its strength.

Increasing Muscle Power

Power is increased by having a muscle work dynamically against resistance within a specified period. Olympic weightlifting is an excellent means to develop power for the athletic population. However, these lifting techniques, which involve a steep learning curve, require total body coordination, strength, and balance.[48] Alternatively, two simpler techniques, using dumbbells, may be more appropriate for rehabilitation[48]:

1. Double-leg dumbbell snatch. T e patient stands with the feet shoulder width apart, holding a dumbbell in one hand (Fig. 12-102A). Using a smooth movement, the patient

FIGURE 12-102 Double-leg dumbbell snatch. (Continued)

FIGURE 12-102 (Continued)

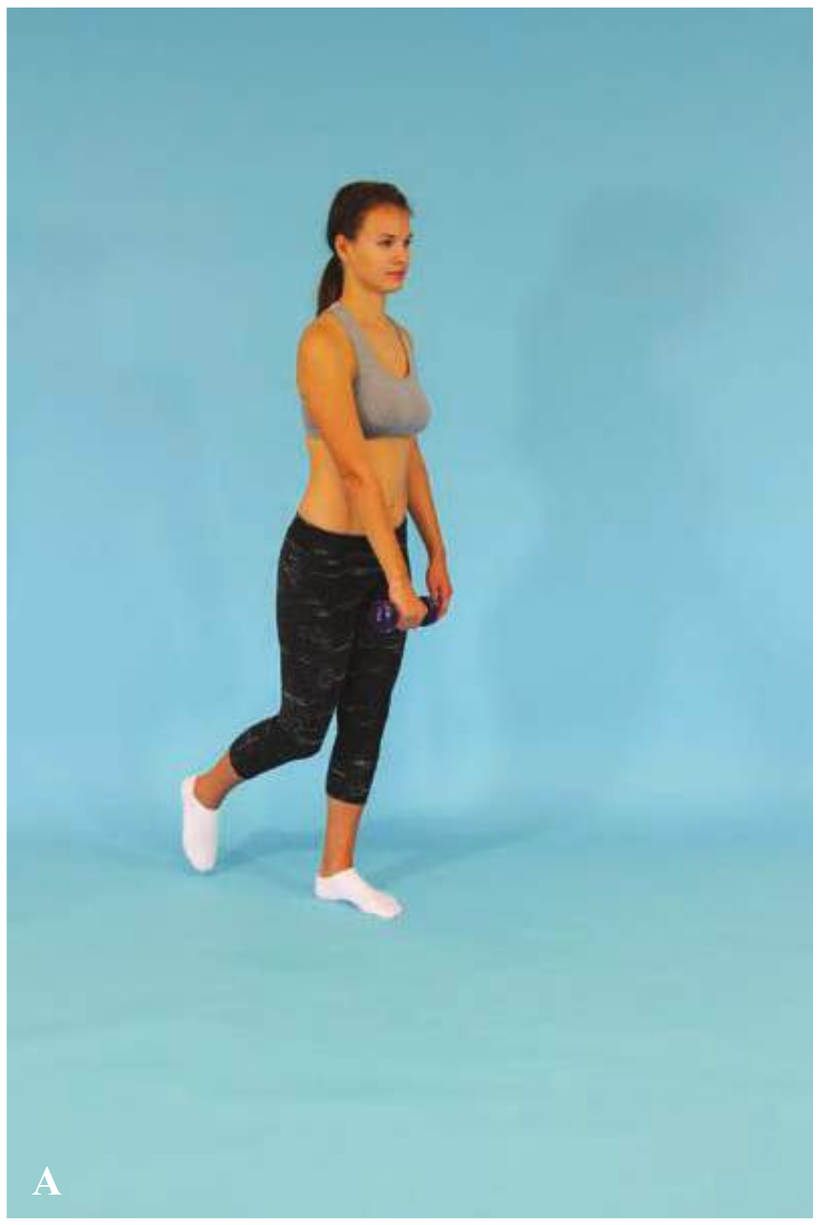

FIGURE 12-103 Single-leg dumbbell snatch.

moves into the squat position (Fig. 12-102B) while raising the dumbbell over the head (Fig. 12-102C).

2. Single-leg dumbbell snatch. T e patient stands on one leg, with the other leg raise slightly behind, and holding a dumbbell in the same upper extremity (Fig. 12-103A). Using a smooth movement, the patient moves into a lunge position while raising the dumbbell over the head (Fig. 12-103B).

Plyometrics

In the context of rehabilitation, plyometric training can be viewed as the bridge between pure strength and sports-related exercises.[119] It has been demonstrated that when a concentric contraction is preceded by a phase of active or passive stretching, elastic energy is stored in the muscle. T is stored energy is then used in the subsequent contractile phase. For example,

during some functional activities, such as jumping, the movement involves an eccentric loading of a muscle or muscle group, followed immediately by a concentric muscle action, as part of a stretch-shortening cycle.[31] The eccentric/concentric actions utilize the stretch reflex or stretch-shortening cycle in which the muscle is preloaded with energy during the eccentric phase (much like stretching a rubber band apart) and the release of that stored energy for subsequent muscular actions (releasing the rubber band).[120] The stored elastic energy within the muscle is used to produce more force than can be provided by a concentric contraction alone.[121–123]

The goal of plyometric training is to decrease the amount of time between the yielding eccentric muscle contraction and the initiation of the overcoming concentric contraction.[124]

The training system of plyometrics is credited to Yuri Verhoshanski,[125] the renowned Soviet jump coach of the late 1960s, although the actual term plyometrics was first introduced in the mid-1970s by an American track coach Fred Wilt.[126] The term plyometrics, when broken down to the roots of the words, is a little confusing. Plyo comes from the Greek word pleythein, which means to increase, and metric, which means to measure. Plyometrics is associated with an enhancement of the ability of the muscle–tendon unit to produce maximal force in the shortest amount of time through activation of the myotatic reflex.[127–130] The tendon portion of the muscle–tendon unit has been found to be the main contributor to muscle–tendon unit length changes and the storage of elastic potential energy.[131] The amount of available elastic energy is affected by time, the magnitude of the stretch, and the velocity of the stretch.[50]

Movement patterns in both athletics and activities of daily living involve repeated stretch-shortening cycles, in which an eccentric movement must be stopped and converted into a concentric movement in the opposite direction. When a muscle contracts in a concentric fashion, most of the force produced comes from the muscle fiber filaments sliding past one another. Force is registered externally by being transferred through the series elastic component of the muscle, and as the muscle lengthens like a spring during the eccentric contraction, the series elastic component is also stretched and contributes to the overall force production.[124]

Acceleration and deceleration are the most important components of all task-specific activities.[101] These activities use variable speed and resistance throughout the range of contraction, stimulating neurologic receptors and increasing their excitability. The nerve receptors involved in plyometrics are the muscle spindle, the Golgi tendon organ, and the joint capsule/ligamentous receptors (see Chapter 3). These neurologic receptors play an important role in fiber recruitment and physiologic coordination. Plyometric activities serve to improve the reactivity of these receptors. Two other reflex mechanisms, which result from neural signals generated by muscle receptors that project back to the muscle of origin as well as other muscles, can be initiated by plyometric exercise and may assist with motor coordination and joint stability:[132]

- Length *f*eedback. These signals, generated by muscle stretch, occur around the same time frame as the stretch reflex, and serve to link muscles that are synergists through excitatory feedback and those with opposite actions by reciprocal inhibition.[133] Length feedback also links monoarticular muscles with excitatory feedback and contributes to joint stiffness.[133]
- Force *f*eedback. These are signals generated by muscle force, which are provided by stimulation of the Golgi tendon organ, and which connect muscles that cross different joints and exert torque in different directions through inhibitory feedback. Force feedback regulates coupling between joints.[133]

Together, length and force feedback induced during the loading phase of a plyometric activity have the potential to improve neuromuscular control.[132]

The physiology of plyometrics can be broken down into a number of phases:

1. A loading phase (eccentric, deceleration, setting, yielding, or cocking phase), in which the muscle–tendon units of the prime movers and synergists are stretched as a result of kinetic energy or loading applied to the joint and begin to perform negative work.[132] Stretching of the muscle–tendon unit during this phase elicits the stretch-shortening cycle, which results in enhanced force production and performance when compared to the absence of stretch.[50] The stretch of active muscle during the loading phase elicits two mechanisms associated with the stretch-shortening cycle: muscle "potentiation" and activation of the muscle spindle:[132]
   - Muscle potentiation. An alteration of the muscle contractile properties that leads to higher-force production through an increase in the proportion of cross-bridges attached to actin, and a decrease in the cross-bridge detachment rate.
   - Muscle spindle activation. Sensory information from the muscle spindle is passed through a monosynaptic reflex loop to provide excitatory feedback to the same muscle (see Chapter 3). This results in short-latency reflex muscle activity (myotatic or stretch reflex). However, the stretch reflex may not be elicited in all muscles that are stretched during a plyometric activity. Monoarticular muscles are consistently activated, but biarticular muscles are not. Differences in reflex muscle activity between monoarticular and biarticular muscles may be explained by differences in muscle length changes during loading. In certain activities, some of the fascicles of biarticular muscles undergo lengthening (eccentric action), while the other muscle fascicles act nearly isometrically. This suggests that monoarticular muscles may benefit more than biarticular muscles from stretch reflex force augmentation for enhanced work output.
2. A coupling (amortization, transmission, pay-off, or reversal) phase: This phase marks the transition between the loading phase and the unloading phase.[50] The coupling phase, the definitive phase of the plyometric exercise, is generally a period of quasi-isometric muscle action.[132] If this transition phase is not continuous, the activity will no longer be considered plyometric because the benefits of the stretch-shortening cycle will be lost.[132]
3. An unloading phase: The unloading (rebound, shortening, push-off, or propulsion) phase of a plyometric exercise occurs immediately after the coupling phase and involves shortening of the muscle–tendon unit. In the biphasic

analysis of plyometric jumps, the unloading phase begins at the start of upward movement of the center of mass and ends when ground contact ceases.[134] Most plyometric activities terminate in a momentum phase, during which body segments continue to move as a result of the forces generated in the unloading phase.[132]

By reproducing these stretch-shortening cycles at positions of physiologic function, plyometric activities stimulate proprioceptive feedback to fine-tune muscle activity patterns. Stretch-shortening exercise trains the neuromuscular system by exposing it to increased strength loads and improving the stretch reflex (see Chapter 3)[50] The degree of performance enhancement during the momentum phase is dependent on the magnitude of the forces and quickness of movement during the plyometric activity.[132] In particular, higher forces are associated with a shorter coupling phase[135] and greater energy storage in the series elastic component.[136] Performance is also a consequence of the total contact duration (loading through unloading phases), because as the contact duration becomes shorter, higher forces and joint moments are generated,[137] and the tendon contribution to work is increased.[132,138]

The mechanisms by which performance is enhanced during plyometric exercise depend on a number of factors:

- The activity must impart higher forces and faster speeds of movement.
- Prolonged contact times should be avoided. Prolonged contact times may result when the intensity is too high during the loading phase or when the transition between the loading and unloading phases is not continuous.[132]
- Plyometric exercises must be initiated at a lower intensity and progressed to more difficult, higher-intensity levels according to tolerance. Before initiating plyometric exercises, the clinician must ensure that the patient has an adequate strength and physical condition base.[50] Initially, the patient is instructed to perform fewer sets and reps. Later, the patient is permitted to do more sets, but not more reps.

Plyometric exercises were traditionally designed to enable lower extremity muscles—primarily the thighs, quadriceps, hamstrings, and calves—to attain maximal power using high-intensity workouts in short spurts of hops, leaps, or bounds. Therefore, care should be taken when applying the physiological principles derived from lower extremity investigations to upper-body and trunk applications, as it is unknown whether the upper extremity and trunk will respond in a similar manner.[132] Plyometric exercise is typically introduced into the rehabilitation program in the later stages as many plyometric exercises, even at low intensities, expose joints to substantial forces and movement speeds. Plyometric exercise is indicated for those patients who desire to return to activities that include explosive movements. Contraindications for initiating plyometric exercise are acute inflammation or pain, immediate postoperative status, and joint instability.[50] Joint pathologies such as arthritis, bone contusion, or chondral injury are relative contraindications, depending on the ability of the tissue to tolerate the high forces and joint loading required in many plyometric activities.[132] Musculotendinous injury is also a relative contraindication until the tissue is able to handle the rapid and high forces of a plyometric exercise.[132]

Guidelines for initiating plyometric exercise in rehabilitation are poorly developed. Most of the criteria have been established for high-intensity exercise in uninjured athletes and are grounded in opinion rather than research.[132] For example, it has been suggested that plyometric exercise should be initiated only after achieving the ability to perform one rep of a parallel squat with a load of 1.5–2.5 times body mass on the back and/or squat 60% of body mass 5 times within 5 seconds (lower extremity), and a bench press with one-third of body weight and/or perform five hand clap push-ups (upper extremity).[119] In addition, success in the static stability tests (Table 12-10) and dynamic stability tests (vertical jump for the lower extremities and medicine ball throw for the upper extremities) have also been used as a measure of preparation.[22]

Many different activities and devices can be used in plyometric exercises. Plyometric exercises may include diagonal and multiplanar motions with tubing or isokinetic machines. These exercises may be used to mimic any of the needed motions and can be performed in the standing, sitting, or supine positions. Generally, 48–72 hours of rest is recommended for recovery between plyometric training sessions.[139]

Lower Extremity Plyometric Exercises

Lower extremity plyometric exercises involve the manipulation of the role of gravity to vary the intensity of the exercise (Table 12-11). Thus, plyometric exercises can be performed horizontally or vertically.

- Horizontal plyometric exercises are performed perpendicular to the line of gravity. These exercises are preferable for most initial clinical rehabilitation plans because the concentric force is reduced, and the eccentric phase is not facilitated.[22] Examples of these types of exercises include pushing a sled against resistance, and a modified leg press that allows the subject to push off and land on the foot plate.
- Vertical plyometric exercises (against or with gravitational forces) are more advanced. These exercises require a greater level of control.[22] The drop jump is an example—the subject steps off a box, lands and immediately executes a vertical jump.

The footwear and landing surfaces used in plyometric drills must have shock-absorbing qualities, and the protocol should

allow sufficient recovery time between sets to prevent fatigue of the muscle groups being trained.[140]

Upper Extremity Plyometric Exercises

Plyometric exercises for the upper extremity involve relatively rapid movements in planes that approximate normal joint function. For example, at the shoulder this would include flexion or abduction at the shoulder, trunk rotation, and diagonal arm motions, and rapid external and internal rotation exercises.

Plyometrics should be performed for all body segments involved in the activity. Hip rotation, knee flexion and extension, and trunk rotation are power activities that require plyometric activation. Plyometric exercises for the upper extremity include push-offs from a table (Fig. 12-104), corner push-ups and weighted ball throws (Fig. 12-105). Medicine

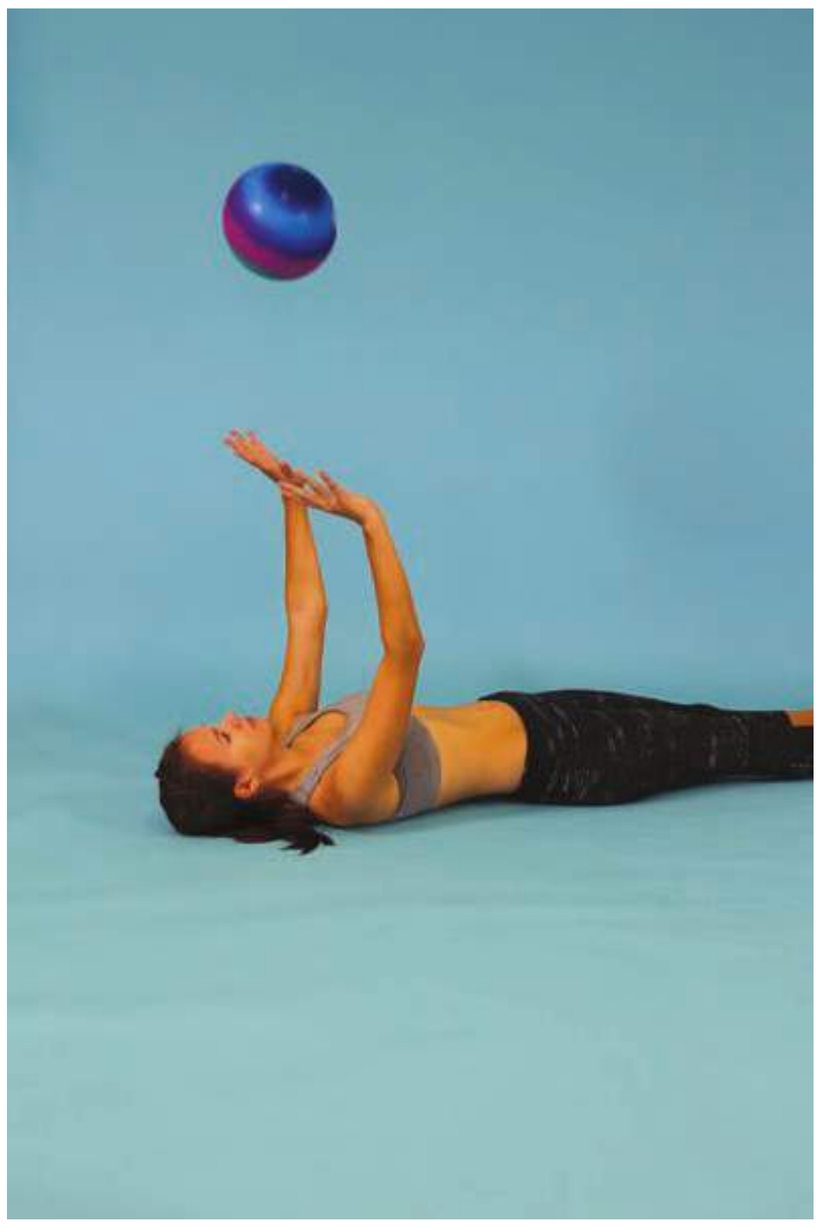

FIGURE 12-105 Medicine ball toss.

and other weighted balls are very effective plyometric devices. The weight of the ball creates a prestretch and an eccentric load when it is caught. This combination creates resistance and demands a powerful agonist contraction to propel it forward again. The exercises can be performed using one arm or both arms at the same time. The former emphasizes trunk rotation and the latter emphasizes trunk extension and flexion, as well as shoulder motion.

A variety of positive changes in athletic performance and neuromuscular function have been attributed to plyometric training, predominantly in the lower extremity:[132]

- Increased maximal vertical jump height.[141]
- Increased leg strength, especially when combined with weight training.[141]
- A faster rate of force development during jumping.[142]
- Delayed onset of muscle fatigue during jumping.[143]
- Correction of neuromuscular imbalances.[144]

Due to the scarcity of research on upper extremity performance plyometric training, the improvements in upper extremity performance remain largely anecdotal. It is also unknown whether patients recovering from injury will respond to plyometric exercise in a manner similar to uninjured subjects.[132]

Based on the concept of postactivation potentiation, complex training may be used to develop power in the athlete by alternating biomechanically similar high load weight training with plyometric exercises, set for set, in the same workout.[145] Based on this concept, the muscle force exerted is increased due to the previous contraction, because the contractile history of a muscle influences the mechanical performance of subsequent muscle contractions.[146] Clinically, this means that while fatiguing muscle contractions impair muscle performance, brief nonfatiguing contractions at high loads enhance muscle performance.[147] There are two proposed mechanisms of postactivation potentiation:[48]

1. Strength training before plyometric exercises causes increased excitation at the spinal cord, resulting in increased postsynaptic potentials and enhanced force generating capacity.[148, 149]
2. The phosphorylation of myosin regulatory light chains renders actin-myosin more sensitive to calcium release from the sarcoplasmic reticulum (see Chapter 1) during subsequent muscle contractions.

An example of using complex training with a lower extremity plyometric exercise would be to have the patient perform a squat followed by a plyometric squat jump. For the upper extremity, the patient can perform a bench press followed by a plyometric push-up.

In addition to complex training, contrast training is another method to enhance power training. Contrast training uses high and low loads in the same training session.[48] The effect is like someone lifting half a gallon of milk when he or she thinks the container is a full. For example, a patient may perform 1–3 repetitions with a load between 80% and 90% of 1 RM, alternating with 3–6 repetitions with a load between 30% and 50% 1 RM performed at maximum speed.[145] The cellular mechanisms behind contrast training are the same as those for complex training.

Functional Muscle Performance

The ultimate goal of any rehabilitation program is to improve function or performance. In the athletic community, safe execution requires multiple components of physical performance, including muscular strength, power, endurance, flexibility, balance, proprioception, speed, agility, and functional movement patterns. The best tested ability to return to sport is one that closely mimics that activity. In the general population, exercise or activities that increase muscle strength or endurance have to be prescribed with functional mobility and stability in mind.

Integration of the Entire Kinematic Chain

At the earliest opportunity, exercises must be introduced that incorporate the entire kinematic chain rather than focusing on an isolated joint. Although force-dependent motor firing patterns should be reestablished, special care must be taken to completely integrate all of the components of the kinetic chain to generate and funnel the proper forces to the appropriate joint. It should be clear that for a kinematic chain to operate efficiently, there must be an optimal sequential activation of the limb segments involved. This then allows for efficient generation and transfer of force along the kinematic chain.[150] When choosing a mode of kinematic exercise, the variables of each type of exercise must be considered. The clinician should understand the principles of exercise application and the differences between open kinematic chain (OKC) and closed kinematic chain (CKC) movements (see Chapter 1) (Table 1-5), in order to accomplish a specific intervention goal (Table 12-12). Although it is commonly believed that all weight-bearing exercises involve some elements of a CKC activity, not all CKC exercises are performed in weight-bearing positions.[151]

A number of studies have illustrated the importance of the sequential activation of these kinetic links.[152, 153] The benefit of closed kinematic chain exercises (CKCEs) over open kinematic chain exercises (OKCEs) is based on the premise that CKCEs, particularly in the lower extremities, appear to replicate functional tasks better than OKCEs. This is because the CKCEs appear to allow the entire linkage system of the kinematic chain to be exercised together.[49,99,154–160] In addition, CKCEs have been shown to enhance joint congruency, decrease the shearing forces, and stimulate the articular mechanoreceptors using axial loading and increased compressive forces.[157,161–165] Thus, CKC activities are purported to help reinforce the synchronization of the necessary muscle-firing patterns for both antagonist and agonist muscle groups used during stabilization and ambulation.[49] However, there also appears to be much in the literature to suggest that OKCEs have a beneficial effect on function,[82,166,167] especially when combined with specific closed-chain exercises or when used to strengthen individual muscles.[154]

A comprehensive rehabilitation program thus should integrate the entire kinematic chain, using a blend of OKCEs and CKCEs. This integration must occur during functional exercises, with the emphasis determined by the activity to be restored. Typically, OKCEs are used initially in non–weight-bearing positions where the forces of gravity can be controlled better. CKCEs can

TABLE 12-12 Differential Features of OKC and CKC Exercises

Exercise Mode	Characteristics	Advantages	Disadvantages
Open kinematic chain	1. Single muscle group 2. Single axis and plane 3. Emphasizes concentric contraction 4. Nonweight bearing	1. Isolated recruitment 2. Simple movement pattern 3. Isolated recruitment 4. Minimal joint compression	1. Limited function 2. Limited function 3. Limited eccentrics 4. Less proprioception and joint stability with increased joint shear forces
Closed kinematic	1. Multiple muscle groups 2. Multiple axes and planes 3. Balance of concentric and eccentric contractions 4. Weight-bearing exercise	1. Functional recruitment 2. Functional movement patterns 3. Functional contractions 4. Increase proprioception and joint stability	1. Difficult to isolate 2. More complex 3. Loss of control of target joint 4. Compressive forces on articular surfaces

Data from Greenfield BH, Tovin BJ. The application of open and closed kinematic chain exercises in rehabilitation of the lower extremity. J Back Musculoskel Rehabil. 1992;2:38–51.

be introduced gradually by controlling the percentage of body weight that is used during the exercise, using a wider base of support (BOS), using a stable support surface, and performing exercises in a uniplanar direction. As the program progresses, more body weight can be used, the BOS becomes narrowed, the support surface becomes more unstable, and exercises are performed in multiplanar directions.

CLINICAL PEARL

The rehabilitation of the kinematic chain should address the strength and flexibility of the entire kinematic chain, using the principle of specificity, with the specific elements of the rehabilitation program being determined by both the existing pathology and the functional goals of the patient.[154,168]

In addition, under the concept of specificity, rather than isolating OKCEs or CKCEs, it may be wise to emphasize functional positioning during the exercise training, while striking a balance between mobility and stability.[154,169]

Several objectives must be met if the rehabilitation of the functional kinematic chain is to be comprehensive:[154]

1. The first objective of the rehabilitation program, the healing phase, is the restoration of functional stability, which is the ability to control the translation of the joint during dynamic functional activities, through the integration of both the primary and the secondary stabilizers.[170]
2. The second objective, the functional phase, is to restore sports- or functional-specific movement patterns. The functional phase begins once the patient has near-full, pain-free range of motion.
3. The final objective is assessing the readiness of the patient to return to his or her prior level of function or level of athletic performance.

Increasing Dynamic Stabilization

A key component of functional activity and athletic performance is controlled stability, a blend of power and balance. Balance and stability can improve with strength and power, and balance training without resistance can improve proprioception.[171, 172] Instability resistance training (IRT) is used to improve both static and dynamic stabilization. Since most CKCEs are performed in weight-bearing positions, they help to facilitate coactivation of agonists and antagonists thereby promoting dynamic stability. Thus, stabilization and balance exercises should be introduced to the rehabilitation program as early as feasible (see Chapter 14). There are two components to IRT:[171]

1. Progressive challenges to balance
2. The addition of load or resistance

According to Voight,[173, 174] once the patient has mastered the progressions outlined in Chapter 14, the following progressions operatic and dynamic exercises can be used as appropriate:

- Static stabilization exercises with closed-chain loading and unloading (weight shifting). This phase initially employs isometric exercises around the involved joint on solid and even surfaces, before progressing to unstable surfaces. The early training involves balance training and joint repositioning exercises, and is usually initiated (in the lower extremities according to weight-bearing restrictions) by having the patient placing the involved extremity on a 6–8-in stool, so that the amount of weight bearing can be controlled more easily. The proprioceptive awareness of a joint can also be enhanced by using an elastic bandage, orthotic, or through taping.[175–180] As full weight bearing through the extremity is restored, a number of devices such as a mini-trampoline, balance board, stability ball, and wobble board can be introduced. Exercises on these devices are progressed from double limb support, to single-leg support, to support while performing sports-specific skills.

CLINICAL PEARL

One of the advantages of using the stability ball is that it creates an unstable base, which challenges the postural stabilizer muscles more than using a stable base. It is important to choose the correct and appropriate size of stability ball, which is dependent upon patient size.

45 cm ball: shorter than 5'
55 cm ball: 5'to 5'8"
65 cm ball: 5'9"to 6'3"
75 cm ball: taller than 6'3"

With the patient sitting on the ball with both feet firmly planted on the ground, the patient's thigh should be parallel to the floor (the knee may be slightly above the hips).

- Pumping up the ball to increase firmness increases the level of difficulty in any given exercise.
- The further away the ball is from the support points, the greater the demand for core stability.
- Decreasing the number of support points increases the difficulty of the exercise.

- Transitional stabilization exercises. The exercises during this phase involve conscious control of motion without impact and replace isometric activity with controlled concentric and eccentric exercises throughout a progressively larger range of functional motion. The physiological rationale behind the exercises in this phase is to stimulate dynamic postural responses and to increase muscle stiffness. Muscle stiffness (see Chapter 2) has a significant role in improving dynamic stabilization around the joint, by resisting and absorbing joint loads. [181]
- Dynamic stabilization exercises. A delicate balance between stability and mobility is achieved by coordination between muscle strength, endurance, flexibility, and neuromuscular control.[182] Such exercises involve the unconscious control and loading of the joint and introduce both ballistic and impact exercises to the appropriate patient. The exercises can involve unstable conditions with body mass or external loads (e.g., dumbbells, water exercises) as resistance, unstable surfaces (e.g., Swiss/stability ball, foam rollers, wobble boards, and suspended chains), uneven natural surfaces (e.g., sand and gravel), and reducing the BOS using unilateral stance (e.g., one-legged squats). In addition, the use of unilateral resistance exercises, where one side of the body exercises while the other half stabilizes, can provide a disruptive torque thereby enhancing the instability challenge. For example, greater erector spinae activation occurs during a unilateral shoulder press and increased abdominal activity with the unilateral chest press.[183] In addition, crossover fatigue can occur from a unilateral exercise in the contralateral limb, and by training unilaterally, the ipsilateral and contralateral limbs received normal stimulation while activating the core muscles.[184, 185]

Most of the following exercises require advanced strength and power and should therefore only be used with the very athletic patient.

- Seated push-ups on an unstable surface.
- Weight shifting on an unstable surface while in a kneeling position (Fig. 12-106).
- Weight shifting on a Swiss ball with the feet on the floor, and the patient reaching in various directions (Fig. 12-107). The exercise can be made more difficult by raising the height of elevation of the feet, such as placing the feet on a chair.
- Prone push-up with legs elevated.
- Arm step ups with a push-up.

FIGURE 12-106 Weight shifting on an unstable surface while in a kneeling position.

- Plyometric exercises. T e can include squat jumps, bounding, four quadrant jumps, tuck jumps, lunge jumps, zigzag hopping, and multiple platform jumping and hopping.

Functional Performance Tests

Functional performance testing can provide quantitative and qualitative information on specialized movements in sport, exercise, and occupations.[186] T e test chosen must be appropriate for the individual's condition, stage of injury, and abilities. In general, approximately 12 to 16 weeks is needed to following soft-tissue repairs before aggressive loading can be attempted to injured shoulders or knees.[187] In addition, the most fatiguing (aerobic) portion of the test should be performed last, with the most explosive tests being performed first, as aerobic, or endurance exercises decrease isotonic and isokinetic muscle performance.[186,188] Functional performance tests have been devised based on body areas as follows:[189]

- *Trunk.* A balance between the anterior, posterior, and lateral local and global trunk muscles is necessary to maintain neutral spine alignment necessary for dynamic stability (see Chapter 28).[190] T e following two tests are recommended:
  - Backward medicine ball throw. T e patient is positioned holding a medicine ball with the arms in front of the body (Fig. 12-108A). Following a counter movement, the patient extends forcefully backward to throw the ball over the shoulder (Fig. 12-108B).
  - Sidearm medicine ball throw. T e patient is positioned sideways to the throwing direction in a crouched position, with the hips and knees flexed while holding a medicine ball with the arms straight. T e medicine ball is held on the lateral aspect of the knee which is furthest away from the throwing line (Fig. 12-109). T e patient

FIGURE 12-109 Sidearm medicine ball throw—start position.

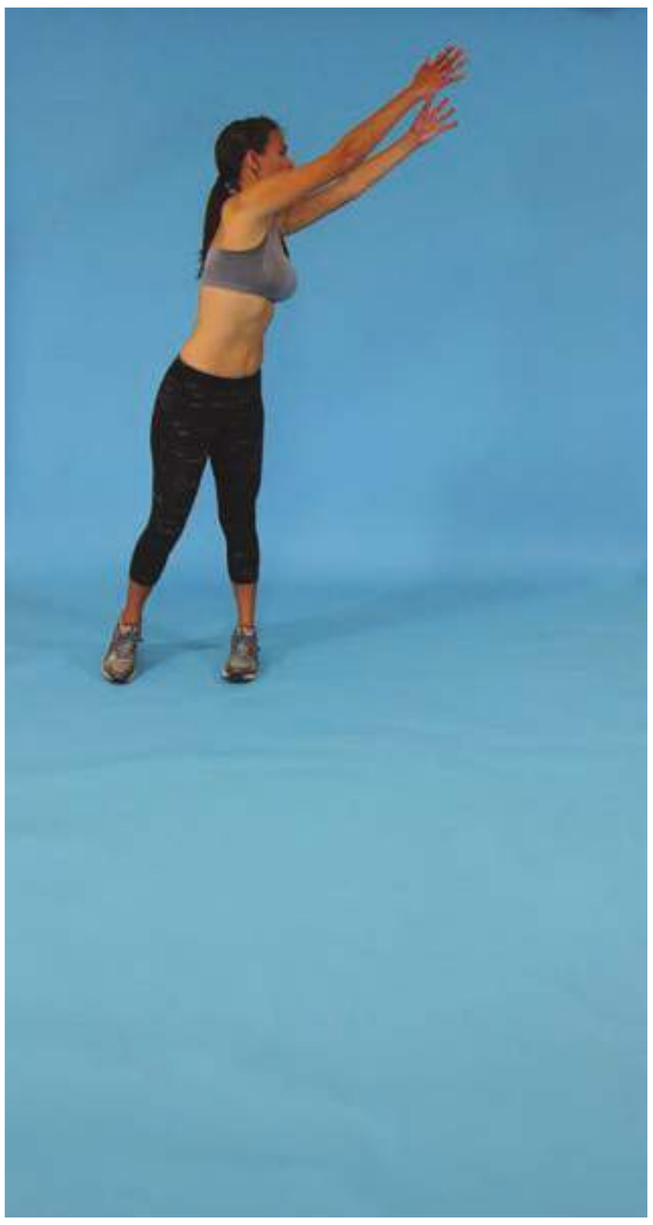

FIGURE 12-110 Sidearm medicine ball throw—end position.

is then instructed to swing the medicine ball across the body and to throw it as far as possible (Fig. 12-110).

- Lower extremity. These tests are designed to assess the ability of the lower extremities to produce velocity.
  - Vertical jump. The vertical jump test can assess overall lower extremity power, bilaterally or unilaterally.

FIGURE 12-111 Standing long jump.

FIGURE 12-112 Single-leg hop.

The test can be done with a piece of chalk and a wall, or using the Vertec Vertical Jump System (Senoh, Columbus, Ohio). The patient is positioned in standing with equal weight placed on both lower extremities and reaching as high as possible with a single arm. The patient is then asked to jump as high as possible, and the height achieved by the reaching hand is recorded.

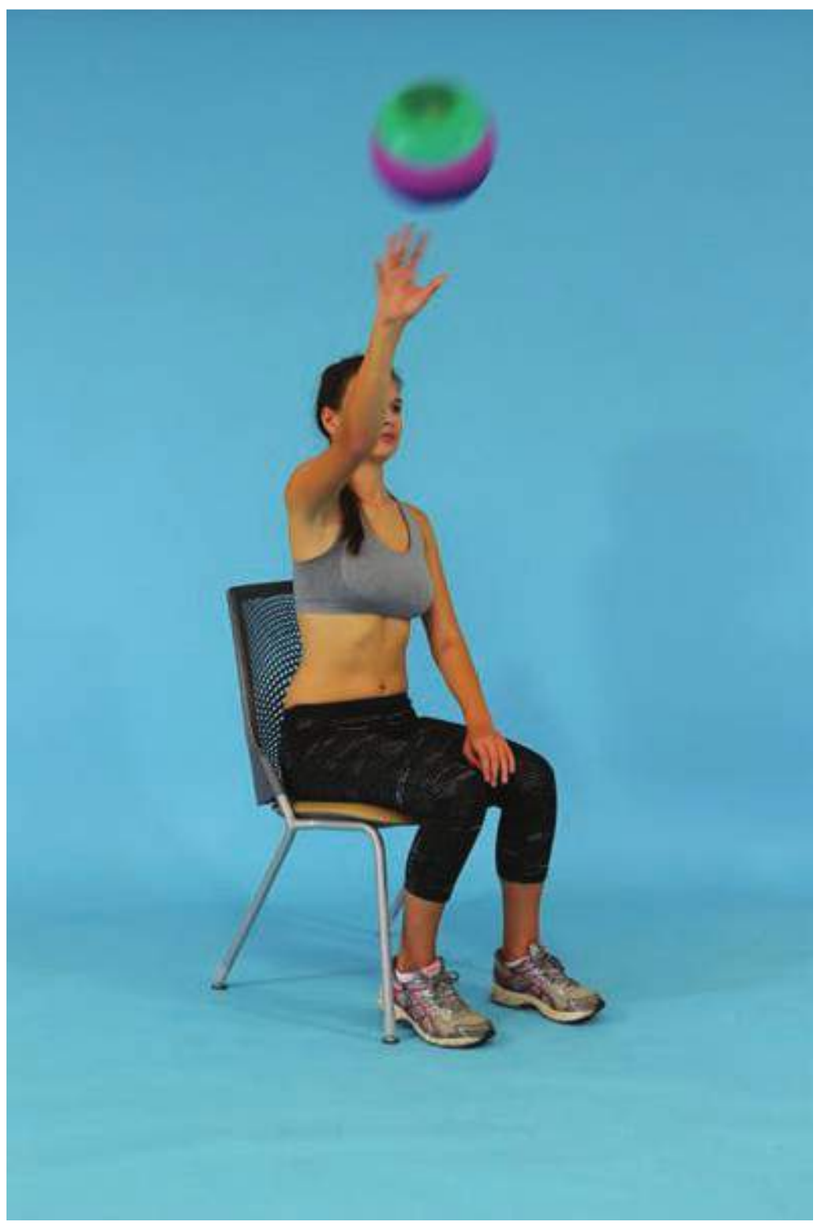

FIGURE 12-113 Seated shot-put throw.

- Standing long jump. The patient stands in front of a line and is asked to jump and land on both feet as far forward as possible (Fig. 12-111).
- Single-leg hop. The patient stands in front of a line on one leg and is asked to hop forward as far as possible (Fig. 12-112). The score is the distance from the start line to the location of the posterior heel on the landing leg.

- Upper extremity. This test is designed to isolate the upper extremities thereby preventing any contributions from the trunk or lower extremities.
- Seated shot-put throw. The patient is positioned in sitting, holding a medicine ball, with his or her back against the wall (Fig. 12-113). The patient is then asked to throw the medicine ball, using both arms, as far as possible.

CHAPTER 13 Improving Mobility

CHAPTER OBJECTIVES

At the completion of this chapter, the reader will be able to:

1. Describe the three components of mobility and their differences.
2. Describe the two different types of flexibility.
3. Perform a goniometric assessment of each joint.
4. Describe strategies to increase range of motion (ROM) using different techniques.
5. Describe the indications and contraindications for the various types of ROM exercises.
6. Define active insuf ciency and passive insuf ciency of a muscle.
7. Outline the indications and contraindications for continuous passive motion (CPM).
8. Define flexibility and describe its importance in rehabilitation.
9. Explain the differences between the various stretching techniques.
10. Describe strategies to increase flexibility using different techniques.

OVERVIEW

Normal mobility is necessary for ef cient movement. T e terms range of motion (ROM), flexibility, and accessory joint motion are often listed as components of mobility.

- ROM refers to the distance and direction a joint can move. T e direction in which a joint moves is described using terms like flexion, extension, abduction, adduction, internal rotation, and external rotation. Each specific joint has a normal ROM that is expressed in degrees. Within the field of physical therapy, goniometry is commonly used to measure the total amount of available motion at a specific joint. ROM of a joint may be limited by the shape of the articulating surfaces, adaptive shortening of the muscles, and capsular and ligamentous structures surrounding that joint. Under normal circumstances, it is the muscles that move the joints. T e full range of extensibility of a muscle is called its functional excursion. T e amount of excursion depends on the arrangement of the muscle fibers and whether the muscle is a one-joint or a multi-joint muscle (see later).
- Flexibility refers to the passive extensibility of connective tissue that provides the ability for a joint or series of joints to move through a full, nonrestricted, injury-free, and pain-free ROM. Flexibility is also dependent upon pain levels and neuromuscular control. Magnusson[1] identified three factors that might contribute to improving flexibility: passive tissue properties, segmental reflex excitability, and tolerance of discomfort. When an injury occurs, there is almost always some associated loss of the ability to move normally due to the pain, swelling, muscle guarding, or spasm. T e subsequent inactivity results in a shortening of connective tissue and muscle, loss of neuromuscular control, or a combination of these factors.[2]
- Accessory joint motion. Accessory joint motion is the amount of the arthrokinematic glide that occurs at the joint surfaces, termed joint play (see Chapter 1). A number of anatomic factors can limit the ability of a joint to move through a full, unrestricted ROM, including the integrity of the joint surfaces, increasing age, and the mobility and pliability of the soft tissues that surround a joint. Before attempting to improve the arthrokinematic glide at a particular joint, the clinician must always consider the status of the neighboring joints in terms of their hypermobility or hypomobility (see Chapter 2). Joint mobilization is a technique that preserves or increases arthrokinematic motion. Techniques to enhance joint motion are described in Chapter 10.

A decrease in accessory joint motion, ROM and/or in the flexibility of one joint can affect the mobility of the kinetic chain. For example, a decreased ROM or flexibility in the shoulder can impact the mobility of the entire arm. In order to provide treatment for a loss of mobility, the clinician must make the determination as to the specific cause, that is, loss of joint motion, ROM, or decreased flexibility. For example, is the specific cause due to joint effusion, adaptive shortening of connective tissue structures, a change in bony architecture,

or malalignment of the articular surfaces? Attempting to perform ROM and flexibility techniques in the absence of normal arthrokinematic motion at the joint surface will not result in an improvement in the impaired mobility, but may instead increase the patient's symptoms.

Flexibility

Flexibility is the ability to move a single joint or series of joints through an unrestricted and pain-free ROM. Flexibility depends on sound joint arthrokinematics, full ROM (normal osteokinematics), and soft-tissue extensibility. It also depends on the mechanical and neurophysiological properties of the tissues involved and how those tissues react to physical loading (see Chapters 1 and 2). Stretching techniques are designed to improve the extensibility of both contractile and noncontractile tissues, including neural tissues (see Chapter 11). Indications for stretching include those scenarios when ROM is limited due to a loss of extensibility in the soft tissues because of scar tissue formation, adhesions, and contractures that have resulted in functional limitations or participation restrictions. Contraindications for stretching include a bony end feel, an incomplete bony union, recent fracture, acute inflammatory or infectious process, sharp pain with joint movement, or in the presence of hypermobility.

CLINICAL PEARL

It is widely believed that stretching enhances athletic performance. However, a number of studies[3,4] have indicated that acute stretching either has no effect or decreases, rather than enhances, muscle performance immediately following the stretching session. In addition, acute stretching has been shown to have no benefit on the performance of activities that require strength, such as jumping or sprinting.[5] In contrast, when stretching is performed as part of a regular and comprehensive conditioning program for a number of weeks, beneficial effects on physical performance have been reported.[3,6]

When referring to flexibility, two types are recognized, static and dynamic.

- Static flexibility. Static flexibility, also referred to as passive mobility, is defined as the range or motion available to a joint or series of joints.[7,8] Increased static flexibility should not be confused with joint hypermobility, or laxity, which is a function of the joint capsule and ligaments. Decreased static flexibility indicates a loss of motion. T e end-feel encountered may help the clinician differentiate the cause among adaptive shortening of the muscle (muscle stretch), a tight joint capsule (capsular), and an arthritic joint (hard). Static flexibility can be measured by a number of tests, such as the toe touch and the sit and reach, both of which have been found to be valid and reliable.[9,10]
- Dynamic flexibility. Dynamic flexibility also referred to as active mobility, refers to the ease of movement within the obtainable ROM. Dynamic flexibility is measured actively. T e important measurement in dynamic flexibility is stiffness, a mechanical term defined as the resistance of a structure to deformation.[11,12] An increase in ROM around a joint does not necessarily equate to a decrease in the passive stiffness of a muscle.[13–15] However, strength training, immobilization, and aging have been shown to increase stiffness.[16–19] T e converse of stiffness is pliability. When soft tissue demonstrates a decrease in pliability, it has usually undergone an adaptive shortening, or an increase in tone, termed hypertonus. T ere is growing research to suggest that the limiting factors in preventing increases in ROM are not only the connective tissues but are also the result of neurophysiological phenomena controlled by the higher centers of the CNS.[20]

In addition to those already mentioned, a number of other factors influence connective tissue deformation:

- Sensory receptors. Two sensory receptors that monitor muscle activity, the muscle spindle, and Golgi tendon organs (GTOs) (see Chapter 3), play an important role when attempting to increase flexibility through stretching. T ese two receptors can activate both spinal reflexes and long-loop pathways involving supraspinal centers. When a muscle is stretched, both the muscle spindles and the GTOs immediately begin sending a stream of sensory impulses to the spinal cord. Initially, impulses coming from the muscle spindles notify the CNS that the muscle is being stretched. Impulses return to the muscle from the spinal cord, causing the muscle to reflexively contract, thus resisting the stretch.[2] T e GTOs respond to the change in length and the increasing tension by firing off sensory impulses of their own to the spinal cord and, if the stretch of the muscle continues for an extended period of time (at least 6 seconds), impulses from the GTOs begin to override muscle spindle impulses and cause a reflex relaxation of the antagonist muscle (autogenic inhibition).[2]

CLINICAL PEARL

In any synergistic muscle group, a contraction of the agonist causes a reflex relaxation of the antagonist muscle, allowing it to stretch and protecting it from injury—this phenomenon is referred to as autogenic inhibition.[2]

- Tissue temperature. At temperatures above 37°C (98.6°F), the cross-links between collagen fibrils are broken more easily and more rapidly, with the most profound changes occurring between 40 and 45°C (104–113°F).[21,22] A number of key points must be remembered by the clinician in order to effectively manipulate temperature:[23]
  - T e amount of force required to attain/maintain a desired deformation decreases as temperature increases.
  - T e time required to deform collagen to the point of failure is inversely related to temperature.
  - T e higher the temperature, the greater the load collagen is able to tolerate before failure.
  - T e higher the temperature, the greater the amount of deformation possible before failure.

It is important to make a distinction between stretching and warm-up as the two are not synonymous but are often

confused by the layman. While stretching places neuromusculotendinous units and their fascia under tension, a warm-up requires the performance of an activity that raises total body and muscle temperatures to prepare the body for exercise.[24] Research has shown that warm-up prior to stretching results in significant changes in joint ROM.[25] Anecdotally, it would make sense not to perform stretching at the beginning of the warm-up routine because the tissue temperatures are too low for optimal muscle–tendon function, and are less compliant and less prepared for activity. Some advocate stretching after an exercise session, citing that the increased musculotendinous extensibility leads to the potential for improved joint flexibility.[26] In one study, static stretching was done before, after, and both before and after each workout. All produced significant increases in ROM.[27]

- The amount of force used. Viscoelastic changes are not permanent, whereas plasticity changes, which are more difficult to achieve, result in a residual or permanent change in length. The key factor for any change in connective tissue length is the deforming force, in particular, the magnitude and velocity applied. The application of low-load, long duration forces is recommended, although a muscle may require a greater stretching force initially, possibly to break up adhesions or cross-linkages, and to allow for viscoelastic and plastic changes to occur in the collagen and elastin fibers.[28]
- The direction of the stretch. To stretch a muscle appropriately, the stretch must be applied parallel to the muscle fibers. The orientation of the fibers can be determined by palpation. Typically, in the extremities, the muscle fibers run parallel to the bone.
- The duration and frequency of the stretch. The duration refers to how long the clinician applies the stretching force. The frequency refers to the number of times or repetitions the stretch is performed. There continues to remain a lack of agreement on the ideal combination of either the duration of a single stretch or the number of repetitions of a stretch in a single session that is necessary to achieve the best results. Researchers have reported that techniques utilizing cyclic and sustained stretching for 15 minutes on 5 consecutive days increased hamstring muscle length and that a significant percentage of the increased length was retained 1 week posttreatment.[29] Other researchers have reported that after using four consecutive knee flexor static stretches of 30 seconds, the new knee ROM was maintained for 3 minutes but had returned to prestretch levels after 6 minutes.[30] A similar study using a sequence of five modified hold–relax stretches reported producing significantly increased hamstring flexibility that lasted 6 minutes after the stretching protocol ended.[31] Frequent stretching ensures that the lengthening is maintained before the muscle has the opportunity to recoil to its shortened state.[32] Frequency of stretching needs to occur at a minimum of two times per week.[33,34] In contrast, it has been determined that 80% of the length changes occur in the first four stretches of 30 seconds each.[26] It is important for the clinician to remember that any gains in flexibility and ROM achieved from a stretching program are only temporary.[35] Thus, it is important to integrate functional activities such as reaching, bending, squatting, twisting, and pushing into the patient's exercise program that utilize the regained range on a regular basis.
- The speed of the stretch. Two common stretching techniques, static and ballistic, use different speed parameters. The static stretch allows for a steady speed to allow lengthening of the entire myotendinous unit, and a hold or delay at the end of the available motion.[36] The ballistic stretch uses various speeds of singular or repetitive bouncing at the end of motion to stretch a particular muscle. The muscle is stretched by the momentum created from the bouncing movements supplying the tensile force used for the stretch.[26] The patient quickly relaxes the muscle when reaching the end of ROM. This is performed in a cyclical bouncing motion and repeated several times, thus engaging a neurological component called active resistance—the contraction of muscles that resist elongation in the form of muscle reflex activity.[26,37] In comparisons of the ballistic and static methods, two studies[38,39] have found that both produce similar improvements in flexibility. However, the ballistic method appears to cause more residual muscle soreness or muscle strain, than those techniques that incorporate relaxation into the technique and are therefore not appropriate for elderly or sedentary individuals.[39,40] Instead, the application of any stretch should be applied and released gradually to minimize muscle activation and injury to tissues.
- Positioning and stabilization of the structure being stretched. As described in Chapter 10, when performing any manual technique, correct positioning of the patient is essential both to help the patient relax and to ensure safe body mechanics from the clinician. For example, when stretching the hip musculature, it is important to protect the lumbar spine by maintaining it in a neutral position. When patients feel relaxed, their muscle activity is decreased, reducing the amount of resistance encountered during the technique. Accurate hand placement is essential for efficient stabilization and for the accurate transmission of force. The clinician can stabilize either the proximal or distal attachment site of the muscle tendon unit being stretched, although it is more common to stabilize the proximal attachment and move the distal segment.
- The type of stretch. The type of stretch refers to the method by which the stretch is imparted. Stretching can be applied manually or mechanically.

A variety of stretching techniques can be used to increase the extensibility of the soft tissues.

Static Stretching

Static stretching involves the application of a steady force for a sustained period. The stretch should be performed at the point just shy of the pain, although some discomfort may be necessary to achieve results.[28] Small loads applied for long periods produce greater residual lengthening than heavy loads applied for short periods.[41] Restoration of the normal length of the muscles may be accomplished using the guidelines outlined in

TABLE 13-1 Static Stretching Guidelines

- Heat should be applied to increase intramuscular temperature prior to, and during, stretching.[a–d] This heat can be achieved with either through low-intensity warm-up exercise, or through the use of thermal modalities. The application of a cold pack following the stretch is used to take advantage of the thermal characteristics of connective tissue, by lowering its temperature and thereby theoretically prolonging the length changes—the elasticity of a muscle diminishes with cooling.[a–d]
- Effective stretching, in the early phase, should be performed every hour, but with each session lasting only a few minutes.
- With true muscle shortness, stronger resistance is used to activate the maximum number of motor units, followed by vigorous stretching of the muscle.
- Stretching should be performed at least two times a week using:
  - Low force, avoiding pain
  - Prolonged duration
  - Rapid cooling of the muscle while it is maintained in the stretched position

Table 13-1. Weighted traction or pulley systems may be used for this type of stretching. It is important for the patient to realize that the initial session of stretching may increase symptoms.[42] However, this increase in symptoms should be temporary, lasting for a couple of hours, at most.[32,43]

Dynamic Stretching

Dynamic stretching involves stretching by a muscular contraction to increase or decrease the joint angle where the muscle crosses, thereby elongating the musculotendinous unit as the end ROM is obtained[26] Dynamic stretching is a specific warm-up using activity-specific movements to prepare the muscles by taking them through the movements used in a particular sport.[26] Dynamic stretching does not incorporate end-range ballistic movements, as in ballistic stretching, but rather the use of controlled movements through a normal ROM.[26]

There is some debate as to whether the static or dynamic method is better to stretch a muscle. Static stretching is considered the gold standard in flexibility training.[44] However, recent studies have found that static stretching is not an effective way to reduce injury rates,[45,46] and may actually inhibit athletic performance.[6] This is likely because the nature of static stretching is passive and does nothing to warm a muscle.[47] More dynamic methods of stretching involve either a contraction of the antagonist muscle group, thus allowing the agonist to elongate naturally in a relaxed state, or eccentrically training a muscle through its full ROM.[44] The latter method would appear to address the problem that most injuries occur during the eccentric phase of activity.[45] A study by Nelson[44] that compared the immediate effect of static stretching, eccentric training, and no stretching/training on hamstring flexibility in high school and college athletes (75 subjects) found the flexibility gains in the eccentric training group to be significantly greater than the static stretch group.

Neurophysiologic Stretching

This type of stretching refers to the use of techniques that rely on the neurophysiological changes that occur in contractile tissues. The goal of these techniques is to reduce the sensory-motor feedback and thereby increase relaxation. Such techniques include proprioceptive neuromuscular facilitation (PNF) and muscle energy (see Chapter 10). The majority of studies have shown the PNF techniques to be the most effective for increasing ROM through muscle lengthening when compared to the static or slow sustained, and the ballistic or bounce techniques,[48–58] although one study found it to be not necessarily better.[59]

The PNF techniques of contract–relax (CR), hold–relax (HR), an agonist contraction (AC), or a hold–relax–agonist contraction sequence (HR–AC) can be used to actively stretch the soft tissues:[2]

- CR and HR. HR and CR stretching techniques begin as per the static stretching techniques in that the clinician supports the patient and brings a limb (and the targeted muscle to be stretched) to the end of ROM until gentle stretching is felt. At that point, the clinician asks the patient to provide a prestretch, end range, isometric contraction of the muscle being stretched for approximately 5 seconds after which the patient is asked to relax the muscle. The clinician then moves the limb passively into the new range until a limitation is again felt and repeats the procedure two to four times. The only difference between the HR technique and the CR technique is that in the former technique the prestretch isometric contraction occurs in all muscles of the diagonal pattern, whereas in the latter technique the rotators of the limb contract concentrically while all of the muscle groups of the diagonal pattern contracts isometrically during the prestretch phase of the procedure.[60]
- AC. AC stretching uses the principle of reciprocal inhibition, and the term agonist refers to the muscles opposite the range limiting target muscle, which can be confusing. The clinician moves the limb to the position of gentle stretch and asks the patient for a contraction of the muscle opposite the muscle being stretched (the antagonist) for about 5 seconds, and for the patient to hold the end range position for another 5 seconds. For example, when stretching the hamstring muscles, a simultaneous contraction of the quadriceps muscles can facilitate the stretch of the hamstrings. The technique is repeated two to four times.
- HR–AC. This technique, also referred to as the CR–AC or slow reversal HR technique, combines the HR and AC procedures. The clinician takes the limb to the point of gentle stretch and performs a CR sequence (i.e., resistance applied against the muscle being stretched). After contracting the muscle being stretched, the patient is asked to relax this muscle while contracting the opposing muscle group (antagonist), thus facilitating the stretch. For example, when stretching the hamstring muscles,

the hamstrings are brought to a stretched position, the hamstrings are then contracted against resistance, and then relaxed, and then the quadriceps are contracted. Each contraction is held for approximately 5 seconds, and the technique is repeated two to four times.

Other techniques that can assist in lengthening of contractile tissue through relaxation include the following:

- T e application of heat, which increases the extensibility of the shortened tissues, will allow the muscles to relax in length and more easily, reducing the discomfort of stretching. Heat without stretching has little or no effect on long-term improvement in muscle flexibility, whereas the combination of heat and stretching produces greater long-term gains in tissue length than stretching alone.
- Massage and other soft-tissue techniques (see Chapter 10), which increase local circulation to the muscle and reduce muscle spasm and stiffness.
- Biofeedback, which teaches the patient to reduce the amount of tension in a muscle.
- Relaxation training.

Following each stretching session, the stretched tissues must be allowed to cool in a lengthened position. T is can be facilitated by using cold packs. Once gains in motion have been achieved, it is important for the patient to gain neuromuscular control of the agonists in the new range. T is can be accomplished with low load resistance exercises throughout the newly acquired range. For example, after having stretched the hamstrings to reduce a knee flexion contracture, the patient is encouraged to activate the quadriceps in the new range. Once the ROM approaches what is normal for the patient, the muscles that were shortened and then stretched must also be strengthened.

Range of Motion

Any given muscle, crossing a single joint, is normally capable of shortening suf ciently to permit a full ROM at that joint. T e functional excursion of a one-joint muscle is limited by the ROM at the joint it crosses. For example, the hip abductors are limited by the range available at the hip joint. For two-joint or multi-joint muscles, the functional excursion goes beyond the limits of any one joint that they cross. For example, the sartorius muscle can flex, abduct, and externally rotate the hip as well as being able to flex the knee. T e absolute amount by which any muscle can shorten depends on:

1. T e length of, and arrangement of, the fibers
2. Structure and design of the joint.
3. T e number of joints traversed.
4. Resistance of antagonist muscle or muscles
5. T e presence of any load that opposes the muscle.

If a muscle that crosses two or more joints produces simultaneous movement at all of the joints that it crosses, it soon reaches a length at which it can no longer generate a functional amount of tension. T is is referred to as active insufficiency (e.g., attempting to achieve maximal hip flexion with the knee fully extended). In contrast, when the full ROM at any joint, or joints, that the muscle crosses is limited by the muscle's own length, it is referred to as passive insuf ciency (e.g., attempting to fully extend the elbow, while simultaneously pronating the forearm and extending the shoulder places the brachialis muscle in a position of passive insuf ciency).

From a rehabilitation viewpoint, to maintain or improve the amount of ROM at a joint or kinematic chain, each joint must be moved through its available ROM at regular intervals. Continuous immobilization of skeletal muscle tissues can cause some undesirable consequences, including weakness or atrophy of the muscles.[61] Muscle atrophy is an imbalance between protein synthesis and degradation. After modest trauma, there is a decrease in whole-body protein synthesis[62] rather than increased breakdown. With more severe trauma, major surgery, or multiple organ failures, both synthesis and degradation increase, the latter being more enhanced.[63,64]

When referring to ROM techniques used in rehabilitation, three major movements are recognized:[2]

- Passive range of motion (PROM). PROM refers to the degree to which a joint can be passively moved to the endpoint in the ROM. PROM exercises are performed by the clinician, family member, caregiver without any muscular activation by the patient. In some cases, the patient is able to perform PROM on one part of their body using another part (using the left arm to flex the right elbow). In addition, pulleys, continuous passive motion (CPM) devices, or various household objects, such as a counter or chair, can be used to assist in the performance of PROM. PROM is indicated when the patient's own muscle force is inadequate to produce suf cient motion at a joint, when active contraction of the muscle would be harmful, or as a means of educating a patient about a particular movement. PROM is contraindicated during any stage of tissue healing in which motion could prevent or inhibit tissue repair, in the presence of muscle guarding, or in the presence of increasing pain. Factors that can limit PROM about a joint include the joint capsule, periarticular connective tissue, adaptive shortening of the musculotendinous unit, bone on bone approximation, loose bodies, pain, and scarring of the overlying skin. If overpressure is applied at the end of the available PROM, a stretching force is imparted, and the clinician can determine the end feel. Patient handling and positioning are critical to allow the patient to relax during treatment by decreasing apprehension. For example, adequate stabilization and the use of a smooth and steady pace. Although PROM is important to enhance vascular dynamic and synovial diffusion, maintain joint motion, ROM, and flexibility, it does not prevent muscle atrophy, increase strength or endurance, or assist circulation to the same extent that active, voluntary muscle contraction does.

CLINICAL PEARL

The use of a CPM device has been promoted as a means to facilitate a more rapid recovery by improving ROM, decreasing the length of hospital stay, and lowering the amount of narcotic use. However, studies have shown that

the effect of CPM devices on analgesia consumption, ROM, hospital stay, and complications has been variable:

- Data support the use of CPM to decrease the rate of manipulation for poor ROM after total knee arthroplasty (TKA). Although it appears that the use of a CPM device does help regain knee flexion quicker post TKA, it is not as effective in the enhancement of knee extension.
- Knee impairment or disability is not reduced with the use of a CPM at discharge from the hospital.
- Because of standardized inpatient hospital clinical pathways, the length of hospital stay is not decreased by the use of a CPM device but, depending on the hospital involved, the overall cost is not increased.
- Wound complications probably are not increased with the use of CPM, provided good technique is used in wound closure.

- Active-assisted range of motion (AAROM). AAROM occurs when ROM of the joint occurs actively but where the effect of gravity has been removed or when manual assistance is necessary to complete the motion due to weakness resulting from trauma, pain, neurologic injury, or postsurgical recovery. AAROM involves some muscle activation and is advocated when some muscle activation through the ROM is permitted or desired. For example, performing shoulder abduction while lying supine, which uses the bed surface for support. The amount of assistance needed varies from minimal or no assistance in some ranges to maximal assistance in other parts of the range. AAROM is important to enhance vascular dynamic and synovial diffusion, maintain joint motion, ROM, and flexibility, and may help prevent muscle atrophy.
- Active range of motion (AROM). AROM refers to the degree to which a joint can be moved by a muscle contraction, usually through the mid-range of movement. AROM exercises are typically used following any passive technique to reinforce proper movement or as part of a warm-up routine. AROM is indicated when the patient is able to perform a movement safely, effectively, and with minimum pain. AROM is contraindicated in the acute stage of healing (12–48 hours after the trauma) or in the presence of any adverse response to the motion (pain that persists more than 2 hours after the activity, an undesired cardiopulmonary response, or an increase in effusion/information). AROM does not maintain or increase strength or develop skill or coordination except in the movement patterns used.

CLINICAL PEARL

In the early stages of the rehabilitation process, ROM exercises are performed in the following sequence: Passive ROM → AAROM → AROM. It is important to remember when making the transition from PROM to AAROM or AROM, that gravity has a significant impact especially in individuals with weak musculature. These individuals may require assistance when the segment moves up against gravity, or moves downward, with gravity.

Goniometry

The term goniometry is derived from two Greek words, gonia meaning angle and metron, meaning measure. Thus, a goniometer is an instrument used to measure angles. Within the field of physical therapy, a goniometer is used to measure the total amount of available motion at a specific joint. Goniometry can be used to measure both active and passive ROM, PROM, AAROM, and AROM.

Goniometers are produced in a variety of sizes and shapes and are usually constructed of either plastic or metal (Fig. 13-1). The two most common types of instruments used to measure joint angles are the bubble inclinometer and the traditional goniometer.

FIGURE 13-1 The various types of goniometers.

FIGURE 13-2 Bubble goniometer.

FIGURE 13-3 Extendable goniometer.

- Bubble goniometer (Fig. 13-2). The bubble goniometer, which has a 360-degree rotating dial and scale with fluid indicator can be used for flexion and extension; abduction and adduction; and rotation of the neck, shoulder, elbow, wrist, hip, knee, ankle, and the spine.
- Traditional goniometer. The traditional goniometer, which can be used for flexion and extension; abduction and adduction; and rotation of the shoulder, elbow, wrist, hip, knee, and ankle, consists of three parts:
  - A body. The body of the goniometer is designed like a protractor and may form a full or half circle. A measuring scale is located on the body. The scale can extend either from 0 to 180 degrees and 180 to 0 degrees for the half circle models or from 0 to 360 degrees and from 360 to 0 degrees on the full circle models. The intervals on the scales can vary from 1 to 10 degrees.
  - A stationary arm. The stationary arm is structurally a part of the body and, therefore, cannot move independently of the body.
  - A moving arm. The moving arm is attached to the fulcrum in the center of the body by a rivet or screw-like device that allows the moving arm to move freely on the body of the device. In some instruments, the screw-like device can be tightened to fix the moving arm in a certain position or loosened to permit free movement. The length of the stationary and moving arms varies among instruments (Fig. 13-1). Extendable goniometers (Fig. 13-3) allow varying ranges in arm length from 9½ to 26 in.

The correct selection of which goniometer device to use depends on the joint angle to be measured. The longer-armed goniometer, or the bubble inclinometer, are recommended when the landmarks are further apart, such as when measuring spine, hip, knee, elbow, and shoulder movements. In the smaller joints, such as the wrist and hand and foot and ankle, a traditional goniometer with a shorter arm is used.

The general procedure for measuring ROM involves the following:

1. The patient is positioned in the recommended test position and should be correctly draped. While stabilizing the proximal joint component, the clinician gently moves the distal joint component through the available ROM until the end feel is determined (see Chapter 4). An estimate is made of the available ROM, and the distal joint component is returned to the starting position.
2. The clinician palpates the relevant bony landmarks and aligns the goniometer.
3. A record is made of the starting measurement. The goniometer is then removed, and the joint is moved through the available ROM. Once the joint has been moved through the available ROM, the goniometer is replaced and realigned, and a measurement is read and recorded.

The standard testing procedures for each of the upper and lower extremity joints are outlined in Tables 13-2 and 13-3.

Goniometry of the Upper Extremity

The following sections describe in detail how to perform a goniometric measurement of the major joints of the upper extremity.

Shoulder Complex

Shoulder motion occurs at the glenohumeral, scapulothoracic, acromioclavicular, and sternoclavicular joints. In addition, for full shoulder motion to occur, they must also be available motion in the cervical and upper thoracic spine. For the following measurements, the patient is positioned in supine with both hips and knees flexed and the feet placed on the bed to flatten the lumbar spine unless otherwise stated.

Shoulder Flexion. When measuring glenohumeral flexion, allowing the motion to occur at the other joints provides a more functional reading. However, if the clinician requires a measurement of pure glenohumeral motion, the

TABLE 13-2 Goniometric Techniques for the Upper Extremity

Joint	Tested Motion/Range (degrees)	Patient Position	Fulcrum/Axis	Stationary Arm	Moving Arm
Shoulder	Flexion/0–170 to 180	Supine	Acromion process	Midaxillary line of the thorax	Lateral midline of the humerus using the lateral epicondyle of the humerus for reference
	Extension/0–50 to 60	Prone/supine with arm over edge	Acromion process	Midaxillary line of the thorax	Lateral midline of the humerus using the lateral epicondyle of the humerus for reference
	Abduction/0–170 to 180	Supine	Anterior aspect of the acromion process	Parallel to the midline of the anterior aspect of the sternum	Medial midline of the humerus
	Adduction (return from abduction)/180–0	Supine	Anterior aspect of the acromion process	Parallel to the midline of the anterior aspect of the sternum	Medial midline of the humerus
	Horizontal adduction/0–120	Seated	Superiorly on the acromion process of the scapula through the head of the humerus	Along the midline of the shoulder toward the neck	Along the midshaft of the humerus, in line with the lateral epicondyles of the humerus
	Horizontal abduction/0–120	Seated	Superiorly on the acromion process of the scapula through the head of the humerus	Aligned on the midline of the shoulder toward the neck	Along the midshaft of the humerus, in line with the lateral epicondyle of the humerus
	Internal rotation/0–60 to 100	Supine	Olecranon process	Parallel or perpendicular to the floor	Ulna using the olecranon process and ulnar styloid for reference
	External rotation/0–80 to 90	Supine	Olecranon process	Parallel or perpendicular to the floor	Ulna using the olecranon process and ulnar styloid for reference
Elbow	Flexion/0–145	Supine/seated	Lateral epicondyle of the humerus	Lateral midline of the humerus using the center of the acromion process for reference	Lateral midline of the radius using the radial head and radial styloid process for reference
	Extension/145–0	Supine/seated	Lateral epicondyle of the humerus	Lateral midline of the humerus using the center of the acromion process for reference	Lateral midline of the radius using the radial head and radial styloid process for reference
Radioulnar	Pronation/0–90	Supine/seated	Lateral to the ulnar styloid process	Parallel to the anterior midline of the humerus	Dorsal aspect of the forearm, just proximal to the styloid process of the radius and ulna
	Supination/0–90	Supine/seated	Medial to the ulnar styloid process	Parallel to the anterior midline of the humerus	Ventral aspect of the forearm, just proximal to the styloid process of the radius and ulna
Wrist	Flexion/0–90	Seated	Lateral aspect of the wrists over the triquetrum	Lateral midline of the ulna using the olecranon and ulnar styloid process for reference	Lateral midline of the fifth metacarpal
	Extension/0–70	Seated	Lateral aspect of the wrists over the triquetrum	Lateral midline of the ulna using the olecranon and ulnar styloid process for reference	Lateral midline of the fifth metacarpal

other joints must be manually blocked. This is best achieved by stabilizing the scapula to prevent it from elevating, upwardly rotating, and posteriorly tilting. In the following description, the scapular is not stabilized; instead the thorax is stabilized to prevent extension of the spine.

Upper Extremity Position. The glenohumeral joint is initially positioned at 0 degrees of abduction, adduction, and rotation, and the forearm is positioned in 0 degrees of supination and pronation so that the palm of the hand faces the body.

Goniometer Placement. The fulcrum is centered close to the acromion process, the proximal arm is aligned with the midaxillary line of the thorax, and the distal arm is aligned with the lateral midline of the humerus, using the lateral epicondyle of the humerus as a landmark.

Technique. The shoulder is moved passively or actively to the end range of available shoulder flexion (Fig. 13-4), and a measurement is made (Fig. 13-5).

Shoulder Extension. The patient is positioned in prone.

Upper Extremity Position. The glenohumeral joint is positioned at 0 degrees of abduction and rotation, the elbow is positioned in slight flexion, and the forearm is positioned in 0 degrees of supination and pronation. If a measurement of pure glenohumeral extension is required, the scapula must be stabilized to prevent elevation and anterior tilting.

Goniometer Placement. The fulcrum is centered close to the acromion process, the proximal arm is aligned with the midaxillary line of the thorax, and the distal arm is aligned with the lateral midline of the humerus, using the lateral epicondyle of the humerus as a landmark.

FIGURE 13-4 Passive shoulder flexion.

FIGURE 13-5 Goniometric measurement of shoulder flexion.

FIGURE 13-6 Passive shoulder extension.

Technique. The shoulder is moved passively or actively to the end range of available shoulder extension (Fig. 13-6). The clinician can take a measurement of AROM (Fig. 13-7) or PROM, or both if a comparison is to be made.

Shoulder Abduction. Although measured here with the patient positioned in supine, shoulder abduction can be measured with the patient in sitting or prone, which has the advantage of allowing free motion of the scapula.

Upper Extremity Position. The glenohumeral joint is positioned at 0 degrees of flexion and extension, and full external rotation so that the palm of the hand faces anteriorly to prevent the greater tubercle of the humerus impacting on the upper portion of the glenoid fossa or acromion process. Pure glenohumeral abduction can be measured by stabilizing the scapula to prevent its upward rotation and elevation.

Goniometer Placement. The fulcrum is centered close to the anterior aspect of the acromion process, the proximal arm is aligned so that it is parallel to the midline of the anterior aspect of the sternum, and the distal arm is aligned with the medial midline of the humerus using the medial epicondyle as a landmark. If shoulder abduction is measured with the patient in the seated position, the fulcrum is centered close to the posterior aspect of the acromion process, the proximal arm is aligned parallel to the spinous processes of the vertebral column, and the distal arm is aligned with the lateral midline of the humerus, using the lateral epicondyle as a landmark.

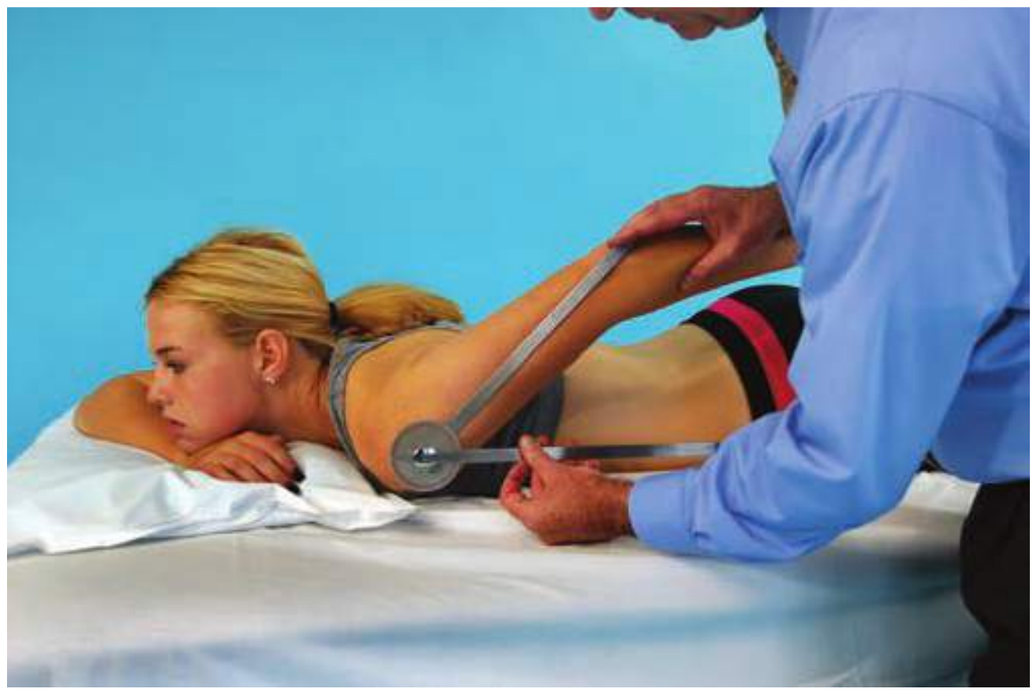

FIGURE 13-7 Goniometric measurement of shoulder extension.

FIGURE 13-8 Passive shoulder abduction.

Technique. The shoulder is moved passively or actively to the end range of available shoulder abduction (Fig. 13-8), and a goniometric measurement is made (Fig. 13-9).

CLINICAL PEARL

Shoulder adduction is not typically measured as it represents the patient's arm by the side. Further motion toward the patient's midline is considered horizontal adduction.

Shoulder Internal Rotation

Upper Extremity Position. The patient is positioned in prone. The glenohumeral joint is positioned at 90 degrees of shoulder abduction with the forearm perpendicular to the supporting surface and in 0 degrees of supination/pronation so that the palm of the hand faces the feet. If necessary, a rolled-up towel can be placed under the humerus so that the humerus is positioned level with the acromion process.

Goniometer Placement. The fulcrum is centered over the olecranon process, the proximal arm is aligned so that it is either parallel to, or perpendicular to, the floor, and the distal arm is aligned with the ulnar, using the olecranon process and ulnar styloid as landmarks.

Technique. The shoulder is moved passively or actively to the end range of shoulder internal rotation (Fig. 13-10), and a measurement is taken (Fig. 13-11).

FIGURE 13-9 Goniometric measurement of shoulder abduction.

FIGURE 13-10 Passive shoulder internal rotation.

Shoulder External Rotation. T e patient position is the same as for internal rotation of the shoulder.

Goniometer Placement. T e goniometer alignment is the same as for shoulder internal rotation.

Technique. T e shoulder is moved passively or actively to the end range of shoulder external rotation (Fig. 13-12), and a measurement is taken (Fig. 13-13).

Alternatively, shoulder internal rotation can be measured with the patient in supine (Fig. 13-14), as can shoulder external rotation (Fig. 13-15), using the start position for the goniometer as depicted in Figure 13-16.

Elbow/Forearm Complex

For the following measurements, the patient is positioned in supine with both hips and knees flexed and the feet placed on the bed to flatten the lumbar spine unless otherwise stated.

Flexion/Extension

A pad can be placed under the distal end of the humerus to allow for elbow extension.

Upper Extremity Position

T e glenohumeral joint is positioned at 0 degrees of flexion, extension, and abduction so that the arm is close to the side of the body.

FIGURE 13-11 Goniometric measurement of shoulder internal rotation.

FIGURE 13-12 Passive shoulder external rotation.

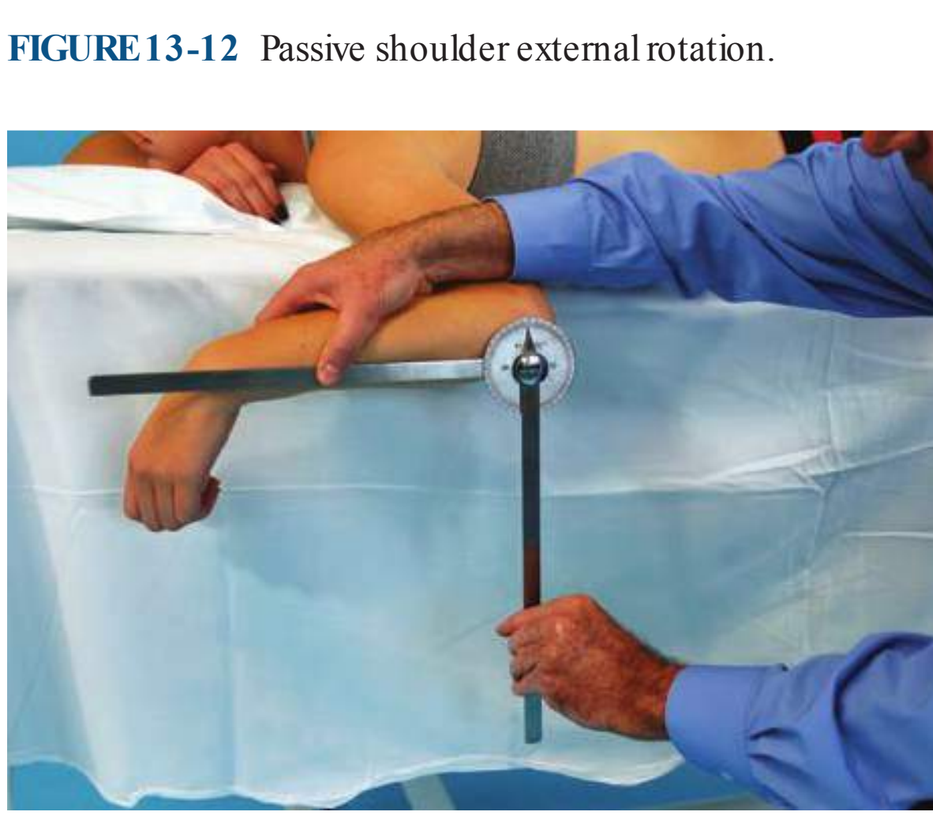

FIGURE 13-13 Goniometric measurement of shoulder external rotation.

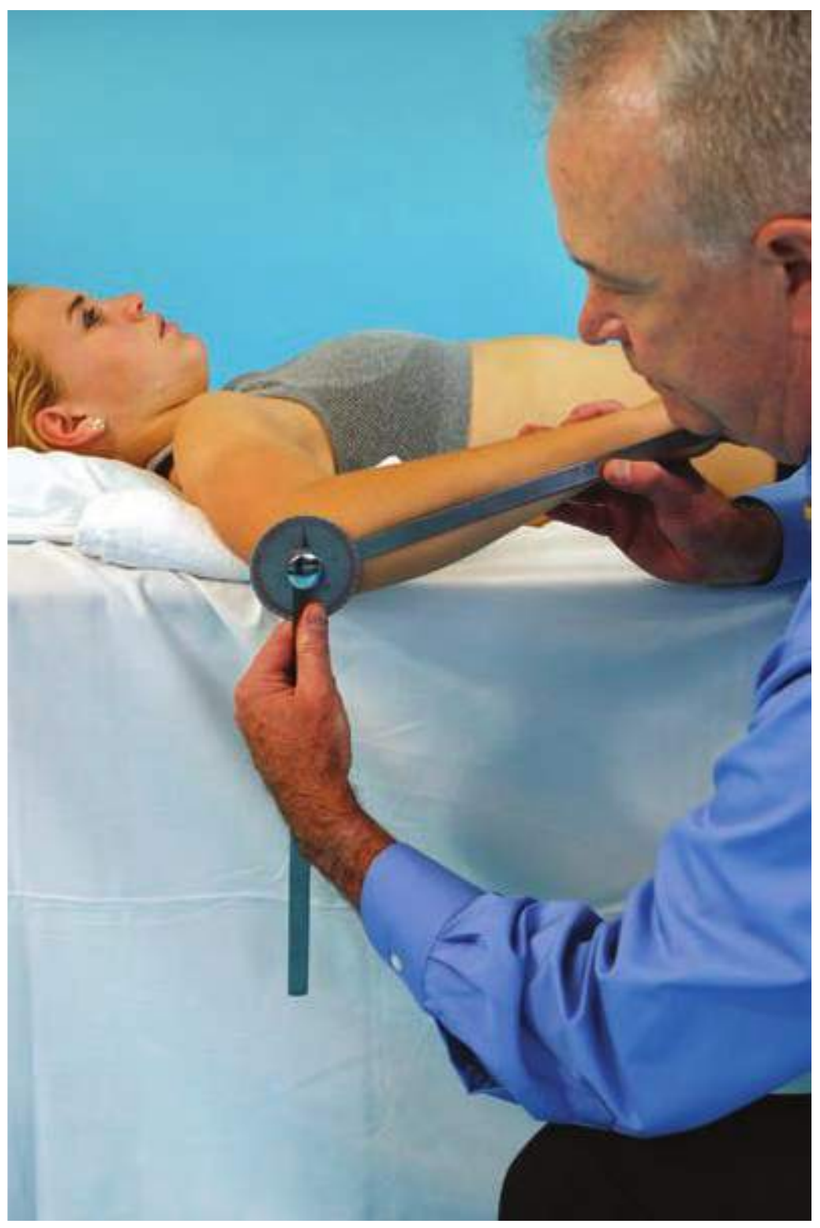

FIGURE 13-14 Goniometric measurement of shoulder internal rotation with the patient in supine.

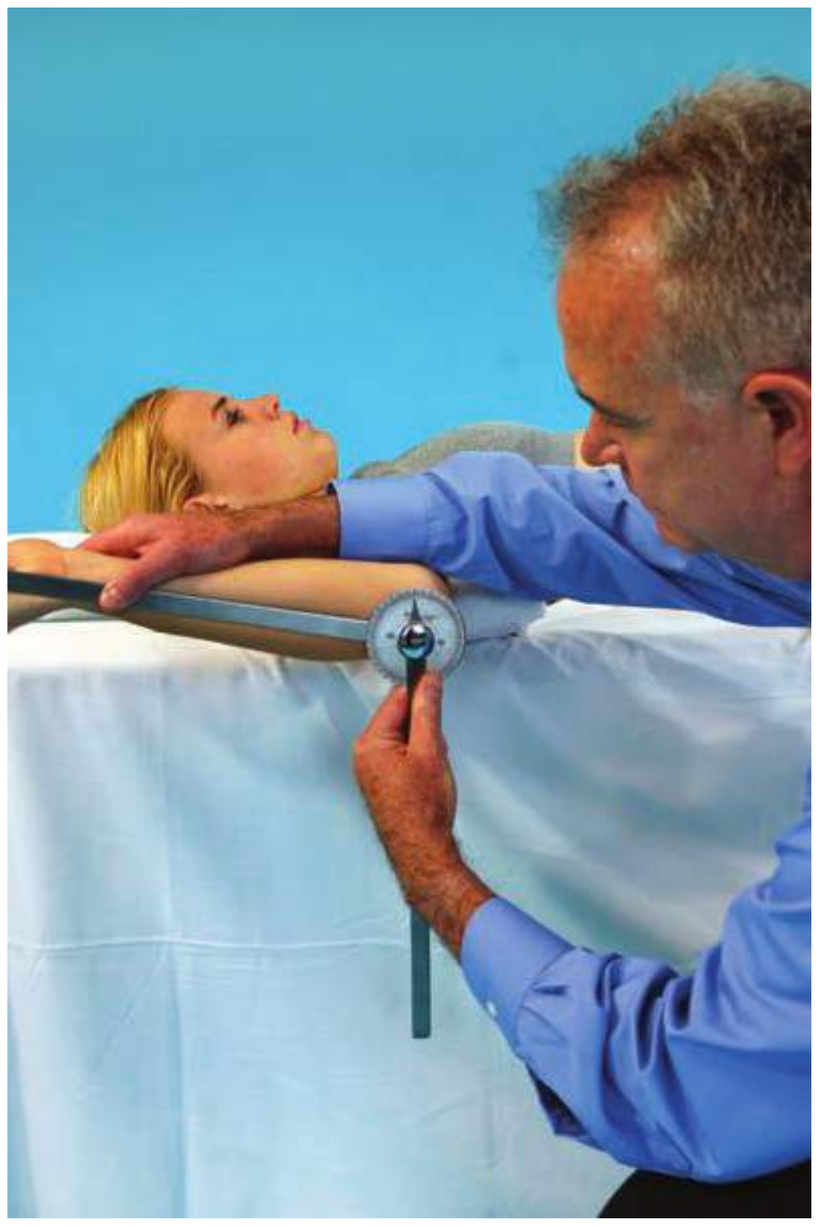

FIGURE 13-15 Goniometric measurement of shoulder external rotation with the patient in supine.

Goniometer Placement. The goniometer placement is the same for flexion and extension. The fulcrum is centered over the lateral epicondyle of the humerus, the proximal arm is aligned with the lateral midline of the humerus (using the acromion process as a landmark), and the distal arm is aligned with the lateral midline of the radius, using the styloid process as a landmark.

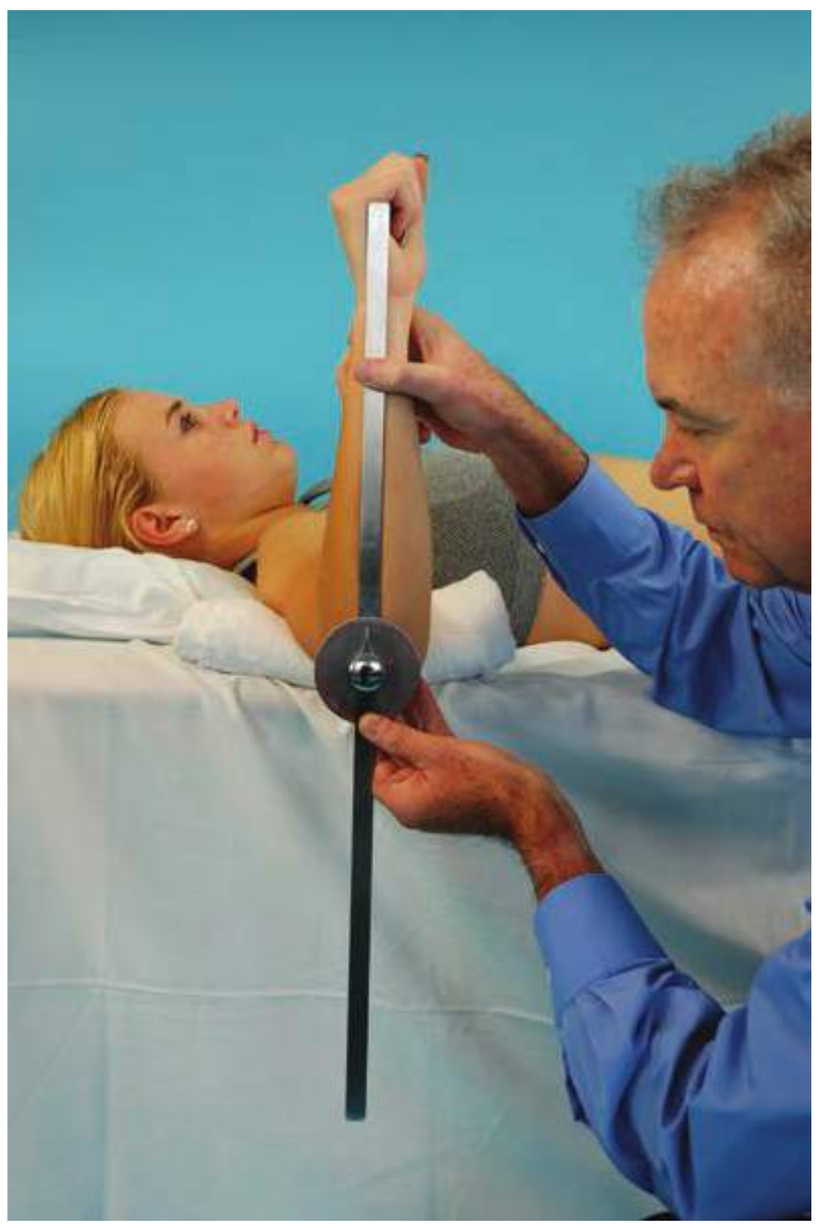

FIGURE 13-16 Start position for the goniometer to measure internal and external rotation with the patient in supine.

FIGURE 13-17 Goniometric measurement of elbow flexion.

Technique. The elbow is passively or actively flexed to the end of the available range, and a measurement is taken (Fig. 13-17). To measure elbow extension, the upper extremity is positioned correctly, and a measurement is taken (Fig. 13-18).

Forearm Pronation. This measurement can also be performed with the patient in sitting.

Upper Extremity Position. The glenohumeral joint is positioned at 0 degrees of flexion, extension, abduction, and rotation so that the upper arm is close to the side of the body, and the elbow is flexed to 90 degrees with the forearm midway between supination and pronation.

Goniometer Placement. The fulcrum is centered laterally to the ulnar styloid process, the proximal arm is aligned parallel to the anterior midline of the humerus, and the distal arm is aligned across the posterior aspect of the forearm, just proximal to the styloid processes of the radius and ulna (Fig. 13-19).

Technique. The forearm is moved passively or actively to the end of the available ROM (Fig. 13-20), and a measurement is taken (Fig. 13-21).

Forearm Supination. The patient position is the same as for forearm pronation.

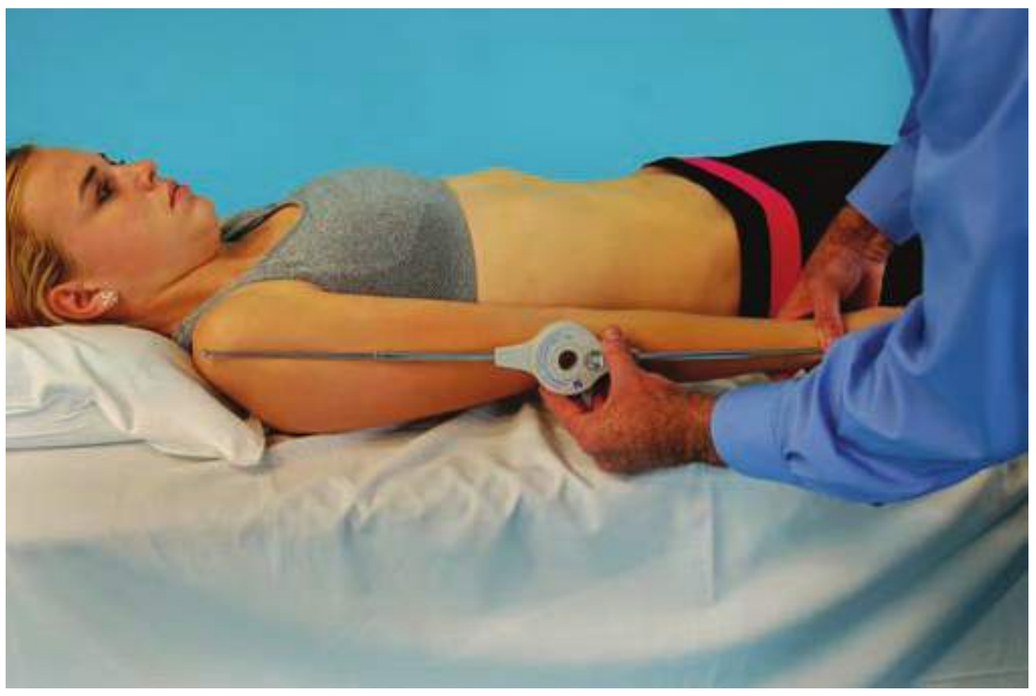

FIGURE 13-18 Goniometric measurement of elbow extension.

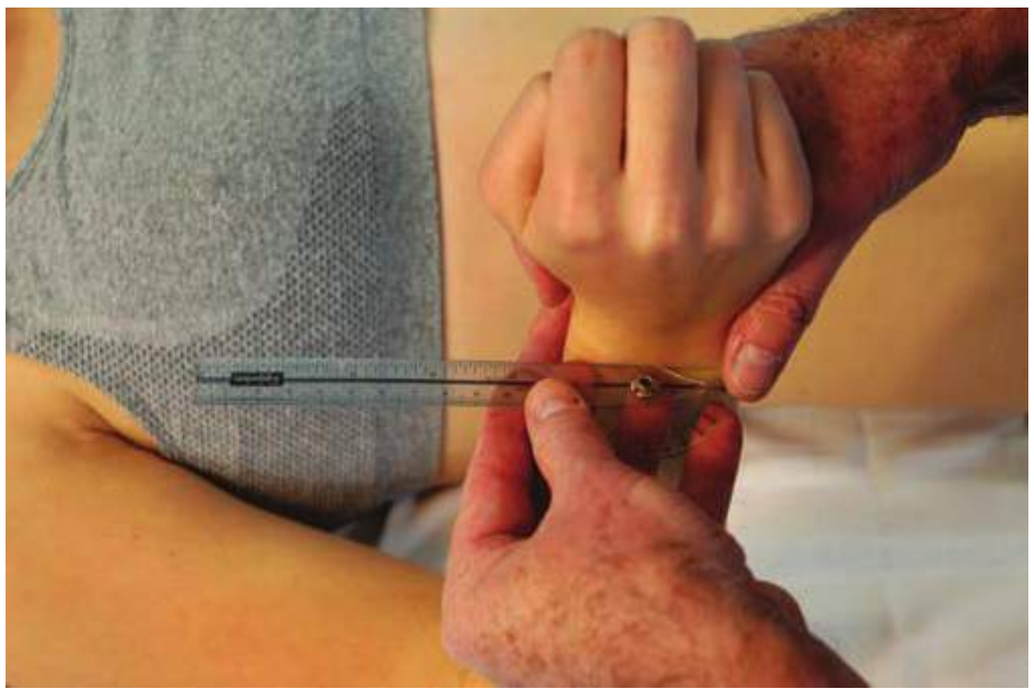

FIGURE 13-19 Start position for goniometric measurement of forearm supination/pronation.

Goniometer Placement. T e fulcrum is aligned medial to the ulnar styloid process, the proximal arm is aligned parallel to the anterior midline of the humerus, and the distal arm is aligned across the anterior aspect of the forearm, just proximal to the styloid process (Fig. 13-19).

Technique. T e forearm is moved passively or actively to the end of the available ROM (Fig. 13-22), and a measurement is taken (Fig. 13-23).

An alternative technique to measure forearm supination and pronation involves having the patient holding a pen or pencil in a close-fisted hand. T e goniometer can then be aligned using the end of the pen as a landmark (Fig. 13-24).

Wrist Joints

For the following measurements, the patient is positioned in sitting next to a supporting surface so that the forearm is supported, but the hand is free to move.

Wrist Flexion and Extension

T e clinician should stabilize the forearm to prevent supination or pronation.

Goniometer Placement. T e goniometer placement is the same for wrist flexion and wrist extension. T e fulcrum is

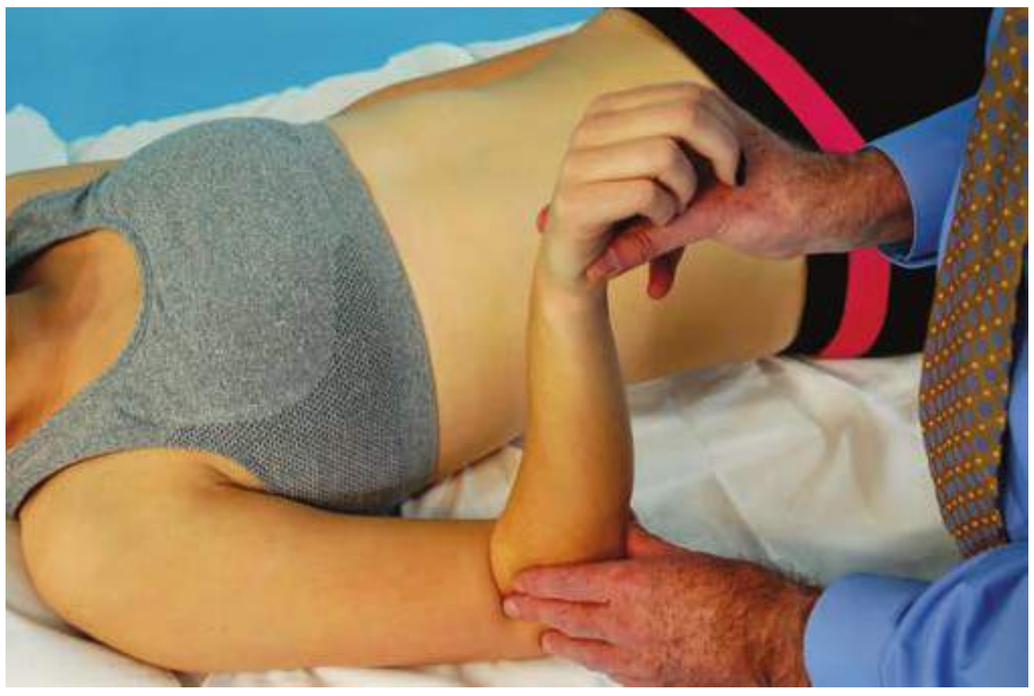

FIGURE 13-20 Passive forearm pronation.

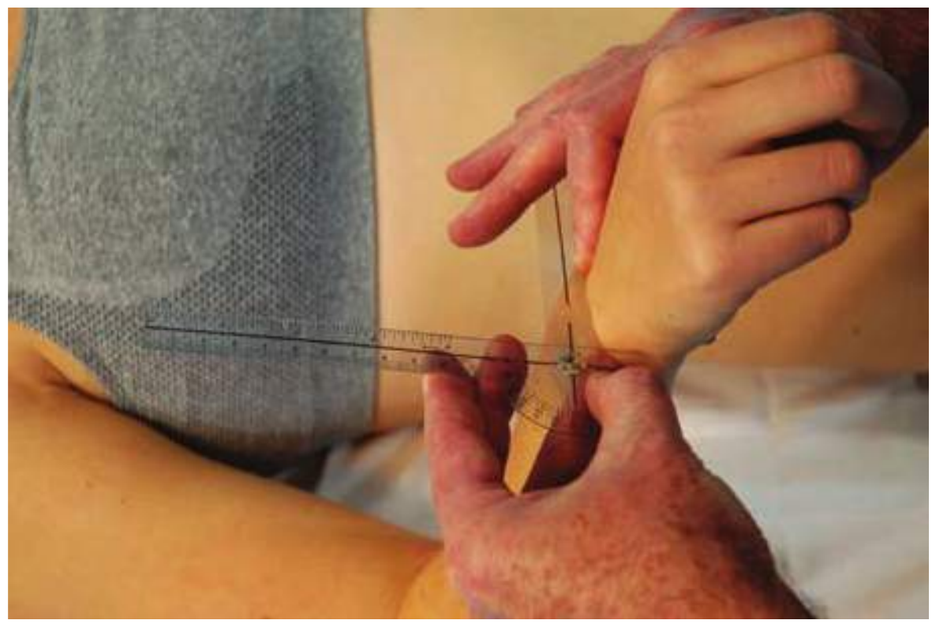

FIGURE 13-21 Goniometric measurement of forearm pronation.

FIGURE 13-22 Passive forearm supination.

FIGURE 13-23 Goniometric measurement of forearm supination.

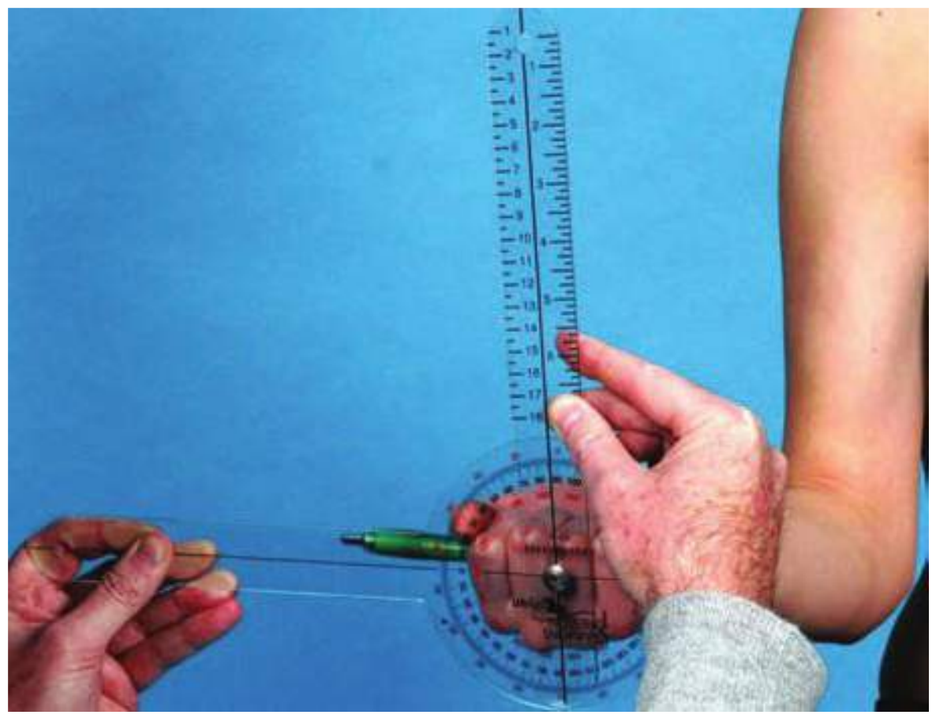

FIGURE 13-24 Alternative method for measuring forearm supination/pronation.

FIGURE 13-25 Passive wrist flexion.

centered over the lateral aspect of the wrist close to the triquetrum, the proximal arm is aligned with the lateral midline of the ulnar, using the olecranon process as a landmark, and the distal arm is aligned with the lateral midline of the fifth metacarpal. The palm of the patient is moved downward for wrist flexion, and upward for wrist extension while avoiding any extension of the fingers.

Technique. To measure wrist flexion, the wrist is actively or passively flexed to the end of the available ROM (Fig. 13-25), and a measurement is taken (Fig. 13-26). To measure wrist extension, the wrist is actively or passively extended to the end of the available ROM (Fig. 13-27), and a measurement is taken (Fig. 13-28).

Radial Deviation and Ulnar Deviation

The patient position is the same as for wrist flexion/extension.

Goniometer Placement. The goniometer placement is the same for radial deviation and ulnar deviation. The fulcrum is centered over the middle of the posterior aspect of the wrist close to the capitate, the proximal arm is aligned with the posterior midline of the forearm, using the lateral epicondyles as a landmark, and the distal arm is aligned with the posterior midline of the third metacarpal. For radial deviation, the patient's hand moves toward the patient's body, while, for ulnar deviation, the patient's hand moves away from the patient's body.

FIGURE 13-26 Goniometric measurement of wrist flexion.

FIGURE 13-27 Passive wrist extension.

Technique. To measure radial deviation, the wrist is passively or actively moved to the end of the available ROM for radial deviation (Fig. 13-29), and a measurement is taken (Fig. 13-30). To measure ulnar deviation, the wrist is passively or actively moved to the end of the available ROM for ulnar deviation (Fig. 13-31), and a measurement is taken (Fig. 13-32).

Finger Joints

The patient position for these joints is typically in sitting, with the forearm supported and midway between pronation and supination, the wrist positioned in 0 degrees of flexion and extension, and in neutral radial and ulnar deviation.

Metacarpophalangeal Joint Flexion/Extension

While performing these measurements, the clinician must ensure that the metacarpophalangeal (MCP) joint is maintained in a neutral position relative to abduction and adduction and to avoid too much motion occurring at the proximal interphalangeal (PIP) and distal interphalangeal (DIP) joints. The same technique is used for all of the MCP joints of the fingers.

Goniometer Placement. The goniometer placement is the same for MCP flexion and MCP extension. The fulcrum is centered over the posterior aspect of the MCP joint, the proximal

FIGURE 13-28 Goniometric measurement of wrist extension.

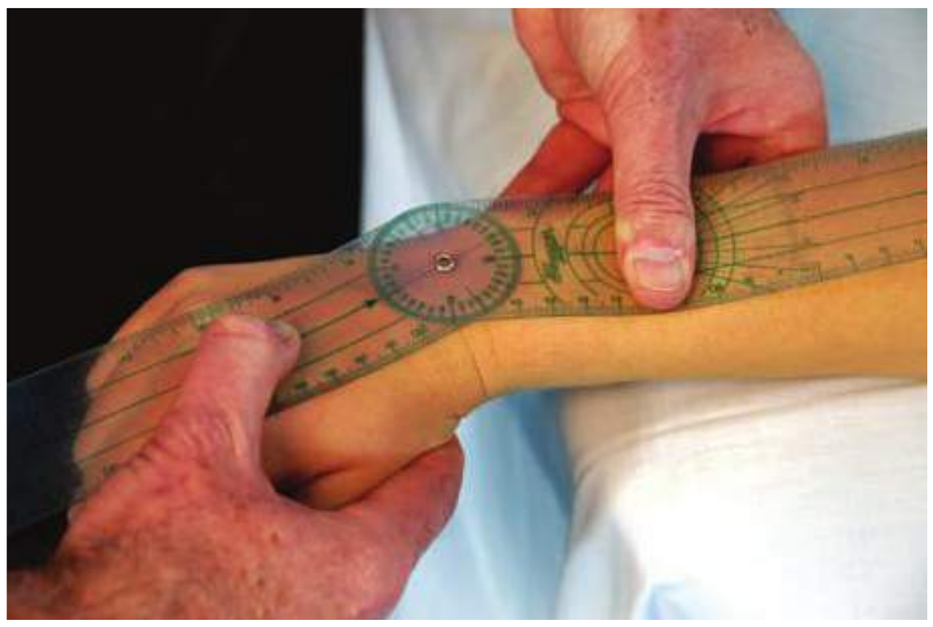

FIGURE 13-30 Goniometric measurement of radial deviation.

FIGURE 13-31 Passive ulnar deviation.

FIGURE 13-32 Goniometric measurement of ulnar deviation.

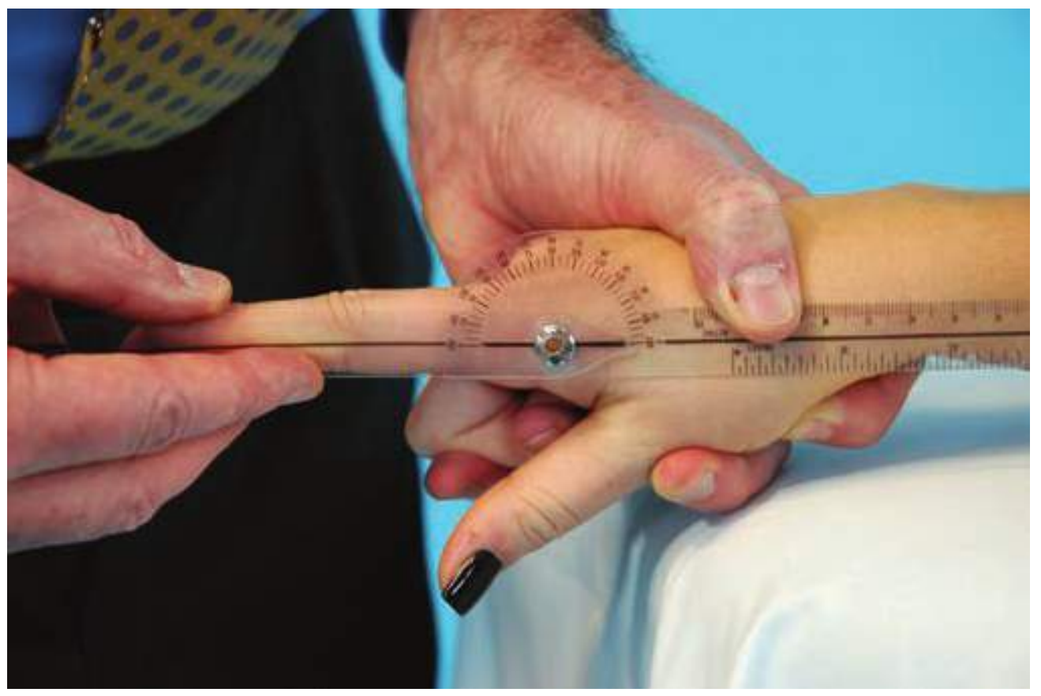

FIGURE 13-33 Goniometer placement for MCP flexion/extension.

arm is aligned with the posterior midline of the metacarpal, and the distal arm is aligned with the posterior midline of the proximal phalanx. For the index finger, the fulcrum is centered over the thumb side of the MCP joint, the proximal arm is aligned with the radial styloid, and the distal arm is aligned on the thumb side of the phalanx (Fig. 13-33).

Technique. A measurement is taken for MCP flexion (Fig. 13-34), and MCP extension (Fig. 13-35).

MCP Joint Abduction/Adduction

The same technique is used for all of the MCP joints of the fingers.

Goniometer Placement. The goniometer placement is the same for MCP joint abduction and MCP joint adduction. The fulcrum is centered over the posterior aspect of the MCP joint, the proximal arm is aligned with the posterior midline of the metacarpal, and the distal arm is aligned with the posterior midline of the proximal phalanx (Fig. 13-36).

Technique. A measurement is taken for MCP abduction (Fig. 13-37), and for MCP abduction (Fig. 13-38).

FIGURE 13-34 Goniometric measurement for MCP flexion of the index finger.

FIGURE 13-35 Goniometric measurement for MCP extension of the index finger.

FIGURE 13-36 Goniometer placement for MCP abduction/adduction.

FIGURE 13-37 Goniometric measurement for MCP abduction.

FIGURE 13-38 Goniometric measurement for MCP adduction.

FIGURE 13-39 Goniometric measurement for PIP joint flexion.

Proximal Interphalangeal Joint Flexion/Extension

The clinician attempts to stabilize the proximal phalanx to prevent motion at the wrist and MCP joint.

Goniometer Placement. The goniometer placement is the same for PIP joint flexion and PIP joint extension. The fulcrum is centered over the posterior aspect of the PIP joint, the proximal arm is aligned with the posterior midline of the proximal phalanx, and the distal arm is aligned with the posterior midline of the middle phalanx. The same technique is used for each of the PIP joints of the fingers. It is questionable whether a measurement of PIP joint extension is possible as any loss of PIP extension is technically a measurement of PIP flexion.

Technique. A measurement is taken for PIP joint flexion (Fig. 13-39).

Distal Interphalangeal Joint Flexion/Extension

The MCP joint is positioned in 0 degrees of flexion, extension, abduction, and adduction, with the PIP joint positioned in approximately 70 to 90 degrees of flexion. The clinician attempts to stabilize the middle phalanx to prevent further flexion or extension of the wrist, MCP joints, and PIP joints.

Goniometer Placement. The goniometer placement is the same for DIP joint flexion and DIP joint extension. The fulcrum is centered over the posterior aspect of the PIP joint, the proximal arm is aligned with the posterior midline of the middle phalanx, and the distal arm is aligned with the posterior midline of the distal phalanx. The same technique is used for each of the DIP joints of the fingers. As with PIP joint extension, it is questionable whether a measurement of DIP joint extension is possible as any loss of DIP extension is technically a measurement of DIP flexion.

Technique. A measurement is taken for DIP joint flexion (Fig. 13-40).

Thumb Joints

The patient position for these joints is typically in sitting, with the forearm supported in supination, the wrist positioned at 0 degrees of flexion and extension, and in neutral radial and

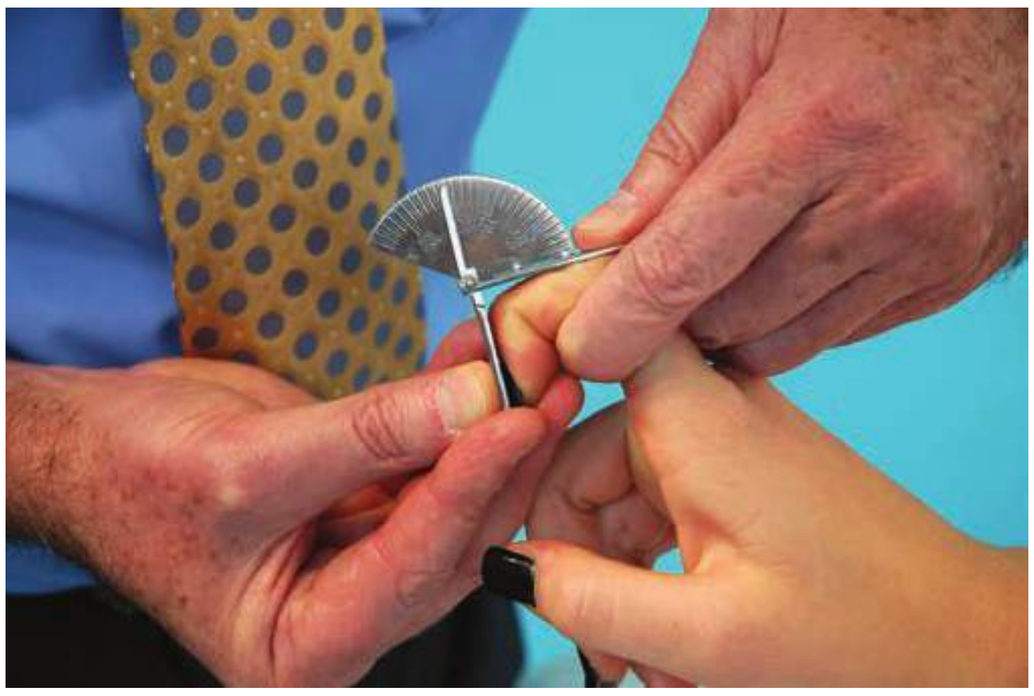

FIGURE 13-40 Goniometric measurement for DIP joint flexion.

FIGURE 13-42 Goniometric measurement of thumb CMC joint flexion.

ulnar deviation. The MCP and interphalangeal (IP) joints of the thumb are positioned at 0 degrees of flexion and extension.

Carpometacarpal Flexion and Extension

Goniometer Placement. The goniometer placement is the same for carpometacarpal (CMC) flexion and CMC extension. The fulcrum is centered over the anterior aspect of the first CMC joint, the proximal arm is aligned parallel to the anterior midline of the radius, and the distal arm is aligned with the anterior midline of the first metacarpal. CMC flexion occurs when the thumb moves toward the palm of the hand, and CMC extension occurs when the thumb moves away from the palm of the hand.

Technique. The CMC joint is passively or actively moved into the available ROM for flexion (Fig. 13-41), and a measurement is taken (Fig. 13-42). The CMC joint is passively or actively moved into the available ROM for extension (Fig. 13-43), and a measurement is taken (Fig. 13-44).

CMC Abduction and Adduction

The patient positioning is the same as for CMC flexion and extension.

Goniometer Placement. The goniometer placement is the same for CMC abduction and CMC adduction. The fulcrum is centered midway between the posterior aspect of the first and second CMC joints, the proximal arm is aligned with the lateral midline of the second metacarpal, and the distal arm is aligned with the lateral midline of the first metacarpal. CMC abduction occurs when the thumb moves away from the hand while CMC adduction occurs when the thumb moves toward the hand.

Technique. The CMC joint is passively or actively moved into the available ROM for abduction (Fig. 13-45), and a measurement is taken (Fig. 13-46).

Thumb Opposition

The patient positioning is the same as for CMC flexion and extension.

Goniometer Placement. The ruler component of a goniometer is typically used to measure the amount of thumb opposition by calculating the distance between the tip of the thumb and the tip of the fifth digit.

Technique. The thumb and little finger are actively or passively move together in the direction of opposition (Fig. 13-47), and a measurement is taken (Fig. 13-48).

MCP Joint of the Thumb Flexion and Extension

The patient positioning is the same as for CMC flexion and extension.

FIGURE 13-41 Passive thumb CMC joint flexion.

FIGURE 13-43 Passive thumb CMC joint extension.

FIGURE 13-44 Goniometric measurement of thumb CMC joint extension.

FIGURE 13-45 Passive thumb CMC joint abduction.

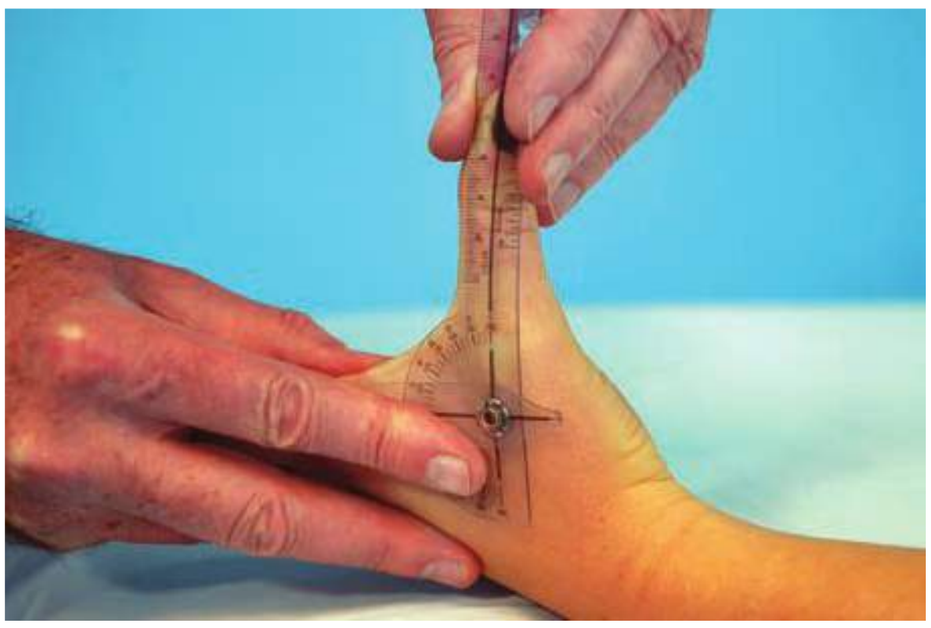

FIGURE 13-46 Goniometric measurement of thumb CMC joint abduction.

FIGURE 13-47 Passive opposition of thumb and little finger.

FIGURE 13-48 Goniometric measurement of active thumb opposition.

Goniometer Placement. The goniometer placement is the same for MCP joint flexion and MCP joint extension. The fulcrum is centered over the posterior aspect of the MCP joint, the proximal arm is aligned with the posterior midline of the metacarpal, and the distal arm is aligned with the posterior midline of the proximal phalanx.

Technique. The MCP joint of the thumb is actively or passively flexed to the end of the available ROM, and a measurement is taken (Fig. 13-49).

IP Joint of the Thumb
Flexion and Extension

The patient positioning is the same as for CMC flexion and extension.

Goniometer Placement. The goniometer placement is the same for IP flexion and IP extension. The fulcrum is centered over the posterior surface of the IP joint, the proximal arm is aligned with the posterior aspect of the proximal phalanx, and the distal arm is aligned with the posterior midline of the distal phalanx.

Technique. The IP joint of the thumb is actively or passively flexed to the end of the available ROM, and a measurement is taken.

FIGURE 13-49 Goniometric measurement of thumb MCP flexion.

Lower Extremity

The following sections describe in detail how to measure joint ROM for the major joints of the upper extremity using a goniometer.

Hip Joint

The patient is positioned in supine to measure hip flexion, hip abduction, and hip abduction, seated to measure hip internal rotation and external rotation, and prone to measure hip extension.

Hip Flexion. Hip flexion can be measured in one of two ways, with the knee allowed to flex, or with the knee extended. Measuring hip flexion with the knee extended is merely an indication of the length of the patient's hamstrings rather than a true measurement of hip joint motion. Hip flexion with the knee flexed is described here.

Lower Extremity Position. The hip is positioned at 0 degrees of abduction, abduction, and rotation, with the knee motion unrestricted.

Goniometer Placement. The fulcrum is centered over the lateral aspect of the hip joint using the greater trochanter of the femur as a landmark, the proximal arm is aligned with the lateral midline of the pelvis, and the distal arm is aligned with the lateral midline of the femur, using the lateral epicondyle of the femur as a landmark (Fig. 13-50).

Technique. The hip is actively or passively flexed to the end of the available ROM, and a measurement is taken (Fig. 13-51).

Hip Extension. The patient is positioned in prone. As with hip flexion, hip extension can be measured in one of two ways, with the knee allowed to flex, or with the knee extended. Measuring hip extension with the knee flexed can be misleading due to tension from the rectus femoris muscle which can restrict motion.

Lower Extremity Position. The hip is positioned at 0 degrees of abduction, adduction, and rotation, with the knee motion unrestricted.

Goniometer Placement. The goniometer placement and alignment are the same as for hip flexion, except that the patient is positioned in prone (Fig. 13-52).

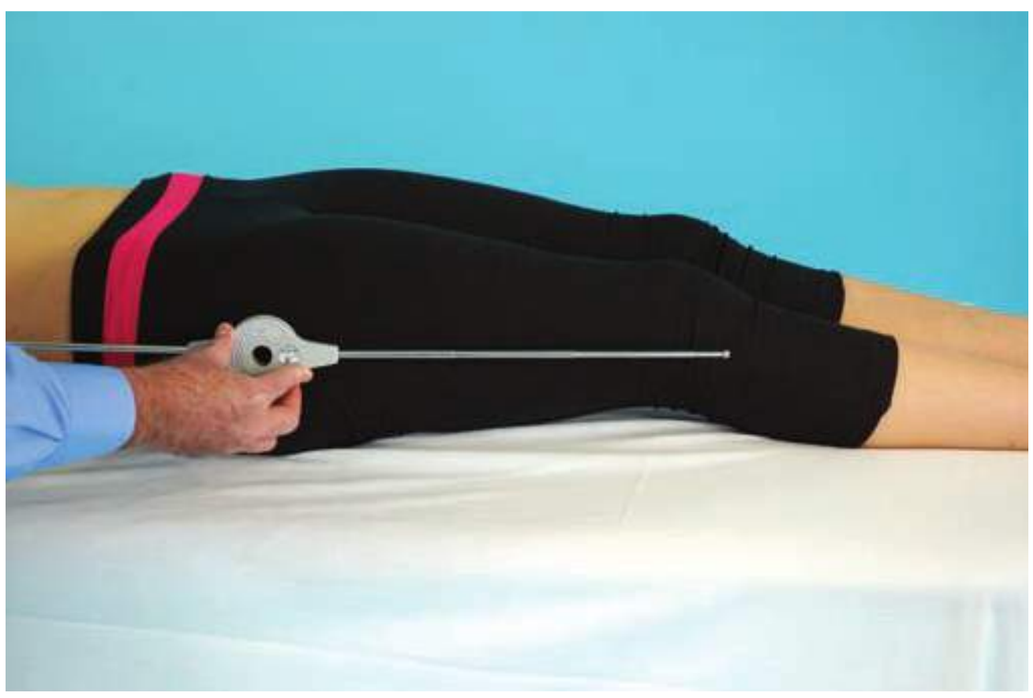

FIGURE 13-50 Goniometer position for hip flexion.

FIGURE 13-51 Goniometric measurement of hip flexion.

Technique. The hip is actively or passively extended to the end of the available ROM, and a measurement is taken (Fig. 13-53).

Hip Abduction/Adduction

Lower Extremity Position. The lower extremity is kept as straight as possible. It is worth remembering that, in order for full hip adduction to take place, the contralateral hip must be abducted to allow the hip being measured to complete its full ROM.

Goniometer Placement. The goniometer placement for hip abduction and hip adduction is the same. The fulcrum is centered over the anterior superior iliac spine (ASIS) of the extremity being measured, the proximal arm is aligned with an imaginary horizontal line extending from one ASIS to the other ASIS, and the distal arm is aligned with the anterior midline of the femur using the midline of the patella as a landmark.

Technique. The hip is actively or passively abducted to the end of the available ROM (Fig. 13-54), and a measurement is taken (Fig. 13-55). To measure hip adduction, the hip is actively or passively adducted to the end of the available ROM (Fig. 13-56), and a measurement is taken (Fig. 13-57).

Hip Internal Rotation/External Rotation. The patient is positioned in sitting on the supporting surface, with the knee flexed over the edge of the table surface.

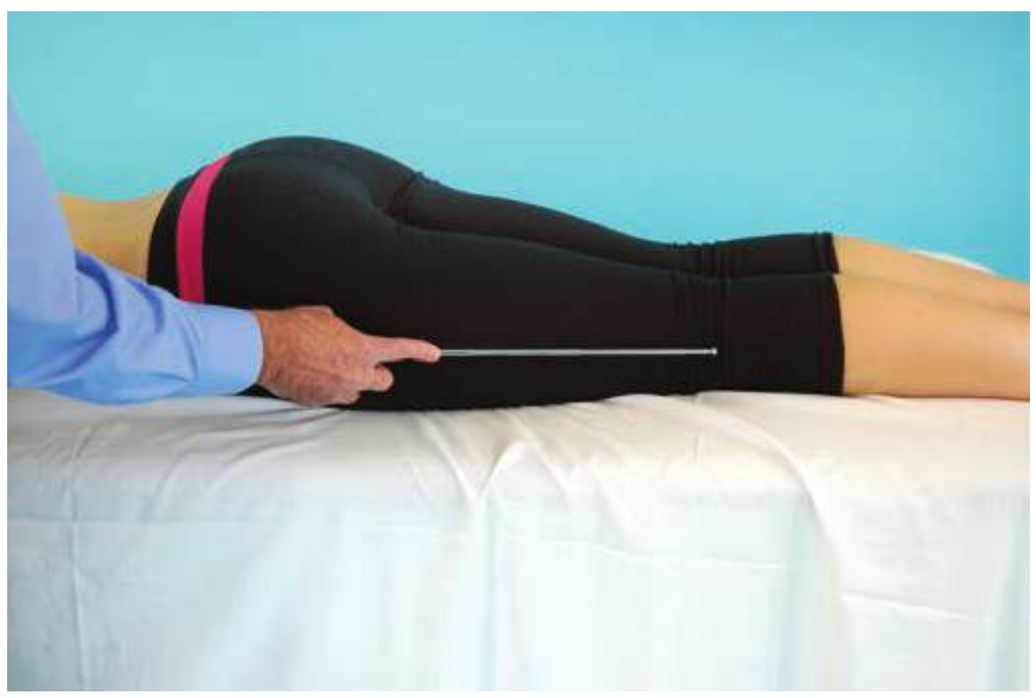

FIGURE 13-52 Goniometer position for hip extension.

FIGURE 13-53 Goniometric measurement of hip extension.

FIGURE 13-54 Passive hip abduction while monitoring contralateral ASIS.

FIGURE 13-55 Goniometric measurement of hip abduction.

FIGURE 13-56 Passive hip adduction while monitoring the contralateral ASIS.

FIGURE 13-57 Goniometric measurement of hip adduction.

Lower Extremity Position. The hip is in 0 degrees of abduction and adduction and 90 degrees of flexion. If necessary, a towel roll is placed under the distal end of the femur to maintain the femur in a horizontal plane.

Goniometer Placement. The goniometer placement for hip internal rotation and hip external rotation is the same. The fulcrum is centered over the anterior aspect of the patella, the proximal arm is aligned so that it is perpendicular to the floor all parallel to the supporting surface, and the distal arm is aligned with the anterior midline of the lower leg, using the tibial crest and a point midway between the two malleoli as reference points.

Technique. The hip is actively or passively internally rotated to the end of the available ROM (Fig. 13-58), and a measurement is taken (Fig. 13-59). To measure external rotation of the hip, the hip is actively or passively externally rotated to the end of the available ROM (Fig. 13-60), and a measurement is taken (Fig. 13-61).

Tibiofemoral Joint

To assess tibiofemoral joint flexion and extension, the patient is typically positioned in prone. However, in the presence of significant adaptive shortening of the rectus femoris muscle, knee flexion can be measured with the patient in supine.

FIGURE 13-58 Passive hip internal rotation.

FIGURE 13-59 Goniometric measurement of hip internal rotation.

Tibiofemoral Joint Flexion/Extension

During these measurements, it is important to stabilize the femur to prevent rotation, flexion, or extension of the hip.

Lower Extremity Position. The hip is positioned at 0 degrees of abduction, adduction, flexion, extension, and rotation.

Goniometer Placement. The goniometer placement for tibiofemoral flexion and tibiofemoral extension is the same. The fulcrum is centered over the lateral epicondyle of the femur, the proximal arm is aligned with the lateral midline of the femur, using the greater trochanter at a landmark, and the distal arm is aligned with the lateral midline of the fibula, using the lateral malleolus as a landmark.

Technique. The knee is actively or passively flexed to the end of the available ROM (Fig. 13-62), and a measurement is taken (Fig. 13-63).

Ankle Joint

The ankle joint can be assessed with the patient in sitting, prone or supine. For a more accurate measurement of ankle motion, the patient's knee should be flexed to at least 30 degrees to remove any influence from the gastrocnemius complex.

Dorsiflexion and Plantarflexion

The patient is positioned in sitting or supine.

FIGURE 13-60 Passive hip external rotation.

FIGURE 13-61 Goniometric measurement of hip external rotation.

Goniometer Placement. The goniometer placement is the same for dorsiflexion and plantarflexion. The fulcrum is centered over the lateral aspect of the lateral malleolus, the proximal arm is aligned with the lateral midline of the fibula, using the head of the fibula as a landmark, and the distal arm is aligned parallel to the lateral aspect of the fifth metatarsal, or parallel to the inferior aspect of the calcaneus.

Technique. The ankle is actively or passively dorsiflexion to the end of the available ROM (Fig. 13-64), and a measurement is taken (Fig. 13-65). To measure ankle plantarflexion, the ankle is actively or passively plantarflexed to the end of the available ROM (Fig. 13-66), and a measurement is taken (Fig. 13-67).

Subtalar Joint Inversion and Eversion

The patient is positioned in sitting or prone.

Goniometer Placement. The goniometer placement is the same for inversion and eversion. The fulcrum is centered over the posterior aspect of the ankle, midway between the malleoli, the proximal arm is aligned with the posterior midline of the lower leg, and the distal arm is aligned with the posterior midline of the calcaneus.

Technique. The ankle is actively or passively inverted to the end of the available ROM (Fig. 13-68), and a measurement is taken (Fig. 13-69). For ankle eversion, the ankle is actively or

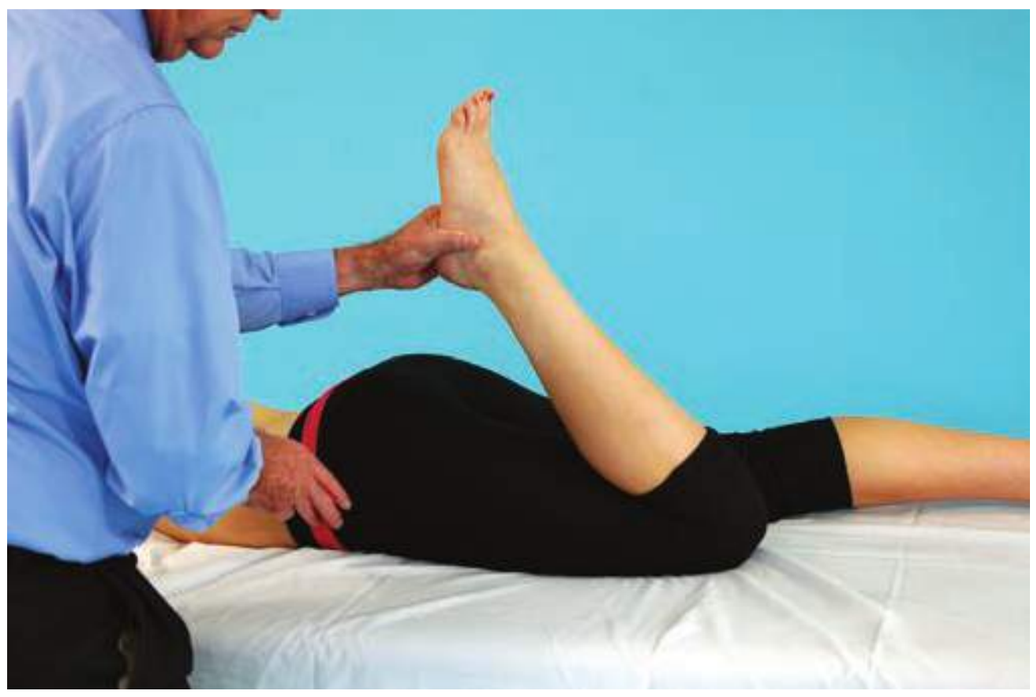

FIGURE 13-62 Passive knee flexion.

FIGURE 13-63 Goniometric measurement of knee flexion with the patient prone.

FIGURE 13-64 Passive ankle dorsiflexion.

FIGURE 13-65 Goniometric measurement of ankle dorsiflexion.

FIGURE 13-66 Passive ankle plantarflexion.

FIGURE 13-68 Passive subtalar joint inversion.

FIGURE 13-69 Goniometric measurement of subtalar joint inversion.

passively everted to the end of the available ROM (Fig. 13-70), and a measurement is taken (Fig. 13-71).

Tarsal Joint Inversion and Eversion

The patient is positioned in sitting.

Goniometer Placement. The goniometer placement is the same for inversion and eversion. The fulcrum is centered over the anterior aspect of the ankle midway between the malleoli,

FIGURE 13-70 Passive subtalar joint eversion.

the proximal arm is aligned with the anterior midline of the lower leg, using the tibial crest for reference, and the distal arm is aligned with the anterior midline of the second metatarsal.

Technique. The tarsal joints are actively or passively inverted to the end of the available ROM (Fig. 13-72), and a measurement is taken (Fig. 13-73). For tarsal joint eversion, the tarsal joints are actively or passively everted to the end of the available ROM (Fig. 13-74), and a measurement is taken (Fig. 13-75).

Toe Joints

Metatarsophalangeal Joint Flexion and Extension

The patient is positioned in sitting or supine with the metatarsophalangeal (MTP) and IP joints positioned at 0 degrees of flexion and extension.

Goniometer Placement. The goniometer placement is the same for MTP joint flexion and MTP joint extension. The fulcrum is aligned over the posterior aspect of the MTP joint, the proximal arm is aligned with the posterior midline of the metatarsal, and the distal arm is aligned with the posterior midline of the proximal phalanx.

FIGURE 13-71 Goniometric measurement of subtalar joint eversion.

FIGURE 13-72 Passive tarsal joint inversion.

FIGURE 13-73 Goniometric measurement of tarsal joint inversion.

FIGURE 13-74 Passive tarsal joint eversion.

FIGURE 13-75 Goniometric measurement of tarsal joint eversion.

FIGURE 13-76 Passive MTP joint flexion of the great toe.

Technique. T e MTP joint is actively or passively flexed to the end of the available ROM (Fig. 13-76), and a measurement is taken (Fig. 13-77). To measure MTP joint extension, the MTP joint is actively or passively extended to the end of the available ROM (Fig. 13-78), and a measurement is taken (Fig. 13-79).

CLINICAL PEARL

Although motions, such as abduction of the great toe (Fig. 13-80), flexion/extension of the individual PIP joints, and flexion/extension of the individual DIP joint, can theoretically be measured, one has to question the usefulness of these measurements. A more practical approach is to perform a visual assessment of combined PIP and DIP joint flexion/extension, and great toe abduction (if the patient is able to perform such an action).

The Spine

Goniometric measurement of spinal motion brings its own set of challenges. Over the years, various methods have been put forward that have incorporated the use of a tape measure, the use of standard goniometers, and the use of specialized goniometers, such as the bubble goniometer (Fig. 13-2). Most

FIGURE 13-77 Goniometric measurement of flexion of the great toe.

FIGURE 13-78 Passive MTP joint extension of the great toe.

FIGURE 13-79 Goniometric measurement of extension of the great toe.

FIGURE 13-80 Goniometric measurement of great toe abduction.

of the problems have stemmed from determining the best appropriate landmarks, the wide variations in body types, and whether such measurements have suf cient inter- and intrarater reliability.

Whichever method is chosen, it is important to remember that, as with other joints in the body, the ROM in the spine may vary according to a number of factors including structural alterations, the individual's age, neck girth and length,

body habitus, diurnal changes,[65] neurologic disease, or other factors unrelated to the disability for which the examination is being performed. Without taking body size into account, measurements may underestimate or overestimate ROM.[66]

Cervical Spine

Cervical Rotation

Traditional Goniometer Method. The fulcrum is centered over the center of the superior aspect of the head, the proximal arm is aligned parallel to an imaginary line between the two acromion processes, and the distal arm is aligned with the tip of the nose.

Tape Measure Method. A tape measure can be used to measure the distance between the tip of the chin and the acromion process.

Bubble Goniometer Method. The inclinometer method, using 1-2 bubble goniometers, is the approach recommended in the American Medical Association's Guides to the Evaluation of Permanent Impairment[67] and is often considered the clinical standard for assessing cervical ROM in the clinic.[68,69] This method requires accurate identification of anatomic landmarks. Both inter- and intrarater reliability studies have shown the inclinometry method to be reliable.[70–73] Others dispute this conclusion and contend that the inclinometer method is flawed and should not be used in clinical settings.[74,75] The normal ROM using this method is 80 degrees or greater from the neutral position for active motion. To measure cervical rotation using a bubble goniometer, the patient is positioned in prone, and the goniometer is aligned over the crown of the head in the transverse plane (Fig. 13-81). The goniometer is zeroed out, and the patient is asked to rotate the head to the right (Fig. 13-82), and then to the left (Fig. 13-83).

FIGURE 13-82 Goniometric measurement for right cervical rotation.

Cervical Flexion and Extension

Traditional Goniometer Method. The fulcrum is centered over the external auditory meatus, the proximal arm is aligned so that it is either perpendicular or parallel to the ground, and the distal arm is aligned with the base of the nares (Fig. 13-84). The patient is then asked to flex the cervical spine (Fig. 13-85), and to extend the cervical spine (Fig. 13-86).

Tape Measure Method. A tape measure can be used to measure the distance between the tip of the chin and the sternal notch while making sure that the patient's mouth remains closed.

Bubble Goniometer Method. The normal ROM for cervical flexion using this technique is 60 degrees or greater from the neutral position, and 75 degrees or greater from the neutral position for active motion.[76] From the start position (Fig. 13-87), the patient is asked to flex the cervical spine (Fig. 13-88), and then to extend the cervical spine (Fig. 13-89).

CLINICAL PEARL

Using the bubble goniometer method, the full arc of passive cervical rotation range depends on the age of the patient[76]:

- 20–29: 183 degrees ± 11
- 30–49: 172 degrees ± 13
- >50: 155 degrees ± 15

CLINICAL PEARL

Using the bubble goniometer method, the full arc of passive flexion/extension range depends on the age of the patient[76]:

- 20–29: 151 degrees ± 17
- 30–49: 141 degrees ± 35
- >50: 129 degrees ± 14

FIGURE 13-81 Bubble goniometer placement for cervical rotation.

FIGURE 13-87 Bubble goniometer placement for the start position for cervical flexion.

FIGURE 13-88 Goniometric measurement of cervical flexion.

FIGURE 13-89 Goniometric measurement of cervical extension.

Cervical Side Bending. When measuring cervical side bending, the clinician should stabilize the shoulder girdle to prevent lateral flexion of the thoracic and lumbar spine.

Traditional Goniometer Method. T e fulcrum is centered over the spinous process of the C7 vertebra, the proximal arm is aligned with the spinous processes of the thoracic vertebra so that the arm is perpendicular to the ground, and the distal arm is aligned with the posterior midline of the head, using the occipital protuberance as a landmark.

Tape Measure Method. A tape measure can be used to measure the distance between the mastoid process and the acromion process.

Bubble Goniometer Method. T e normal range of cervical side bending using this method is 45 degrees or greater from the neutral position for active motion. From the start position (Fig. 13-90), the patient is asked to side bend the cervical spine to the left (Fig. 13-91), and then to the right (Fig. 13-92).

FIGURE 13-90 Bubble goniometer placement for the start position for cervical side bending.

FIGURE 13-92 Goniometric measurement of cervical side bending to the right.

CLINICAL PEARL

Using the bubble goniometer method, the full arc of passive right/left cervical side bending range depends on the age of the patient[76]:

- 20–29: 101 degrees ± 11
- 30–49: 93 degrees ± 13
- >50: 80 degrees ± 17

Thoracic Spine

Oftentimes, thoracic spine motion is measured simultaneously with lumbar spine motion using a variety of methods, none of which is really satisfactory. To objectively measure thoracic motion and differentiate thoracic spine motion from lumbar spine motion, the bubble goniometer techniques of the American Medical Association are recommended.[67]

Flexion

To measure thoracic flexion, two inclinometers are used and are aligned in the sagittal plane. T e center of the first inclinometer is placed over the T1 spinous process. T e center of the second one is placed over the T12 or L1 spinous process (Fig. 13-93). T e patient is asked to slump forward as though trying to place the forehead on the knees (Fig. 13-94), and both inclinometer angles are recorded. T e thoracic flexion angle is calculated by subtracting the T12 from the T1 inclinometer angle. T e patient should be able to flex approximately 50 degrees from the neutral position.[77,78] T e clinician observes for any paravertebral fullness during flexion, which might alter the measurement. T e thoracic spine during flexion should curve forward in a smooth and even manner, and there should be no evidence of segmental rotation or side bending. To decrease pelvic and hip movements, McKenzie advocates examining thoracic flexion with the patient seated.[79]

Extension

Clinical guidelines for measurements of thoracic extension recommend that ROM be defined with reference to the magnitude

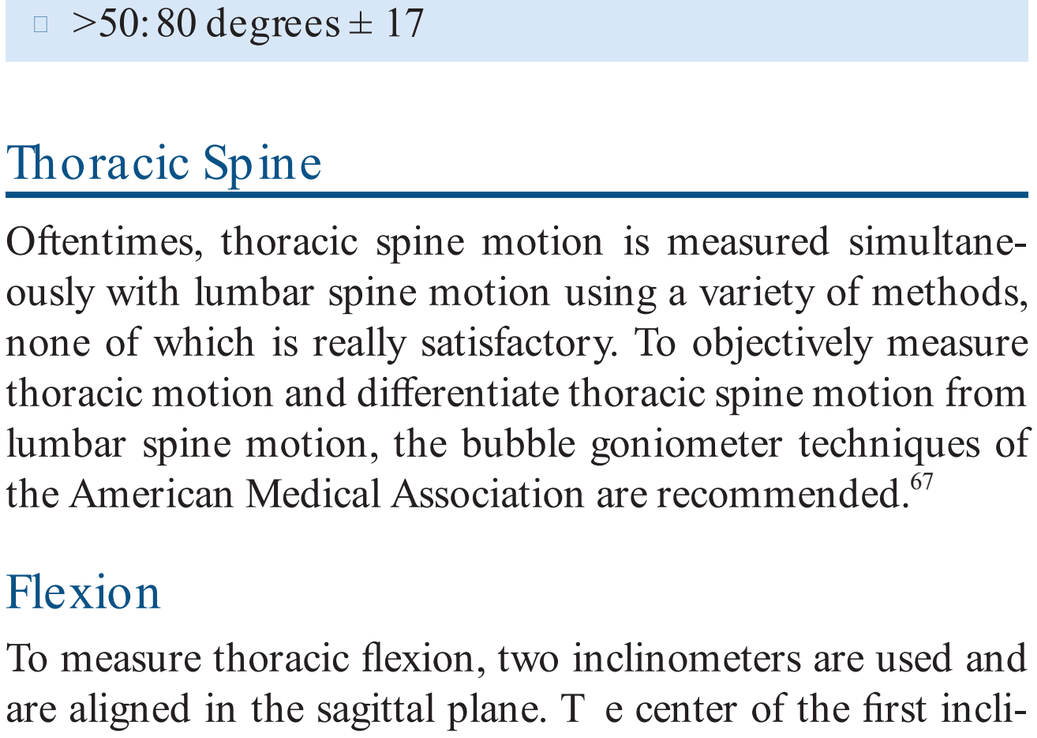

FIGURE 13-91 Goniometric measurement of cervical side bending to the left.

FIGURE 13-93 Bubble goniometer placement for the start position of thoracic flexion and extension.

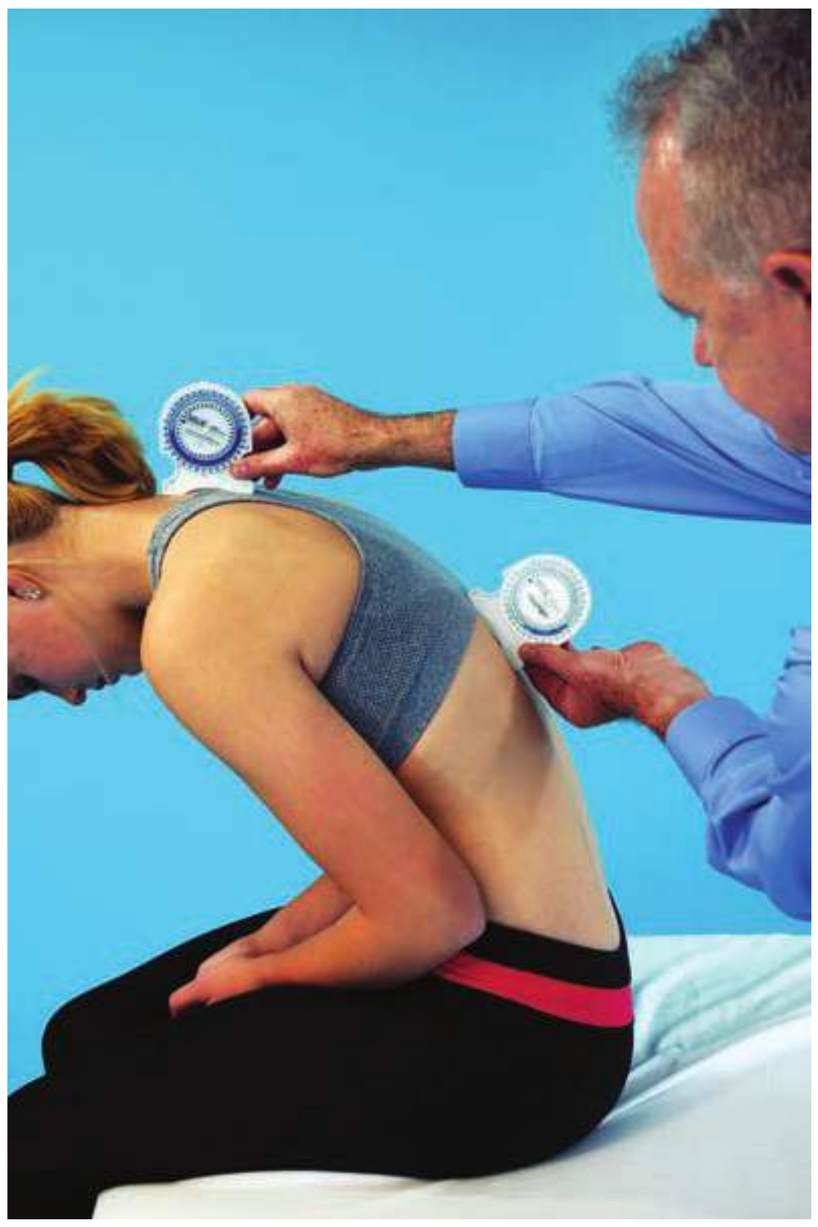

FIGURE 13-94 Goniometric measurement of thoracic flexion.

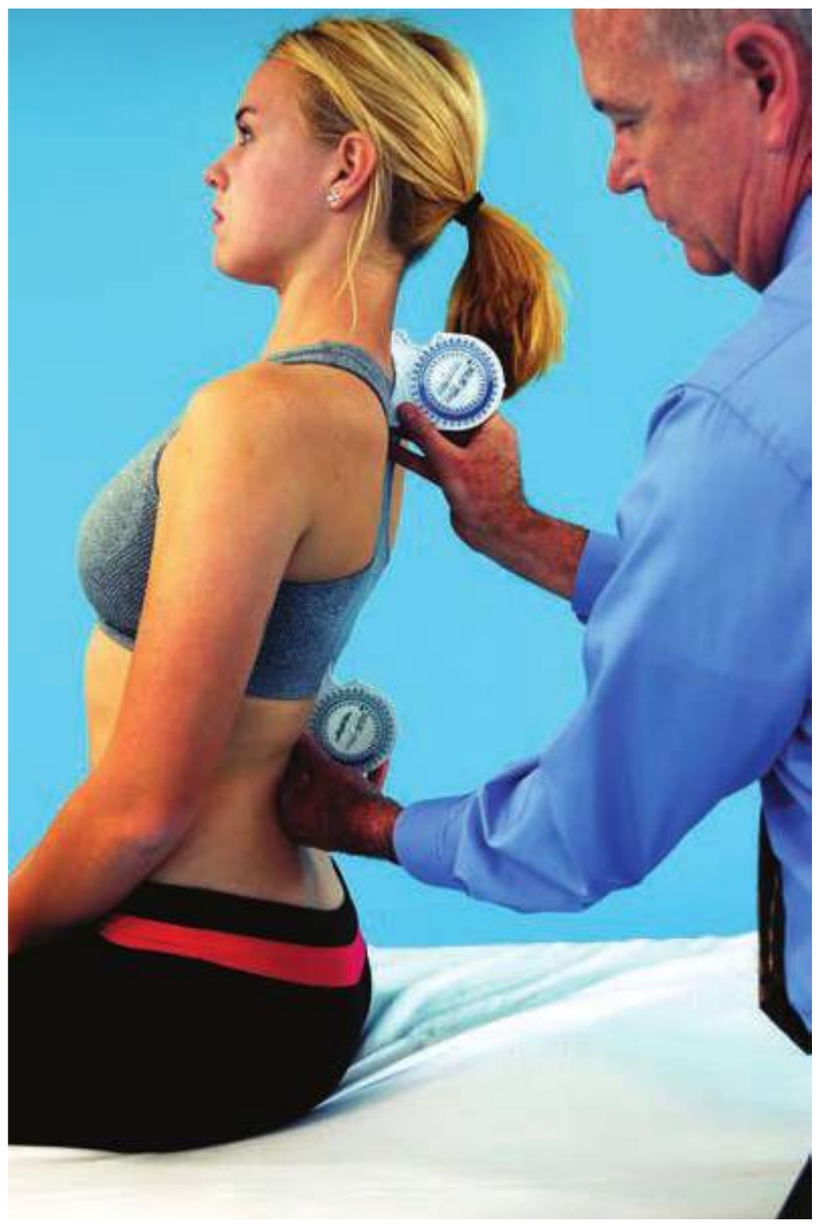

FIGURE 13-95 Goniometric measurement of thoracic extension.

of the kyphosis measured in standing. However, to date, the relationship between the magnitude of the thoracic kyphosis and the amount of thoracic extension movement has not been reported.[80] Thoracic extension may be measured using the same technique and inclinometer positions as described for flexion (Fig. 13-95). The thoracic extension angle is calculated by subtracting the T12 or L1 from the T1 inclinometer angle. The patient should be able to extend approximately 15–20 degrees from the neutral position.[78] Alternatively, the thoracic extension can be measured using a tape measure. The distance between two points (the C7 and T12 spinous processes) is measured. A 2.5-cm difference between neutral and extension measurements is considered normal.[81,82] During thoracic extension, the thoracic curve should curve backward or straighten. As with flexion, there should be no evidence of segmental rotation or side bending.

Rotation

Rotation is a primary movement of the thoracic spine and a key component of functional activities. Thoracic rotation can be measured objectively using a tape measure or two bubble goniometers.

Tape Measure Method. Pavelka[83] devised a simple objective clinical method to measure thoracolumbar rotation using a tape measure that can be used to detect asymmetries in the rotation. The tape is placed over the L5 spinous process and over the jugular notch on the superior aspect of the manubrium. A measurement is taken before and after full trunk rotation. The measurements from each side are then compared.

Bubble Goniometer Method. The patient is positioned in sitting, and is then asked to flex forward as horizontal as possible. One bubble goniometer is positioned at the T1 level and the other at the T12 level, both in the coronal plane. Both goniometers are zeroed out and then the patient is instructed to rotate the trunk to one side. The clinician records both the T1 and the T12 inclinations and subtracts the T12 from the T1 inclination to arrive at the thoracic rotation angle. The technique is then repeated to the opposite side. The patient should be able to rotate 30 degrees or greater from the neutral position.[84,85] Active thoracic rotation of fewer than 20 degrees can result in an impairment of function during activities of daily living involving the thoracic spine.[81]

Side Bending

Side bending can be measured objectively using a tape measure,[86] or using two bubble goniometers.

Tape Measure Method. Two ink marks are placed on the skin of the lateral trunk. The upper mark is made at a point where a horizontal line through the xiphisternum crosses the coronal line. The lower mark is made at the highest point on the iliac crest. The distance between the two marks is measured in centimeters, with the patient standing erect, and again after full ipsilateral side bending. The second measurement is subtracted from the first, and the remainder is taken as an index of lateral spinal mobility.

Bubble Goniometer Method. The patient is positioned in sitting, and one goniometer is placed flat against the T1 spinous process and the other flat against the T12/L1 spinous process (Fig. 13-96). Both goniometers are zeroed out and then the patient is asked to side bend the thoracic spine to the left side (Fig. 13-97) and then to the right side (Fig. 13-98). The T1 inclination angle is subtracted from the T12/L1 inclination angle to arrive at the thoracic side bending angle. The patient should be able to side bend 20–40 degrees from the neutral position.

FIGURE 13-96 Bubble goniometer placement for the start position of thoracic side bending.

FIGURE 13-98 Goniometric measurement of thoracic side bending to the right.

Lumbar Spine

Lumbar spine motion can be measured using a variety of methods.

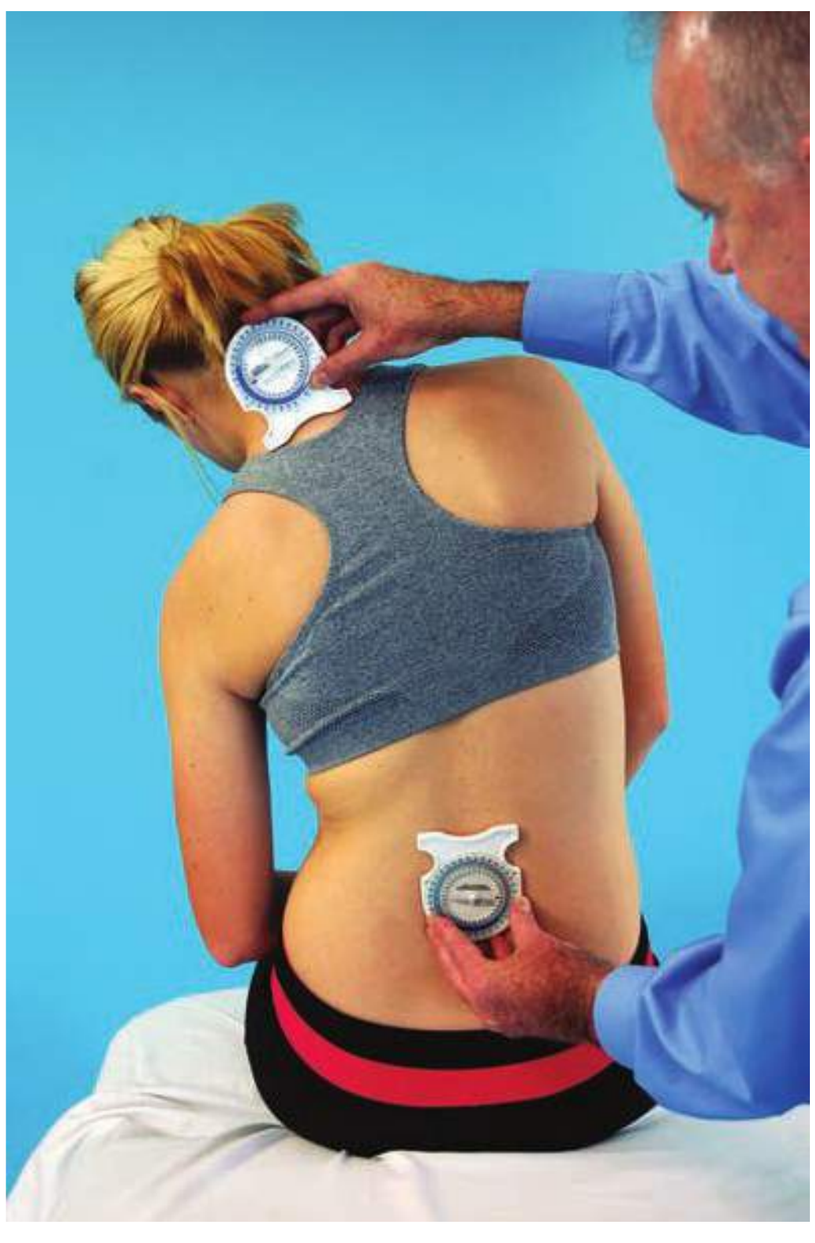

FIGURE 13-97 Goniometric measurement of thoracic side bending to the left.

Flexion and Extension

Flexion and extension can be measured using two bubble goniometers or a tape measure.

Tape Measure Method. Using the modified Schober technique, the patient is positioned in relaxed standing. A point is drawn with the skin marker at the spinal intersection of a line joining S1. Additional marks are made 10 cm above and 5 cm below S1 (Fig. 13-99). T e patient is then asked to bend forward, and the distance between the marks 10 cm above and 5 cm below S1 is measured (Fig. 13-100). Despite this method's simplicity, Reynolds[87] found this measurement of motion to have good reliability, with Pearson correlation coef cients of 0.59 for lumbar flexion and 0.75 for lumbar extension. In another study by Fitzgerald,[88] the Pearson correlation coef cient was found to

FIGURE 13-99 Start position for the modified Schober technique.

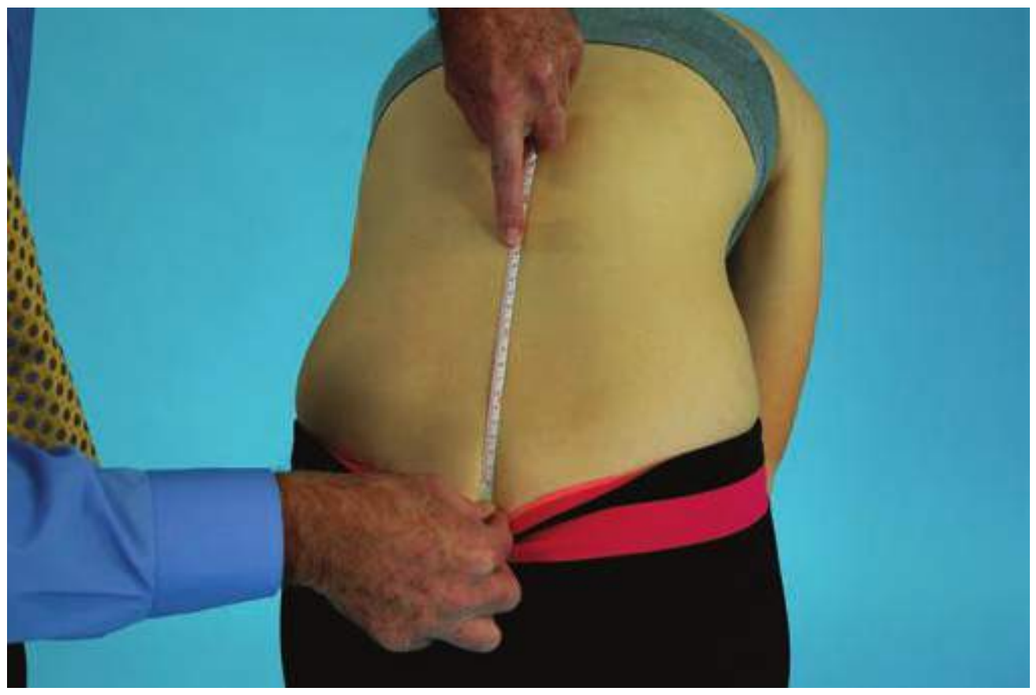

FIGURE 13-100 End position for the modified Schober technique.

be 1.0 for lumbar flexion and 0.88 for lumbar extension in a study of young, healthy subjects.

Bubble Goniometer Method. The patient is positioned in standing with the lumbar spine in a neutral position. The clinician places one bubble goniometer over the T12/L1 spinous process in the sagittal plane, and the other goniometer at the level of the sacrum, also in the sagittal plane (Fig. 13-101). Both goniometers are zeroed out, and the patient is then asked to flex the trunk forward (Fig. 13-102). The clinician notes the inclinations of both goniometers and subtracts the sacral inclination from the T12/L1 inclination to obtain the lumbar flexion angle. The patient is then asked to extend the trunk (Fig. 13-103). The clinician subtracts the sacral inclination from the T12/L1 inclination to obtain the lumbar extension angle. The normal ROM for flexion and extension vary according to patient age and gender.[89]

FIGURE 13-101 Bubble goniometer placement for the start position of lumbar spine flexion and extension.

FIGURE 13-102 Goniometric measurement for lumbar spine flexion.

Side Bending

Side bending can be measured with the patient standing with the feet together using a standard goniometer, a tape measure, or two bubble goniometers.

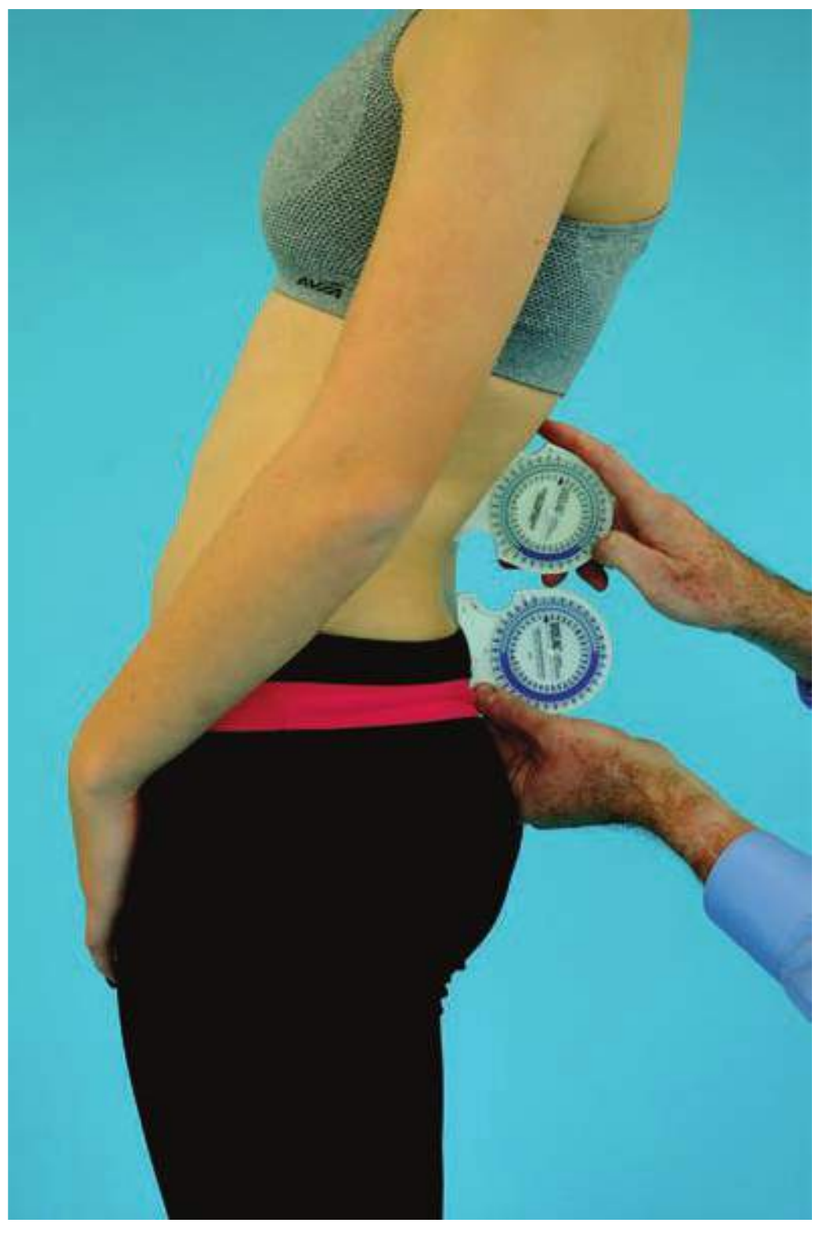

FIGURE 13-103 Goniometric measurement for lumbar spine extension.

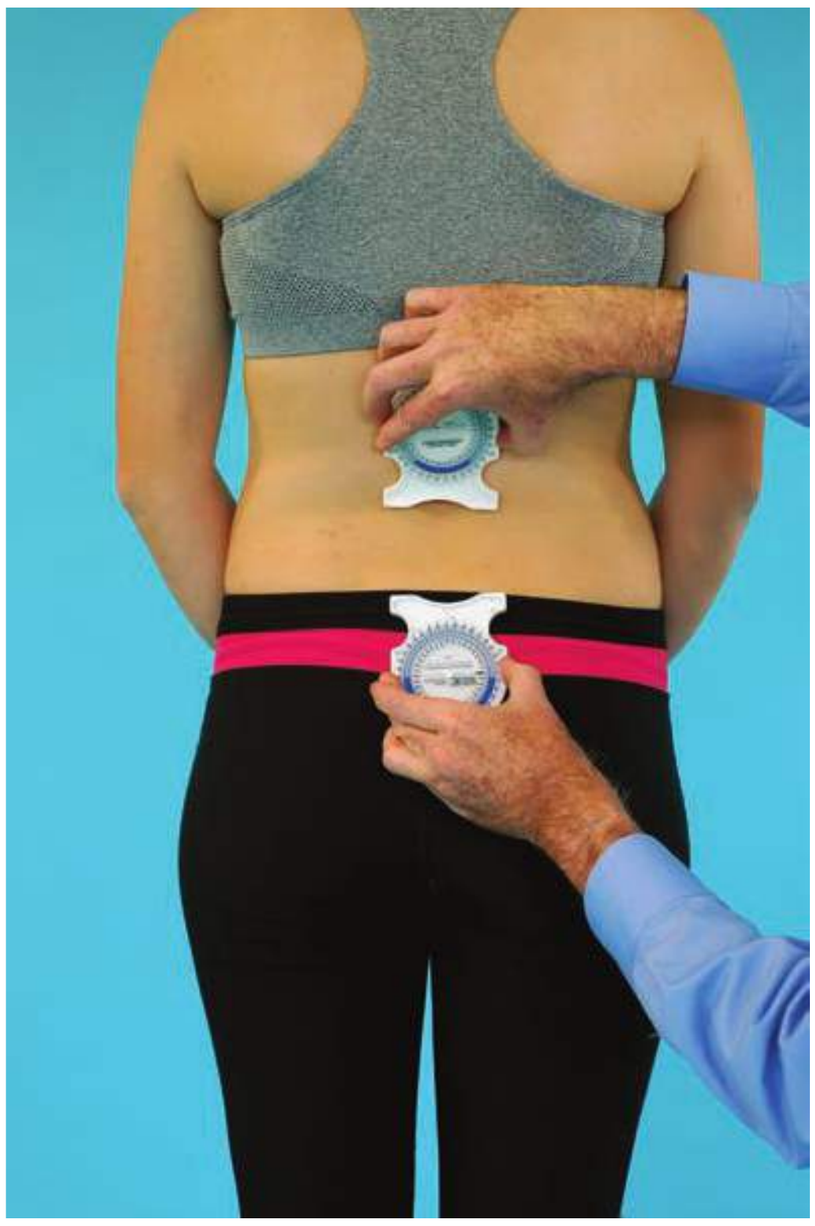

FIGURE 13-104 Bubble goniometer placement for the start position of lumbar spine side bending.

Standard Goniometer Method. The fulcrum is centered over the posterior aspect of the spinous process of S1, the proximal arm is aligned so that it is perpendicular to the ground, and the distal arm is aligned with the posterior aspect of the spinous process of C7.

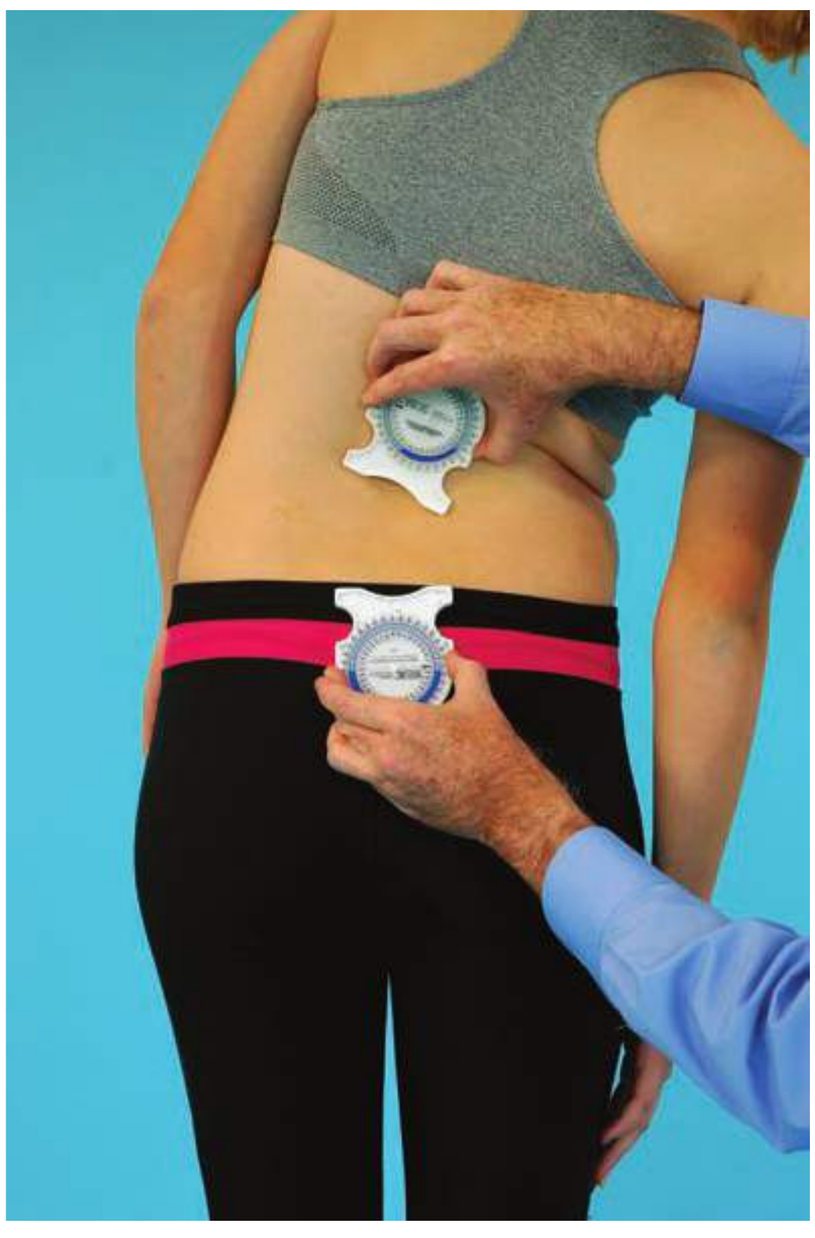

FIGURE 13-105 Goniometric measurement of lumbar spine side bending to the right.

FIGURE 13-106 Goniometric measurement of lumbar spine side bending to the left.

Tape Measure Method. A tape measure is used to measure the distance between the tip of the middle finger and the floor.

Bubble Goniometer Method. The clinician places one a goniometer flat at the T12/L1 spinous process in the coronal plane and the other goniometer at the superior aspect of the sacrum, also in the coronal plane (Fig. 13-104). Both goniometers are zeroed out and then the patient is asked to side bend the trunk to the right side (Fig. 13-105), and the inclination is recorded from both goniometers. The clinician subtracts the sacral inclination from the T12/L1 inclination to obtain the lumbar side bending angle. The technique is then repeated to the left side (Fig. 13-106). The normal ROM for flexion and extension vary according to patient age and gender.[88,90]

CHAPTER 14

Improving Neuromuscular Control

CHAPTER OBJECTIVES

At the completion of this chapter, the reader will be able to:

1. Define the components of neuromuscular control.
2. Describe ways in which neuromuscular control can be improved.
3. Describe a number of exercises that can be used to improve proprioceptive control.
4. Provide examples to enhance balance retraining.
5. Explain the concepts related to stabilization retraining.

OVERVIEW

The entire rehabilitation process is focused on restoring function as quickly and as safely as possible. An important component of function is neuromuscular control. Neuromuscular control involves the detection, perception, and utilization of relevant sensory information in order to perform specific tasks (see Chapter 3). It is now well accepted that a neuromuscular control impairment can change normal movement patterns and increase the risk of musculoskeletal injury. Successful performance of a task requires the intricate coordination of various body parts using the information provided by peripheral receptors located in and around the articular structures. This feedback provides information that assists with proprioception, balance, and kinesthesia (see Chapter 3). In terms of segmental joint control and spinal posture and orientation, each joint in the kinetic chain must have the ability to maintain the optimal alignment, biomechanics, and/or control required for the task being performed. If there is a loss of optimal alignment, biomechanics, and/or control, this is defined as *f*ailed load trans*f*er (FLT) at that joint.[1] While a single segmental loss of control often correlates with changes in posture orientation, multisegmental loss of control results in an inability to maintain the required spinal posture or orientation required for the task to be performed. The presence of a loss of segmental or multisegmental control involves an assessment of:

- whether there is adequate range of motion;
- whether there is sufficient strength output;
- whether there is the ability for automatic control of the joints in the kinetic chain that exhibit FLT;
- whether pain negatively impacts the performance of the task.

Neuromuscular rehabilitation (NMR) is a method of training used to enhance these unconscious motor responses, by stimulating both the afferent signals and the central mechanisms responsible for dynamic joint control.[2] The aims of NMR are to improve the ability of the nervous system to generate a fast and optimal muscle-firing pattern, to increase joint stability, to decrease joint forces, and to relearn movement patterns and skills.[2] Electromechanical delay (EMD) is defined as the time interval between the onset of electrical activity of the muscle and the mechanical response of the muscle.[3] It corresponds to the time needed for the contractile component in the muscle-tendon complex to initiate stretching of the elastic component series,[4] and its duration is related to the mechanical properties of the elastic component series (see Chapter 1).[5] The shorter the EMD duration, the faster the muscle force transmission and the better the performance and protective reflex. Significantly longer EMDs in the vastus lateralis, vastus medialis obliquus, and fibularis (peroneous) longus have been reported in patients with anterior cruciate ligament reconstruction,[6] patellofemoral pain syndrome,[5] and unstable ankles,[7] respectively, compared to healthy individuals. In addition, a number of studies have shown a decrease in EMD following neuromuscular reeducation training.[8–11]

Before developing an NMR program, the faulty movement pattern or absent motor skill must be identified.[12] In addition, individuals must have the adequate muscle strength to perform training exercises correctly. If weaknesses are present, training activities must begin at a more baseline level that includes weight training, technique instruction, and performing single plane versus multiplanar movements.[12] The three major components of NMR are proprioceptive retraining, balance retraining, and stabilization retraining.

PROPRIOCEPTIVE RETRAINING

Because the afferent input is altered after joint injury, proprioceptive training must focus on the restoration of proprioceptive sensibility to retrain these altered afferent pathways and

enhance the sensation of joint movement.[13] In designing exercises to improve three-dimensional dynamic upper and lower extremity postural stability, the clinician should consider the following:[4]

- Postural differences between patients
- Upper and lower extremity loading pathomechanics
- T e joint positions for optimal muscle moment arm lengths
- T e interplay between global and local proprioceptive mechanisms
- T e concept of rehabilitating movements that facilitate the development of synergistic upper and lower extremity muscle function[14]

Although ROM and progressive resistance exercises (PREs) help reestablish joint proprioception, they are not as effective in restoring function as exercises that involve a technique or task training. Technique or task training involves the performance of specific movements with an emphasis on proper technique, with a progression to weight shifting, and changing directions, and then more advanced techniques, such as performing a cut maneuver, as appropriate.[12] According to Voight and Blackburn,[13,15] the standard progression for proprioceptive retraining involves:

1. Static stabilization exercises with closed-chain loading and unloading (weight shif ing). T is phase initially employs isometric exercises around the involved joint on solid and even surfaces, before progressing to unstable surfaces. T e early training involves balance training and joint repositioning exercises and usually is initiated (in the lower extremities) by having the patient place the involved extremity on a 6–8-inch-high stool, so that the amount of weight bearing can be controlled more easily. T e proprioceptive awareness of a joint can also be enhanced by using an elastic bandage or orthotic, or through taping.[16–21] As full-weight-bearing through the upper or lower extremity is restored, a number of devices, such as a mini trampoline, balance board, Swiss ball, and wobble board, can be introduced to increase the level of dif culty.
2. Transitional stabilization exercises. T e exercises during this phase involve conscious control of motion without impact and replace isometric activity with controlled concentric and eccentric exercises throughout a progressively larger range of functional motion. T e physiologic rationale behind the exercises in this phase is to stimulate dynamic postural responses and increase muscle stiffness. Muscle stiffness has a significant role in improving dynamic stabilization around the joint, by resisting and absorbing joint loads.[22]
3. Dynamic stabilization exercises. T ese exercises involve the unconscious control and loading of the joint and introduce both ballistic and impact exercises to the patient.

A delicate balance between stability and mobility is achieved by coordination among muscle strength, endurance, flexibility, and neuromuscular control.[23] T e neuromuscular mechanism that contributes to joint stability is mediated by the articular mechanoreceptors (see Chapter 3). T ese receptors provide information about joint position sense and kinesthesia.[20,21,24,25] T e objective in NMR is to restore proximal stability, muscle control, and flexibility through a balance of proprioceptive retraining and strengthening.

Initially, closed kinetic chain exercises (CKCEs) are performed within the pain-free ranges or positions. Open kinetic chain exercises (OKCEs), including low-level plyometric exercises, may be built upon the base of the closed-chain stabilization to allow normal control of joint mobility (see Chapter 12).

T e neuromuscular emphasis during these exercises is on functional positioning during exercise rather than isolating open- and closed-chain activities.[23] T e activities should eventually involve sudden alterations in joint positioning that necessitate reflex muscular stabilization coupled with an axial load.[21,23] Such activities include rhythmic stabilization performed in both a closed- and an open-chain position[26] and in the functional position of the joint (see Chapter 12).[23] T e use of a stable, and then an unstable, base during CKCEs encourages cocontraction of the agonists and antagonists.[26]

Following treatment of any joint, retraining of the muscles must be carried out to reestablish coordination. Proprioceptive neuromuscular facilitation (PNF) techniques are especially useful in this regard. PNF techniques require motions of the extremities in all three planes.[27] PNF techniques that use combinations of spiral and diagonal patterns are designed to enhance coordination and strength.[28] T e diagonal patterns 1 and 2 (see Chapter 10) are appropriate, with resistance being added if needed.

BALANCE RETRAINING

Neuromuscular control and balance testing are described in Chapter 3. Deficits in the motor components of balance control can be caused by sensorimotor integration impairments, neuromuscular impairments, and deficits due to aging (see Chapter 3). As outlined in Chapter 3, impaired balance can be caused by injury or disease to any structures involved in the stages of information processing: somatosensory input, visual and vestibular input, sensory motor integration, and motor output generation.[29] Age-related balance dysfunctions can occur through a loss of sensory elements (degenerative changes in the otoconia of the utricle and saccule; loss of vestibular hair cell receptors), the ability to integrate information and issue motor commands (decreased number of vestibular neurons), and muscle weakness. Diseases common in aging populations can lead to further deterioration in balance function in some patients (Ménière's disease, benign paroxysmal positional vertigo [BPPV], cerebrovascular disease, vertebrobasilar artery insuf ciency, cerebellar dysfunction, and cardiac disease). Falls can be markers of poor health and declining function, and they are often associated with significant morbidity.[30] More than 90% of hip fractures occur as a result of falls, with most of these fractures occurring in persons older than 70 years of age.[30,31] One-third of community-dwelling elderly persons and 60% of nursing home residents fall each year.[32] Risk factors for falls in the elderly include increasing age, medication use, cognitive impairment, and sensory deficits.[30,33] Elderly persons who survive a fall experience significant morbidity.[34] Hospital stays are almost twice as

long in elderly patients who are hospitalized after a fall than in elderly patients who are admitted for another reason.[30,35]

Balance retraining focuses on the ability to maintain a position through both conscious and subconscious motor control. T ere are many factors to consider when developing an intervention program for balance impairment. T e clinician needs to consider the patient's impairments across all systems and decide which impairments can be rehabilitated and which require compensation or substitution.

It is also important to determine the cause of the impairment—whether the problem results from musculoskeletal, neuromuscular, sensory, or cognitive (e.g., fear of falling) impairment.[36] T e key elements of a comprehensive evaluation of individuals with balance problems include the following:[37]

- A thorough history of falls, including whether the onset of falls are sudden versus gradual; the frequency and direction of the falls; the environmental conditions, activities, presence of dizziness, vertigo, and lightheadedness at time of falls; current and past medications, and the presence of a fear of falling.
- Assessments to identify sensory input and/or sensory processing deficits, abnormal biomechanical and motor alignment, poor muscle strength and/or endurance, and decreased range of motion and/or flexibility. Of particular importance is core strength.[36]
- Assessment of coordination, and awareness of posture and the position of the body in space.
- Tests and observations to determine the impact of balance control system deficits on functional performance.
- Environmental assessments to determine full-risk hazards in a person's home.

Studies have shown that proprioception and kinesthesia do improve following rehabilitation.[20,38] For example, habituation exercises have proven beneficial for patients with acute unilateral vestibular loss, and adaptation and balance exercises have produced positive outcomes in patients with chronic bilateral vestibular deficits.[39] T e type of intervention will depend on the deficits found during the clinical examination and typically involves improving one or more of the following categories:[37]

- Static balance control
- Dynamic balance control
- Anticipatory balance control
- Reactive balance control
- Sensory reorganization
- Vestibular rehabilitation

Because balance training often involves activities that challenge the patient's limits of stability, it is important that the clinician takes steps to ensure the patient's safety. T is may necessitate the use of a gait belt, performing the exercises near a railing, and closely guarding the patient. Examples of agility and perturbations activities are outlined in Table 14-1. Balance training to promote static balance control during the early phase involves changing the base of support (BOS) of the patient while performing various tasks, first with their eyes open and then with the eyes closed. T e lower the center of gravity (COG), the more stable the patient feels. T us, the prone or supine positions provide the lowest COG and the most support, sitting the next, with standing providing the highest COG and the least support. T e usual progression employed in balance retraining involves a narrowing of the BOS while increasing the perturbation and changing the weight-bearing surface from hard to soft or from flat to uneven.

CLINICAL PEARL

It is important for the clinician to be aware of a number of factors that can affect balance and increase the risk of fall:

- Medications: the risk of falling can be increased when the patient is prescribed sedatives and antidepressants.
- Low vision: patients with balance issues should be advised to have regular eye examinations and to avoid areas with poor lighting.
- Sensory loss: sensory loss in the lower extremities, which can occur in conditions such as diabetes mellitus, can result in dif culties when walking on soft or uneven surfaces.

Balance training for adults usually begins in the short sitting position, which allows the feet to provide anterior support. T is position can be made more challenging by placing a wobble board or Swiss ball under the patient's buttocks. T e patient is then progressed to a quadruped position, through tall kneeling, and finally to the standing position. Balance training for the pediatric population usually begins in the "W" sitting position, then to "Indian-style sitting," then to a quadruped position, through tall kneeling, and finally to the standing position.

T e emphasis during these exercises is to concentrate on functional positioning during exercise rather than isolating open- and closed-chain activities.[23] T e activities should involve alterations in joint positioning that necessitate reflex muscular stabilization coupled with an axial load.[21,23] Such activities include rhythmic stabilization (an isometric contraction of the agonist followed by an isometric contraction of the antagonist) performed in both a closed- and an open-chain position,[26] and in the functional position of the joint.[23] T e use of a stable, and then unstable, base during closed-chain exercises encourages cocontraction of the agonists and antagonists.[26]

Weight-shifting exercises are ideal for this. For example, the following weight-shifting exercises may be used for the upper extremity:

- Standing and leaning against a treatment table or object.
- In the quadruped position, rocking forward and backward with the hands on the floor or on an unstable object.
- Slide board exercises in the quadruped position, moving the hands forward and backward, in opposite diagonals and in opposite directions.

Once the patient is able to stand, a structured sequence, such as the one that follows, is recommended.

- Static control of the trunk without extremity movement. T ese exercises involve closed-chain loading/unloading. T e patient is positioned in standing, with the feet

TABLE 14-1 Agility and Perturbation Training Examples

Activity	Progression
Sidestepping: the patient steps sideways, moving right to left and then left to right, approximately 10–20 ft, repeating two times in each direction for a total of four times.	The width of steps and the speed of steps are progressed every 1–2 sessions. The activity is initiated on a level surface and progressed to sidestepping over low obstacles when the patient is able to sidestep on level surfaces without difficulty.
Braiding activities: the patient combines front and back crossover steps while moving laterally (walking carioca). During each activity, the patient moves right to left and then left to right, approximately 10–20 ft, repeating two times in each direction for a total of four times.	The activity is progressed by increasing the width of steps and the speed of steps every 1–2 sessions.
Front and back crossover steps during forward ambulation: the patient crosses one leg in front of the other, alternating legs with each step, while walking forward approximately 10–20 ft. The patient then walks backward to the start position while crossing one leg behind the other, alternating legs with each step.	Two repetitions are performed, beginning with partial crossover steps and progressing to full crossover steps when the patient's performance improves. The width of steps and the speed of steps can be progressed every 1–2 sessions.
Shuttle walking: plastic pylon markers are placed at distances of 5, 10, and 15 ft. The patient walks forward to the first marker, then returns to the start by walking backward. The patient then walks forward to the 10-ft marker, then returns to the 5-ft marker walking backward. The patient then walks to the 15-ft marker, returns to the 10-foot marker walking backward, then finishes by walking to the 15-ft marker.	The activity is progressed by increasing the width of steps and the speed of steps every 1–2 sessions.
Multiple changes in direction on command during walking: the clinician directs the patient to either walk forward, backward, sideways, or on a diagonal by cueing the patient randomly with hand signals.	The duration of the exercise bout is approximately 30 seconds.
Double-leg foam balance activity: the patient stands on a soft firm surface with both feet on the ground and the clinician attempts to perturb the patient's balance in a random fashion.	The duration of the activity is approximately 30 seconds. The difficulty is progressed as the patient improves by progressing to ball catching with the clinician perturbing the patient's balance while standing on foam and progressing to single-leg support if tolerated.
Tilt board balance training: the patient stands on a tilt board with both feet on the board. The clinician perturbs the tilt board in forward and backward and side-to-side directions for approximately 30 seconds each.	The difficulty of the activity is progressed by adding ball catching during the perturbations and progressing to single limb support perturbations based on patient tolerance.
Rollerboard and platform perturbations: the patient stands with one limb on a stationary platform and the other limb on a rollerboard. The clinician perturbs the rollerboard in multiple directions, at random, and the patient attempts to resist the perturbations. The activity lasts approximately 30 seconds and is then repeated by changing the limbs on the platform and the rollerboard.	If the patient has difficulty doing the activity in full standing, the activity may begin with the patient in a semi-seated position, with the hips resting on the bed. The activity is progressed to the full standing position as tolerated.

Data from Fitzgerald GK, Piva SR, Gil AB, et al. Agility and perturbation training techniques in exercise therapy for reducing pain and improving function in people with knee osteoarthritis: a randomized clinical trial. Phys Ther. 2011;91(4):452–469.

positioned approximately shoulder-width apart. The purpose of the starting position is to provide a stable base for the proximal segments and trunk onto which challenges can be superimposed. For example:

- Manual perturbations to a stable trunk. The clinician applies gentle perturbations to the patient's trunk in different directions.
- Weight shifting while maintaining postural equilibrium. Initially, the patient, with the feet positioned approximately shoulder-width apart, is instructed to alternate transferring weight through one lower extremity then the other. Then the patient is asked to put one foot in front of the other and to transfer the weight from the rear foot to the front foot and back again.
- Dynamic control of trunk without extremity movement. For example, maintaining both feet on the ground while bending at the waist. As indicated, the range of motion is increased from a small range to a larger range.

Once this is mastered, the progression moves to exercises that incorporate static control of the trunk with extremity movement(s) superimposed using the following progression:

- Standing with the feet positioned approximately shoulder-width apart, the patient is asked to flex the hip and knee

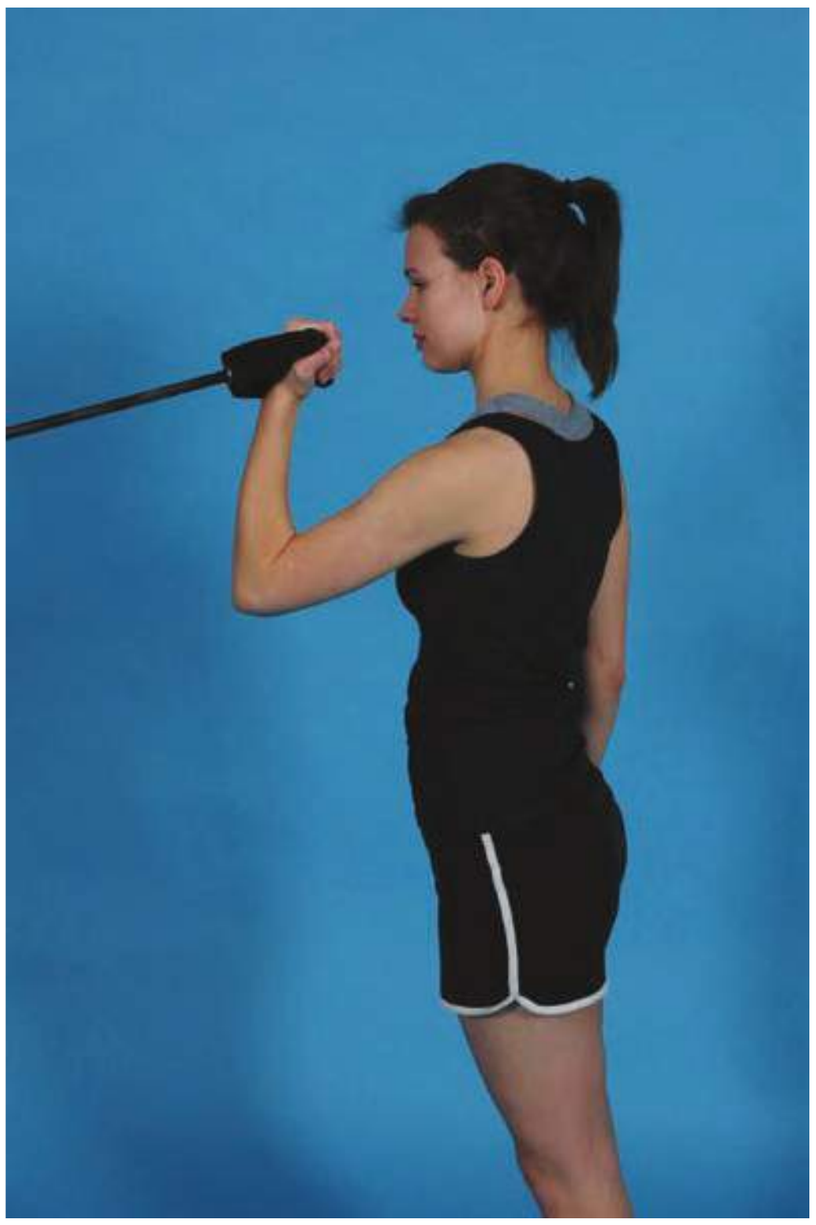

FIGURE 14-1 Forward weight shift exercise.

FIGURE 14-2 Lateral weight shift exercise.

so that the foot is approximately 6–8 in off the floor. T e exercise is repeated using the other leg. To add a challenge to the exercise, the patient can be trained with the eyes closed, or the patient can stand on an unstable surface.

- Standing with the feet positioned approximately shoulder-width apart, the patient grasps resistive-tubing with one hand and pulls the tubing toward the body using a smooth, comfortable motion (Fig. 14-1). T is produces a forward weight shift that is stabilized with an isometric counterforce consisting of hip extension, knee extension, and ankle plantarflexion.[40]
- T e patient stands sideways to the resistive-tubing. T e tubing is pulled by one hand in front of the body and the other hand behind the body to equalize the force and minimize the rotation (Fig. 14-2). T is causes a lateral weight shift, which is stabilized with an isometric counterforce consisting of hip abduction, knee cocontraction, and ankle eversion.[40]
- T e patient stands with his/her back to the tubing in the frontal plane (Fig. 14-3). T e tubing is pulled to the body from behind, causing a posterior weight shift, which is stabilized by an isometric counterforce consisting of hip flexion, knee flexion, and ankle dorsiflexion.[40]

T e aforementioned single plane exercises are progressed to multiplanar exercises in the following manner:

- PNF movement patterns are initiated using resistive-tubing. Initially the patient stands with both feet shoulder-width apart, and then the exercises are progressed so that the patient is standing on one leg. In addition to using resistive-tubing, medicine balls can be used.
- Ballistic extremity movements while maintaining trunk stability are introduced, first in sitting and then in standing. For example, maintain the sitting position while throwing a medicine ball (Fig. 14-4).

FIGURE 14-3 Posterior weight shift exercise.

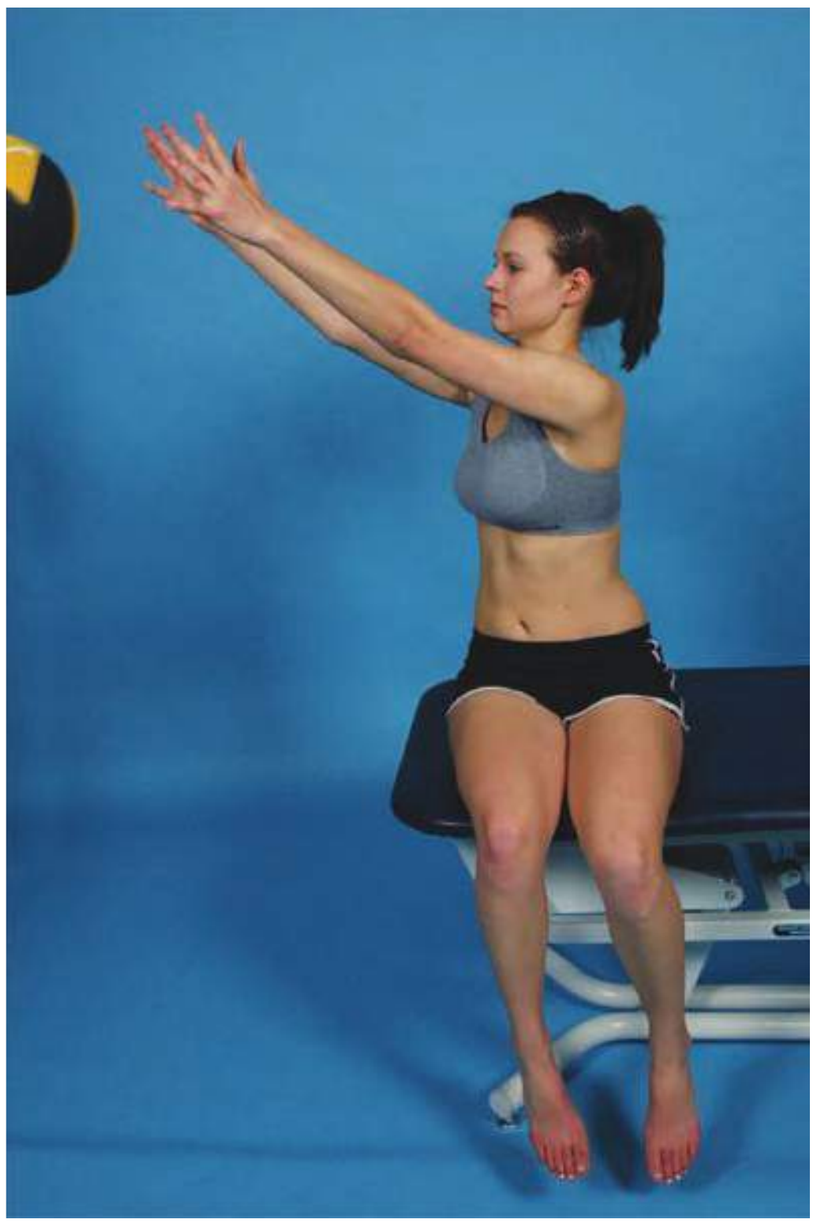

FIGURE 14-4 Medicine ball throw in sitting.

At the earliest opportunity, functional tasks must be incorporated. A typical functional activity progression includes:

- Closed-chain activities (squats, lunges) initially, then open-chain activities superimposed on the closed chain by adding extremity motions to the squats and lunges (Fig. 14-5).

FIGURE 14-5 Lunge with arms raised out to sides.

FIGURE 14-6 Hopping on one leg.

- Sit-stand-sit activities focusing on moving the body mass forward over the BOS, extending the lower extremities and raising the body mass over the feet, and then reversing the procedure.
- Stand-to-sit transitions focusing on balance control while pivoting and changing direction.
- Floor to standing raises using a progression of side-sit to quadruped to kneeling to half kneeling to standing.
- Gait activities: ambulating forward, backward, sideward at varying speeds and BOS widths (narrow to wide). Resisted walking and/or running can also be used.
- As appropriate, multidirectional drills, including jumping (two-foot takeoff followed by two-foot landing), hopping (one-foot takeoff followed by landing on the same foot) (Fig. 14-6), and bounding (one-foot takeoff followed by an opposite-foot landing).[40]

CLINICAL PEARL

Various clinical devices have been designed to assist with proprioceptive training for the upper and lower extremities. These include, but are not limited to:

- Mini trampoline (Fig. 14-7)
- Biomechanical ankle platform system (BAPS)®
- Foam rollers
- Wobble board
- Kinesthetic ability training device (KAT)®
- Fitter®, Rocker boards, or foam balance mats

FIGURE 14-7 Mini-trampoline standing on one leg.

STABILIZATION RETRAINING

Stability normally involves the interaction of three systems—the neurological or central control system, the passive or inert tissues (e.g., ligaments, capsule), and the contractile (muscular) or active system (see Chapter 3).[41] The neuromuscular mechanism that contributes to joint stability is mediated by the articular mechanoreceptors (see Chapter 3). These receptors provide information about joint position sense and kinesthesia.[20,21,24,25]

The neutral zone is a term used to define a region of laxity around the neutral resting position of a joint (see Chapter 2).[42] The neutral zone refers to the position of a joint in which minimal loading is occurring in the passive structures (all of the noncontractile elements of the joint, including the ligaments, fascia, joint capsules, and noncontractile components of muscle), and the contribution of the active system (the muscles and tendons which surround and control joint motion) is most critical.[43,44]

CLINICAL PEARL

The size of the neutral zone is determined by the integrity of the passive restraint and active control systems, which in turn are controlled by the neural system.[42] Studies have demonstrated that a larger than normal neutral zone caused by injury or microtrauma is related to a lack of segmental muscle control and is associated with injury.[42,45–48] Unfortunately, there is as yet no clinical method to measure the size of the neutral zone.

In both the spine and the extremities, certain muscles work as either mobilizers or stabilizers. The peripheral stabilizers rely on stabilization of the two primary dynamic bases or core structures—the pelvis and the scapula. The pelvis acts as a base for the whole body, especially for the spine and the lower limbs, whereas each scapula acts as a base for its respective upper limb.[41] During peripheral joint movement, the peripheral stabilizer muscles normally contract first to stabilize the core structures from which the mobilizers work.[41,49] The mobilizers then contract, resulting in a controlled movement pattern. For example, during upper extremity activity, the scapular stabilizers contract first to stabilize the scapula before the other shoulder muscles move the upper extremity into a functional position. However, with an injury, a pathologic process, or other abnormality, an abnormal stabilizer recruitment pattern can develop, resulting in a dominance of the mobilizer muscles and eventual weakening of the local stabilizers.[41,49]

For stabilization retraining to be effective, the clinician must, therefore, ensure that a stable base is present from which the mobilizers can act. Once the stabilizer muscles are functioning efficiently, training of the mobilizer muscles can begin using the following sequence: isometric to concentric, to eccentric, and ecocentric (pseudo-isometric) contractions, and finally to functional movement (see Chapter 12).[41]

CLINICAL PEARL

An ecocentric contraction occurs when a two-joint muscle shortens at one end while lengthening at the other end. An example involves the hamstrings when moving from standing to sit.

The body has several natural stabilization methods, including muscle contraction, muscle spasm, osteophyte formation, scar tissue formation, and adaptive shortening of inert tissue or muscle.[41] While the clinician cannot impact some of these natural stabilization methods such as muscle spasm, osteophyte, and scar tissue formation, the clinician can use muscle contraction and adaptive shortening to the patient's advantage.

Initially, closed-chain exercises are performed within the pain-free ranges or positions. Open-chain exercises may be built upon the base of the closed-chain stabilization to allow normal control of joint mobility. Stabilization retraining involves approximately 6 stages with 12 steps:[41,49,50]

- Stage 1. This stage typically occurs in the acute phase of healing.

  Step 1: Decrease pain. This can be accomplished through muscle relaxation techniques, patient education on joint resting positions and proper body mechanics, the use of electrophysical agents, working in the pain-free range, and the use of medication.[51]

  Step 2: Allow freedom of movement and proper arthrokinematic movement of the joint. This can be accomplished through joint mobilization (joint capsule), prolonged passive stretch (inert tissue and muscle), muscle energy techniques (muscle), active release techniques (muscle), high-velocity thrust techniques (joint), and neurodynamic techniques (nerve), depending on the tissue causing the restriction.[41]
- Stage 2. This stage is initiated once the pain is under control, and normal arthrokinematics are restored.

Step 1: Ensure that the individual muscles contract when and how they should, starting with an isometric contraction of the isolated muscle (stabilizers first). T e initial emphasis is directed toward strengthening any weak stabilizer muscles using the inner range or muscle test position.

Step 2: Ensure proper muscle recruitment and reeducation so that the muscles contract in the correct order—stabilizers first, then mobilizers. Once the patient can contract the muscle isometrically, concentric movement within the range that the patient has control using the mobilizers can be initiated, but only if the stabilizer muscles function properly.[41] Finally, training progresses to the use of eccentric contractions which allow the patient to maintain control of the base while lengthening during functional movements or slowing down a particular motion.[41]

Step 3: Ensure muscle imbalance between muscle groups to ensure that the various force couples work together correctly and function to enable control and eliminate incoordination. In general, to correct muscle length, one should exercise lengthened muscles in the inner range to shorten them, and stretch short muscles to lengthen them.[41]

- Stage 3. T is stage should only be initiated when the patient has learned to statically control the core structures.

  Step 1: Correct endurance and strength discrepancies. Exercises for stabilizer muscles may involve high-load, low-repetition training, although the focus should be on lower loads and high repetitions to build up resistance to fatigue.

- Stage 4. T is stage is typically initiated at the same time as Stage 3, provided the patient has successfully completed Stages 1 and 2 and can demonstrate control of the core.

  Step 1: Retrain proprioception. Proprioceptive retraining is outlined at the beginning of the chapter.

- Stage 5. T is stage involves the integration of five different steps into the program.[52]

  Step 1: Reeducate the stabilizing muscle statically. T is is achieved by ensuring proximal stabilization of the core while allowing distal movement through the extremities. Short arc movements are performed initially while the clinician observes for the expected proper sequence of muscle contractions (stabilizers then mobilizers), correct force-couple action, and good muscle cocontraction (static stabilization).

  Step 2: Teach advanced static stabilization exercises. T is involves taking the patient into the mechanism of injury position and asking him or her to hold the position statically against resistance.

  Step 3: Teach dynamic stabilization exercises. T is involves the use of controlled movement patterns to ensure the development of proper movement patterns (engrams—see Chapter 3) and voluntary control. Exercises during this step involve movement of the core, with the control muscles acting eccentrically while distal joints are moved concentrically through the full range of movement.

  Step 4: Teach advanced dynamic stabilization exercises. Exercises during this step include multidirectional stability training that require control of functional speeds, progressive eccentric exercises at functional speeds, and stressing of functional diagonal patterns used in the activities to which the person plans to return.

  Step 5: Teach functional stabilization. Functional activities are initially broken down into their component parts before performing the whole movement.

- Stage 6

  Step 1: Maintain or restore fitness throughout. Depending on the location of the injury, endurance exercises are prescribed for the upper extremities or lower extremities to improve or maintain cardiovascular fitness (see Chapter 15).

  Step 2: Return to sports or heavy manual labor as appropriate. In order to return to sport or heavy manual labor, there should be:[41]

  - Complete resolution of acute signs and symptoms
  - Suf cient dynamic, functional range of motion of all joints involved in the activity
  - Adequate strength, endurance, and proprioceptive/kinesthetic sense to perform the expected skills/tasks successfully
  - No alteration of the patient's normal mechanics that could predispose him or her to reinjury

CHAPTER 15

Improving Cardiovascular Endurance

CHAPTER OBJECTIVES

At the completion of this chapter, the reader will be able to:

1. Explain the importance of cardiovascular endurance in the overall health of an individual.
2. Describe the physiology of the cardiovascular system.
3. Explain how the FITT principle can be applied to cardiovascular training.
4. Explain how the various muscle types are involved with endurance and aerobic activities.
5. Outline the precautions with aerobic conditioning.
6. Discuss the various methods by which aerobic conditioning can be enhanced through a rehabilitation program.

OVERVIEW

Physical activity has been defined as "any bodily movement produced by the contraction of skeletal muscles that results in a substantial increase in resting energy expenditure."[1] When a person undertakes work or exercise, a number of body systems adapt to the demands of the required tasks, particularly the cardiorespiratory and neuromuscular systems.[2] The maximum work capacity of the cardiorespiratory system is a factor of the maximal amount of oxygen that can be taken in and used by the body, or $VO_{2\,max}$, whereas the capacity of the neuromuscular system is a factor of the maximum tension that can be developed by the working muscle, or muscles—the maximal voluntary contraction. Assessment of the cardiovascular system provides the clinician with the justification for monitoring or not monitoring activities during a patient's rehabilitation, or providing modifications in the exercise prescription.[3]

If our sedentary society is to change to one that is more physically active, clinicians must play their role in communicating with their patients the amounts and types of physical activity that are needed to prevent disease and promote health, because patients respect their advice.[4,5] Whenever possible, the clinician should address the impact on the patient resulting from the loss of physical activity. The loss of activity affects both the cardiovascular and the musculoskeletal systems and can occur very rapidly. Thus, it is important that the rehabilitation program includes exercises that maintain, or improve, the patient's cardiovascular endurance while monitoring safety concerns. Patients should be routinely counseled to adopt and maintain regular physical activity. While policy makers work to improve reimbursement for preventive services, clinicians should develop effective ways to teach physical activity counseling.[5] The personal physical activity practices of health professionals should not be overlooked. Health professionals should be physically active, not only to benefit their own health but also to make more credible their endorsement of an active lifestyle.[5]

PHYSICAL FITNESS

According to the Department of Health and Human Services, physical fitness is a set of attributes a person has in regard to his/her ability to perform physical activities that require aerobic fitness, endurance, strength, or flexibility and is determined by a combination of regular activity and genetically inherited ability.[6] Although commonly associated with the state of the cardiorespiratory system, which includes the ability to perform work or participate in activity over time using the body's oxygen uptake, delivery, and energy release mechanisms,[7] physical fitness also encompasses a number of attributes, including:[8]

- Muscle strength, which is the ability of muscles to exert or resist force (see Chapter 12).
- Muscle endurance, which is the ability of the muscle to perform work (see Chapter 12).
- Muscle power, which is the ability of a muscle to exert high force at high speed (see Chapter 12).
- Balance, which is the ability to maintain equilibrium when the body is static or moving (see Chapter 14).
- Agility, which is the ability to perform functional or powerful movements in opposite directions (see Chapter 14).
- Flexibility, which is the ability to stretch, easily bend, or be pliable (see Chapter 13).

PHYSICAL ACTIVITY

Physical activity is closely related to, but distinct from, the subsets of exercise and physical fitness. Exercise is defined as "planned, structured, and repetitive bodily movement done to improve or maintain one or more components of physical fitness."[1] T is differs from the definition of physical fitness, which is "a set of attributes that people have or achieve that relates to the ability to perform physical activity."[1] Regular physical activity has long been regarded as an important component of a healthy lifestyle, and it is well established from controlled experimental trials that active individuals have high levels of cardiorespiratory fitness. Intermittent activity provided it is continued also confers substantial benefits.[9–11] Studies have demonstrated that within a few weeks of discontinuing an endurance training program, the positive effects of exercise are almost completely lost, with approximately half of that loss occurring within the first 2 weeks.[12,13]

Clinical experience and limited studies suggest that people who maintain or improve their levels of physical activity may be better able to perform daily activities, may be less likely to develop pain, and may be better able to avoid disability, especially as they advance into older age.[5] Regular physical activity may also contribute to better balance, coordination, and agility, which in turn may help prevent falls in the elderly.[14] Epidemiologic research has demonstrated protective effects of physical activity and risk of several chronic diseases, including coronary heart disease,[9,15,16] hypertension,[17,18] non–insulin-dependent diabetes mellitus,[19,20] osteoporosis,[21,22] colon cancer,[23] and anxiety and depression.[24] Patterns of physical activity appear to vary with demographic characteristics. Men are more likely than women to engage in regular activity,[1] vigorous exercise, and sports.[25] T e total amount of time spent engaging in a physical activity normally declines with age.[1,26] Adults at retirement age (65 years) show some increased participation in activities of light-to-moderate intensity, but, overall, physical activity declines continuously as age increases.[1,27] Elderly African Americans, and other ethnic minority populations, are less active than white Americans,[28–30] and this disparity is more pronounced for women.[30] People with higher levels of education participate in more leisure-time physical activity than do people with less education.[1] Differences in education and socioeconomic status account for most, if not all, of the differences in leisure-time physical activity associated with race and ethnicity.[31]

CARDIOVASCULAR PHYSIOLOGY

Oxygen is a vital component of life, and the cardiovascular system provides a means by which oxygen is supplied to the various tissues of the body via the heart, blood vessels, blood, and lungs.

CLINICAL PEARL

The basal metabolic rate (BMR) is the amount of energy required to sustain the body at rest in a supine position. A kilocalorie (kcal) is a measure of expressing the energy value of food. Five kilocalorie equal approximately 1 L of oxygen consumed.[1] Thus, physical activity is measured as a ratio between the BMR and the fuel required to perform a particular task. This ratio is measured as a metabolic equivalent of the task (MET). A MET is defined as the oxygen consumed (milliliters) per kilogram of body weight per minute (mL/kg/min). Light work for the average male (65 kg) requires 2.0–4.9 kcal per minute or 1.6–3.9 METs. Moderate work for the average male is an activity performed at an intensity of 4–6 METs and is the equivalent of brisk walking at 3–4 mph for most healthy adults.[5] Heavy work for the average male requires 7.5–9.9 kcal per minute, or 6.0–7.9 METs.

By definition, cardiorespiratory endurance is the ability to perform whole body activities (walking, jogging, rowing, swimming, etc.) for extended periods of time without unwarranted fatigue. T e maximal amount of oxygen that can be used during exercise is referred to as maximal aerobic capacity ($VO_{2\,max}$). It is also common to see aerobic capacity expressed in METs.

A number of adaptations occur within the circulatory system in response to exercise:

- Heart rate (HR). As the body begins to exercise, the working tissues require an increased supply of oxygen to meet increased demand. Monitoring HR is an indirect method of estimating oxygen consumption as, normally, these two factors have a linear relationship (this relationship is consistent with very low and very high-intensity exercise). If a physical therapy intervention requires an increase in systemic oxygen consumption expressed as either an increase in MET levels, kcal, or $VO_{2\,max}$, then HR should also be seen to increase.[32] Increases in HR produced by exercise are met by a decrease in diastolic filling time. T e extent at which the HR increases with escalating workloads is influenced by many factors, including age, fitness level, type of activity being performed, body position, presence of disease, medications, blood volume, and environmental factors such as temperature, humidity, and altitude. Failure of the HR to increase with increasing workloads, referred to as chronotropic incompetence, should be of concern, even if the patient is taking beta blockers—beta blockers slow the HR, which can prevent the increase in HR that typically occurs with exercise.[32]
- Stroke volume (SV). SV is the amount of blood pumped out by the left ventricle of the heart with each beat (the difference between end-diastolic volume and end-systolic volume). T e volume of blood being pumped out with each beat increases with exercise, but only to the point when there is enough time between beats for the heart to fill up (approximately 110–120 beats per minute). In the normal heart, as workload increases, SV increases linearly up to 40–50% of aerobic capacity, after which it increases only slightly. Factors that influence the magnitude of change in SV include exercise intensity, body position, and ventricular function.
- Cardiac output (CO). CO is the amount of blood (approximately 5 L) discharged by each ventricle (not

both ventricles combined) per minute, usually expressed as liters per minute. CO, the product of HR and SV, increases linearly with workload because of the increases in HR and SV in response to increasing exercise intensity. During exercise, CO increases to approximately four times than that experienced during rest. Factors that influence the magnitude of change in CO include age, posture, body size, the presence of disease, and level of physical conditioning. A long-term beneficial training effect that occurs with regard to HR is a reduced resting HR and reduced HR at a standard exercise load. T is occurs because the heart becomes more ef cient—the SV increases, brought about by increased venous return, and increased contractile conditions in the myocardium.

- Blood flow. T e amount of blood flowing to the various organs increases during exercise, but there is a change in the overall distribution of the CO—it is increased to active skeletal muscle, but decreased to nonessential organs. Total peripheral resistance, the sum of all forces that resist blood flow within the circulatory system, decreases during exercise primarily because of the vessel vasodilation in the active skeletal muscles.[33]
- Blood pressure (BP). BP is defined as the pressure exerted by the blood on the walls of the blood vessels, specifically arterial blood pressure (the pressure in the large arteries). Systolic BP normally increases in proportion to oxygen consumption and CO, while diastolic BP normally shows little or no increase, or may decrease. Long-term aerobic training can result in reduced systolic and diastolic BP. Failure of the systolic BP to rise with an increase in intensity, referred to as exertional hypotension, is considered abnormal, and may occur in a patient with a cardiovascular problem. T e minimal change in diastolic BP is due primarily to the vasodilation of the arteries from the exercise bout. T us, the expansion in artery size may lower BP during the diastolic phase.[32]
- Oxygen consumption rises rapidly during the first minutes of exercise and levels off as the aerobic metabolism supplies the energy required by the working muscles. Myocardial oxygen consumption is a measure of the oxygen consumed by the myocardial muscle.[1]

CLINICAL PEARL

The body's demand for oxygen is determined by the heart rate, myocardial contractility systemic blood pressure, and afterload, the latter of which is determined by the central aortic pressure and left ventricular wall tension.

- Mitochondria: An increase in size and number of the mitochondria.
- Hemoglobin concentration. Oxygen is transported throughout the system attached to hemoglobin, an iron containing protein that has the capability of easily accepting or giving up molecules of oxygen as needed.[33] T e concentration of hemoglobin in circulating blood does not change with training; it may actually decrease slightly.[33] However, because training for improving cardiovascular endurance produces an increase in total blood volume, there is a corresponding increase in the amount of hemoglobin.
- Myoglobin: Increased myoglobin content.
- T e use of fat and carbohydrates: Improved mobilization and use of fat and carbohydrates.
- Lung changes that occur due to exercise.
  - An increase in the volume of air that can be inspired in a single maximal ventilation. Ventilation is the process of air exchange in the lungs.
  - An increase in the diffusing capacity of the lungs.

In contrast, deconditioning, which occurs with any extended illness or prolonged inactivity results in a number of negative changes to the cardiovascular system:

- A decrease in maximum oxygen consumption.
- A decrease in CO/SV.
- A decrease in total blood and plasma volume.

During physical exercise, energy turnover in skeletal muscle may increase by 400 times compared with muscle at rest and muscle oxygen consumption may increase by more than 100 times.[34] T e energy required to power this muscular activity comes from a number of energy systems (see Chapter 1).

RECOVERY

T e performance of any activity requires a certain rate of oxygen consumption, so that an individual's ability to perform an activity is limited by the maximal amount of oxygen the person is capable of delivering into the lungs.[33] Fatigue and recovery from fatigue are complex processes that depend on environmental (room temperature, air quality, and altitude), physical, physiologic and psychological factors, including the patient's health status, diet, and lifestyle (sedentary or active). T e physiologic factors include the adequacy of the blood supply to the working muscle and the maintenance of a viable chemical environment, whereas the psychological factors include motivation and incentive.[2] Certain disease processes can also affect fatigue. For example, multiple sclerosis typically allows a patient to function well during the early morning, but by midafternoon the patient can often become notably weak. Cardiopulmonary fatigue is likely to be caused a decrease in blood sugar (glucose) levels, a decrease in glycogen stores in the muscle and liver, and a depletion of potassium. T e threshold for fatigue is the level of exercise that cannot be sustained for indefinitely. After an intense exercise session, anaerobic energy sources must be replenished before they can be called on again to provide energy for muscular contraction. T e anaerobic energy sources of ATP–PCr and lactic acid are ultimately replenished by the oxidative energy system (see Chapter 1). T e extra oxygen that is taken and used to replenish the anaerobic energy sources after cessation of the exercise effort was previously referred to as the oxygen debt, but is now more accurately referred to as excess postexercise oxygen consumption (EPOC).

Adequate time for recovery from fatigue must be built into every intrasession and intersession exercise progression. In addition, the body needs to be prepared for a resumption

of the stresses and demands that the activity or exercise will place upon it. If not, when the patient returns to competitive sports or functional and work activities, fatigue may result in alterations in ef cient movements making the individual susceptible to injury.

PRECAUTIONS WITH AEROBIC CONDITIONING

As part of the initial assessment to identify individuals who should consult a physician before initiating an exercise program, the clinician should perform a health screening check or risk factor assessment. T e following are considered risk factors for cardiovascular disease[35]:

- High BP: > 140 mm Hg systolic, or > 90 mm Hg diastolic
- Smoking
- Elevated serum cholesterol: a total serum level > 200, LDL > 160 (individuals without heart disease, > 100 in individuals with heart disease), or HDL < 40 in men or < 50 in women
- Lack of regular exercise (three or more times per week of regular exercise or moderate physical activity)
- Family history (mother or father with heart disease or stroke before the age of 60 years)
- Stress (particularly personality factors of anger and hostility)
- Diabetes
- Obesity
- Sex: men are at greater risk than women until women reach menopause, then equal risk
- Age: increasing age increases risk

CLINICAL PEARL

In the case of a severe pulmonary disease, the cost of breathing can reach 40% of the total exercise oxygen consumption, thereby decreasing the amount of oxygen available for the exercising muscles.

Obese individuals should exercise at longer durations and lower intensities—they should be able to exercise while maintaining a conversation (talk test).

All patients should be monitored (i.e., HR, BP, and symptoms) during the initial assessment if they have been determined precarious to exercise based on any risk factor or healthy lifestyle assessment.

During exercise, the clinician should note normal clinical responses to progressively increasing aerobic exercise for every patient. T e magnitude of the change in cardiovascular responses during aerobic exercise is related to the physical activity status of the patient. For example, a patient whose HR takes longer than 5 minutes to return to resting levels after 2 minutes of exercise has poor cardiovascular function.[36] Once the individual has demonstrated normal vital signs and lack of symptoms with the activities, it may not be necessary to monitor further activities.

A number of precautions need to be taken when exercising patients who have been determined precarious to exercise. T ese include:

- An appropriate level of intensity must be chosen:
- Too high a level can overload the cardiorespiratory and muscular systems and potentially cause injuries or severe complications.
- Exercising at a level which is too high causes the cardiorespiratory system to work anaerobically, not aerobically. Initially, the patient should be exercising at a level with the HR at 60% of his or her maximum. If the patient is exercising within their target HR, they should be able to carry on a conversation.
- A suf cient period of time should be allowed for warm-up and cool-down to permit adequate cardiorespiratory and muscular adaptation.

CLINICAL PEARL

Conditioned individuals have a cardiovascular and pulmonary system that is more capable of delivering oxygen to sustain aerobic energy production at increasingly higher levels of intensity.

A rapid decline in cardiorespiratory fitness occurs during the first few weeks of deconditioning, for example, one study reported that 20 days of bed rest was associated with a 28% decrease in aerobic capacity.[37] The aforementioned decline in aerobic capacity after 20 days of bed rest was greater than that found after three decades of aging in the same subjects.[38]

Signs and symptoms of exercise intolerance include, but are not limited to:

- BP:
  - Systolic BP > 200–210 mm Hg
  - Drop in systolic BP > 20 mm Hg
  - Diastolic BP > 110 mm Hg
- HR:
  - Increase in HR > 50 bpm with low level activity
  - Significant arrhythmias
- Chest pain
- Nausea, vomiting
- Unusual or severe fatigue
- Syncope or moderate dizziness
- Marked dyspnea (2+ /4+)
- Severe claudication (grade III/IV)
- Cyanosis or severe pallor

CLINICAL PEARL

Currently, only a few studies have examined the acute effect of resistance exercise on cardiovascular function.[39,40] From these studies it has been found that the magnitude and directional change in cardiac volume and function during resistance exercise are, for the most part, opposite to those that occur during aerobic exercise.

TECHNIQUES FOR IMPROVING, MAINTAINING, AND MONITORING CARDIORESPIRATORY ENDURANCE

Aerobic conditioning is especially valuable for those who participate in sports that involve endurance.[41] Nirschl[42,43] recommends general body conditioning for patients, which provides the following benefits:

- Increased regional perfusion
- Neurophysiologic synergy and overflow
- Neurologic stimulation
- Minimization of the domino effect of weakness of adjacent structures
- Minimization of negative psychological effects
- Obesity control

Continuous Training—The FITT (Frequency, Intensity, Time, and Type) Principle

The determinants of any exercise program contain a number of different training factors that must be considered when attempting to maintain or improve cardiorespiratory endurance. The American College of Sports Medicine (ACSM) recommend using the components of the FITT principle as the parameters for an endurance training program.[1]

- Frequency: although there are no clear-cut guidelines provided on the most effective frequency of exercise for adaptation to occur, to see at least minimal improvement in cardiorespiratory endurance, it is necessary for the average person to engage in no less than three sessions per week, but this is dependent on the health and age of the individual. The frequency may be a less important factor than duration or intensity of exercise training.
  - If the intensity is kept constant, there appears to be no additional benefit from twice a week versus four times or three times a week versus five times per week.
  - If the goal is weight loss, 5–7 days per week increases the caloric expenditure more than 2 days per week.
- Intensity: the recommendations regarding training intensity, which can be determined based on the overload principle and the specificity of training principle (see Chapter 12) vary. Since aerobic capacity and HR are linearly related, the relative exercise intensity for an individual can be calculated as a percentage of the maximum function, using $VO_{2\,max}$ or maximum HR (HR max). It is now recognized that an individual's perception of effort (relative perceived exertion or RPE) is closely related to the level of physiological effort (see Chapter 12).[44,45] For aerobic activities, the exercise intensity should be at a level that is 40–85% maximal aerobic power ($VO_{2\,max}$) or 55–90% of maximal HR.[1] Seventy percent HR max is a minimal level stimulus for eliciting a conditioning response in healthy young individuals. It would appear that exercising at high intensity for a shorter period of time results in a greater improvement in the $VO_{2\,max}$ than exercising at a moderate intensity for a longer period of time. This must be weighed against the fact that as exercise approaches the maximum limit, there is an increase in the relative risk of musculoskeletal injury and cardiovascular complications.

CLINICAL PEARL

If an individual is taking medications that may affect heart rate and blood pressure responses (e.g., beta blockers), the Borg rating of perceived exertion is the only recommended method for prescribing exercise intensity.

Two other common methods of monitoring intensity are employed:

- Monitoring HR—two formulas are commonly used:
  - Maximum heart rate (MHR) reserve: this method uses the difference between the MHR and the resting heart rate (RHR), referred to as the maximum heart rate reserve (MHRR). When using this formula, the recommended intensity level range is 50–85% of $VO_{2\,max}$. For example, for a 40-year-old with an RHR of 65 bpm who wants to train at an intensity of 70%:
    - 220–40 = 180 bpm (MHR)
    - 180–65 = 115 bpm (MHRR)
    - (115 × 0.7) + 65 = 145 bpm
  - The age-adjusted maximum heart rate (AAMHR)[46]: MHR = 220 – patient's age. For example, for a 40-year-old, the MHR is 220 – 40 = 180. The recommended level of intensity when using this formula is a range between 60% and 90% of an individual's MHR. Therefore, the target heart range (60–90%) for an MHR of 180 is between 180 × 60% and 180 × 90% = 108–162 bpm.

CLINICAL PEARL

Tanaka and colleagues recently revealed that the AAMHR equation underestimates the actual maximal heart rate by 6–15 bpm in those individuals between 60 and 90 years of age.[47] Based on these findings a new formula has been derived to estimate the age-predicted maximal heart rate: 208 – (0.7 × age).[48]

- Calculating the $VO_{2\,max}$ or HR directly or indirectly:
  - 3-minute step test.
  - 12-minute run.
  - 1-mile walk test.

Regardless of which formula is used, the clinician should keep in mind that formulas are merely estimations (and highly inaccurate when used with patients taking prescribed medications that may affect HR and BP responses), and therefore, it is more important to monitor signs and symptoms and to be conservative in prescribing exercise intensity for any sedentary individual, elderly individual, or someone at moderate-to-high risk for cardiovascular disease.[3]

- Time (duration): the greater the intensity of the exercise, the shorter the duration needed for adaptation. The

converse is also true, the lower the intensity of the exercise, the longer the duration needed. For minimal improvement to occur, the patient must participate in a continuous activity for at least 20 minutes with an HR elevated to its working level. T ree to five minutes per day produces a training effect in poorly conditioned individuals, whereas 20–60 minutes, three to five times a week is optimal for conditioned people. Generally, the greater the duration of the workout, the greater the improvement in cardiovascular endurance.[33]

CLINICAL PEARL

Discontinuous training, also known as interval training, involves the use of repeated high-intensity exercise bouts that are interspersed with rest intervals. Although endurance levels can be improved with this method, more benefits are seen in the development of strength and power.

- Type of exercise: the type of activity chosen in continuous training must be aerobic—involving large muscle groups activated in a repetitive and rhythmic manner. Whenever possible, the type of exercise must closely match the activity to which the patient is returning. For example, running and jumping activities are more appropriate for a soccer player than swimming and cycling. Aerobic exercises allow the individual to speed up or slow down the pace to maintain the HR at a specified or target level.[33] Examples of aerobic activities are running, cycling, swimming, and cross-country skiing. Cross-training exercises, including cycling, upper body ergometer (UBE), and water running, increase cardiovascular endurance. However, it must be remembered that although cross training can produce a similar cardiovascular effort as the original sport, it does not necessarily produce the same musculoskeletal effects (Table 15-1).

TABLE 15-1 Comparison of Physiologic Adaptations to Resistance Training and Aerobic Training

Variable	Result Following Resistance Training	Result Following Endurance Training
Performance		
Muscle strength	Increases	No change
Muscle endurance	Increases for high-power output	Increases for low-power output
Aerobic power	No change or increases slightly	Increases
Maximal rate of force production	Increases	No change or decreases
Vertical jump	Ability increases	Ability unchanged
Anaerobic power	Increases	No change
Sprint speed	Improves	No change or improves slightly
Muscle fbers		
Fiber size	Increases	No change or increases slightly
Capillary density	No change or decreases	Increases
Mitochondrial density	Decreases	Increases
Fast heavy-chain myosin	Increases in amount	No change or decreases in amount
Enzyme activity		
Creatine phosphokinase	Increases	Increases
Myokinase	Increases	Increases
Phosphofructokinase	Increases	Variable
Lactate dehydrogenase	No change or variable	Variable
Metabolic energy stores		
Stored ATP	Increases	Increases
Stored creatine phosphate	Increases	Increases
Stored glycogen	Increases	Increases
Stored triglycerides	May increase	Increases
Connective tissue		
Ligament strength	May increase	Increases
Tendon strength	May increase	Increases
Collagen content	May increase	Variable
Bone density	No change or increase	Increases
Bone composition		
Percentage body fat	Decreases	Decreases
Fat-free mass	Decreases	No change

ATP, adenosine triphosphate.

Aerobic Training Methods

A typical exercise session is outlined in Chapter 12. Using the various exercise parameters outlined in this chapter that focus on improving cardiovascular endurance, the clinician can employ any of the following different aerobic conditioning training programs.

Continuous Training

Continuous training, or steady state, exercise is performed for 20-60 minutes with no rest interval at a submaximal energy requirement, and little variation in HR. A number of pieces of exercise equipment can be used with continuous training:

- Treadmill: progressing from slow to fast walking and short distances to longer distances with or without an incline. Treadmills are also available in pools and combined with vertical traction to better control the forces of gravity.
- UBE: A UBE, also called an arm bike, or arm ergometer is an excellent way of maintaining or improving aerobic fitness, or as a way to warm up the upper extremities prior to resistance training. UBEs work like a bicycle for the arms. Some models offer dual passive movement for the legs, which is controlled by the arms. One of the many benefits of ergometers is their availability to provide exercise for individuals who cannot use the lower extremities for physical activity (e.g., recovering from foot or leg injury/surgery, spinal cord injury, or multiple sclerosis). T ere are a number of training programs available when using the UBE depending on the intent. For example, steady state and high-intensity interval training can be used. In addition, time trial training can be used by setting a distance to be achieved (e.g., 1,000, 2,000, or 5,000 m) together with a speed and intensity level.
- Rowing: Rowing, whether performed on or off water, involves a continuous repetitive motion stressing various anatomic areas depending on the stroke phase (Table 15-2). Similar to training with the UBE, training programs, including steady state, time trial, and high-intensity interval training can be used. However, unlike the UBE, rowing requires both the upper and lower extremities to be injury-free. In addition, due to the fact that rowing is thought to be responsible for a high incidence of diskogenic back pain,[49] care must be used

TABLE 15-2 Rowing Phases and Muscle Activity

Stroke Phase	Description	Muscle Activity
The finish	The rowing stroke begins at "the finish" with the knees fully extended, the back in a laid-back position from vertical, with its relatively extended and the elbows fexed into the body at waist height	The rectus and external oblique muscles fire to stabilize the trunk which is in the extended position
Early recovery	Begins with movement of the hands away from the body toward the feet	With the body in a forward position and the knees and hips fexing and compressing, there is little to no activity from the paraspinal muscles. The hamstrings fire submaximally to fex the knees and to initiate the movement back up the slide to the catch position
Late recovery	Forward fexion at the hip and forward movement of the spine	
The catch	Begins when the body and shoulders are forward of the hips, the hands are past the knees, and the leg slowly begin to fex until the catch position is reached with the knees fexed approximately 110–120 degrees, the hip is maximally fexed, and the elbows are fully extended	The back acts as a brace cantilever and provides an additional source of power by extending from 30 degrees of fexion at the catch to approximately 30 degrees of extension at the finish
Early drive	The legs begin to drive the body back	The back, shoulder, and arms function as a brace cantilever so that the force generated by the legs can be applied to the oar/machine handle. The rectus femoris and lumbar/thoracic paraspinal muscles initiate the drive phase, with the former providing the power, and the latter stabilizing the spine to enable the transfer of the force. As the knees and hips extend during the drive phase, the gluteus maximus and hamstrings fire, controlling the drive and stabilizing the pelvis.
Late drive	The legs continue to drive the body back until "the finish" position is reached

in its prescription. The initial warm-up should be long and slow prior to training with intensity, distance, and frequency adjustments

- Indoor stationary cycling: As its name suggests, indoor stationary cycling involves cycling on a machine against some form of mechanical resistance. In the same way the UBE can be used to warm up the upper extremities prior to resistance training, stationary cycling can be used to warm up the lower extremities for the same purpose. Stationary cycling also allows individuals to maintain or improve their cardiovascular endurance when they cannot use the upper extremities for physical activity.
- Free weights and elastic resistance: the use of low resistance and high repetitions can produce an aerobic effect.

Interval Training

Interval training, or discontinuous training, involves the use of repeated high-intensity exercise bouts that are interspersed with rest intervals, which is perceived to improve strength and power more than endurance. With appropriate spacing of work and rest intervals, a significant amount of high-intensity work can be achieved and is greater than the amount of work accomplished with continuous training. The longer the work interval, the more the anaerobic system is stressed and the duration of the rest period is more important. In a short work interval, a work recovery ratio of 1:1 or 1:5 is appropriate to stress the aerobic system.

Circuit Training

The fundamental feature of circuit training is the use of a series of different exercise activities. Circuit training incorporates a wide variety of modes of training and uses high repetitions and low weight to provide a more general conditioning program aimed at improving body composition, muscular strength, and some cardiovascular fitness.

SECTION IV

The extremities

CHAPTER 16 The Shoulder

Chapter Objectives

At the completion of this chapter, the reader will be able to:

1. Describe the anatomy of the joints, ligaments, muscles, blood, and nerve supply that comprise the shoulder complex.
2. Describe the biomechanics of the shoulder complex, including the open- and close-packed positions, muscle force couples, and the static and dynamic stabilizers.
3. Describe the relationship between muscle imbalance and functional performance of the shoulder.
4. Describe the purpose and components of the tests and measures for the shoulder complex.
5. Perform a comprehensive examination of the shoulder complex, including history, systems review, palpation of the articular and soft-tissue structures, specific passive mobility tests, passive articular mobility tests, and special tests.
6. Evaluate the key findings from the examination data to establish a physical therapy diagnosis and prognosis.
7. Summarize the various causes of shoulder dysfunction.

Overview

The shoulder is the most rewarding joint in the body because when a limited or painful movement is found, the finding is seldom ambiguous and often implicates the offending structure.

—James Cyriax, MD (1904–1985)

The primary function of the shoulder complex is to position the hand in space, thereby allowing an individual to interact with his or her environment and to perform fine motor functions. An inability to position the hand results in profound impairment of the entire upper extremity.[1]

Secondary functions of the shoulder complex include the following:

- Suspending the upper limb.
- Providing sufficient fixation so that motion of the upper extremity or trunk can occur.
- Serving as a fulcrum for arm elevation. Three types of arm elevation are recognized: an upward motion of the upper extremity in the scapular plane (scaption) and the motions in either the coronal plane (abduction) or in the sagittal plane (flexion).

The shoulder is endowed with a unique blend of mobility and stability. Optimal functioning of the shoulder and arm can only take place if a delicate balance between the mobility and stability is maintained. The degree of mobility is contingent on a healthy articular surface, intact muscle–tendon units, and supple capsuloligamentous restraints. The degree of stability is dependent on intact capsuloligamentous structures, proper function of the muscles, and the integrity of the osseous articular structures.[1]

Anatomy

The shoulder complex functions as an integrated unit, involving a complex relationship between its various components. The components of the shoulder joint complex consist of (Fig. 16-1):

- three bones (the humerus, the clavicle, and the scapula);
- three joints (the sternoclavicular [S-C], the acromioclavicular [A-C], and the glenohumeral [G-H] joints);
- one "pseudojoint" (the articulation between the scapula and the thorax);
- one physiological area (the suprahumeral or subacromial space).

For optimal shoulder function, cervicothoracic junction motions, and motions at the connections between the first three ribs and the sternum and spine must be available.

GLeNOh Umer AL JOiNT

T e G-H joint is a true synovial joint that connects the upper extremity to the trunk, as part of the upper kinetic chain. T e G-H joint is described as a ball and socket joint—the humeral head forms roughly half a ball or sphere (Fig. 16-1), whereas the glenoid fossa forms the socket.

T e head of the humerus faces medially, posteriorly, and superiorly with the axis of the head forming an angle of 130–150 degrees with the long axis of the humerus (Fig. 16-2).[2] In the frontal plane, the head of the humerus is angled posteriorly (retroverted) by 30–40 degrees.[3,4] T e joint capsule of the G-H joint is lax inferiorly to permit full elevation of the arm.

T e glenoid fossa of the scapula faces laterally, superiorly, and anteriorly at rest and inferiorly and posteriorly when the arm is in the dependent position (Fig. 16-3).[5] T e glenoid fossa is flat and covers only one-third to one-fourth of the surface area of the humeral head. T is arrangement allows for a great deal of mobility but little in the way of articular stability. However, the glenoid fossa is made approximately 50% deeper (doubling the depth of the glenoid fossa across its equatorial line)[6] and more concave by a ring of fibrous cartilage[7] and dense fibrous collagen[8] called a labrum. T e labrum forms a part of the articular surface and is attached to the margin of the glenoid cavity and the joint capsule.[9] It is also attached to the lateral portion of the biceps anchor superiorly.[10] In addition, approximately 50% of the fibers of the long head of the biceps (LHB) brachii originate from the superior labrum (the remainder originates from the superior glenoid tubercle),[8] with four different variations identified,[11] and continue posteriorly to become a periarticular fiber bundle, making up the bulk of the labrum.[10,12] T e labrum enhances joint stability by increasing the humeral head contact areas to 75% vertically and 56% transversely.[5,9] T e humeral–glenoid contact area provides two primary functions:[13] it spreads the joint loading over a broad area, and it permits movement of opposing joint surfaces with minimal friction and wear.[14] However, because the humeral head is larger than the glenoid (Fig. 16-3), at any point during elevation, only 25–30% of the humeral head is in contact with the glenoid, with the greatest contact occurring

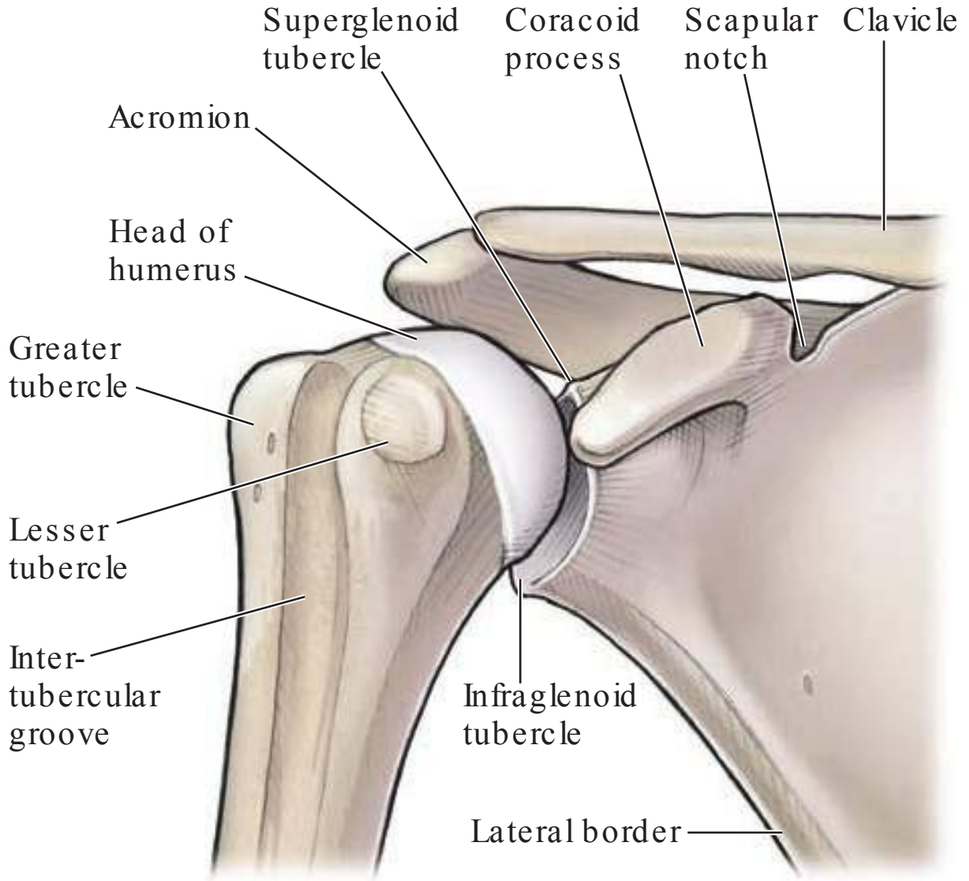

FIGURE 16-3 Glenohumeral joint. (Reproduced, with permission, from Chapter 30. Shoulder and Axilla. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

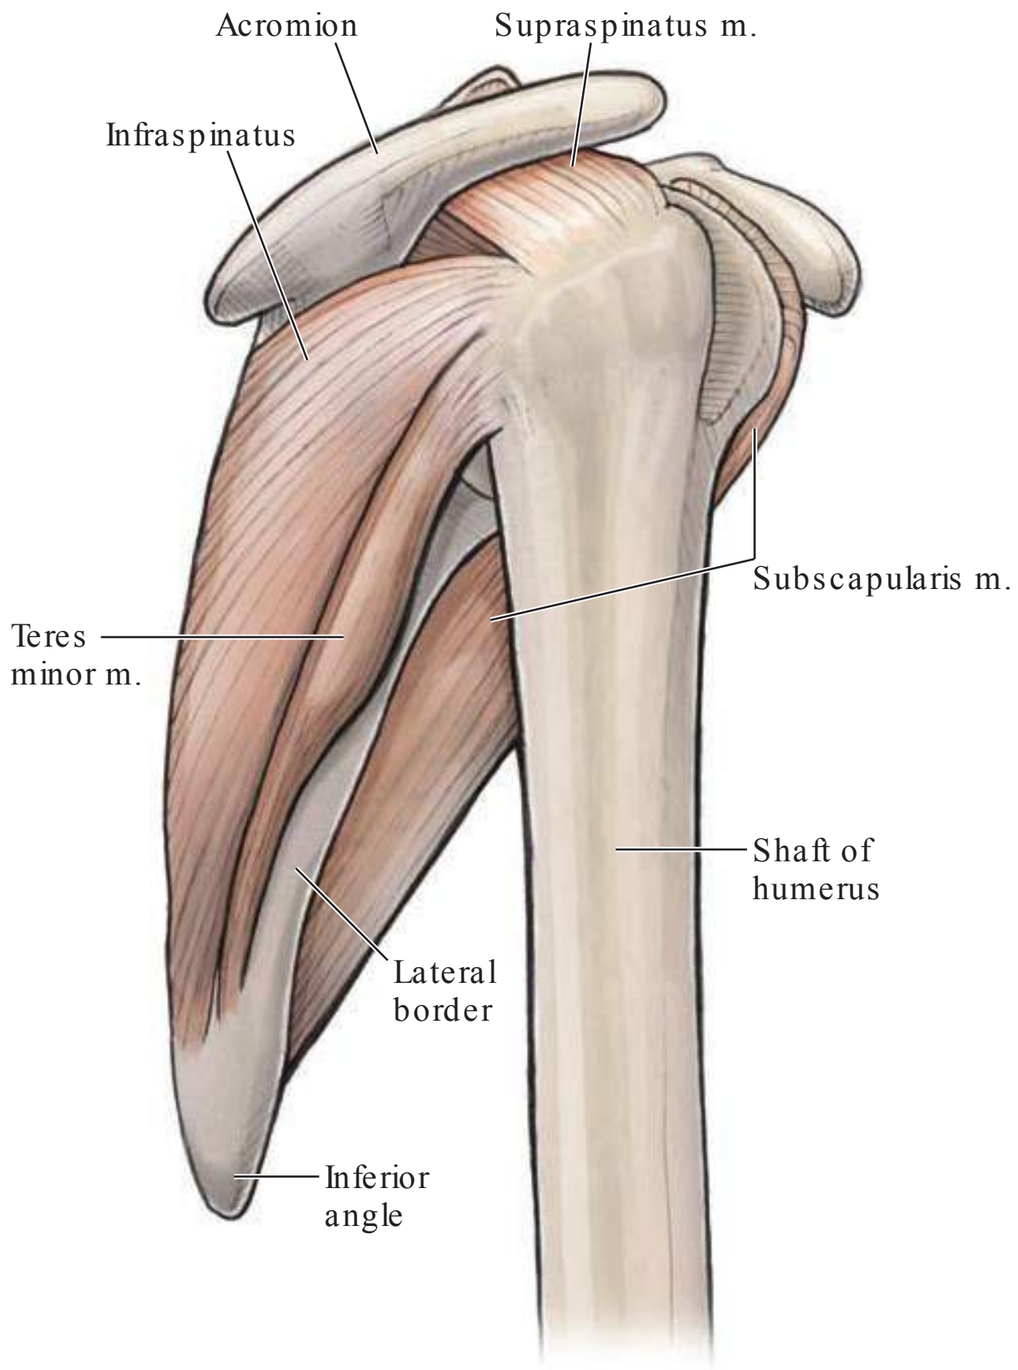

FIGURE 16-4 Rotator cuff muscles. (Reproduced, with permission, from Chapter 30. Shoulder and Axilla. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

during elevation rather than at the extremes. Contact between the humeral head and glenoid fossa is significantly reduced when the humerus is positioned in[15–17]:

- adduction, flexion, and internal rotation (IR);
- abduction and elevation;
- adducted at the side, with the scapula rotated downward.

Although the labrum provides some stability for the G-H joint, additional support is provided by both dynamic and static mechanisms. The dynamic mechanisms include the muscles of the rotator cuff (supraspinatus, infraspinatus, teres minor, and subscapularis muscles) (Fig. 16-4) and a number of muscle force couples described later. The static mechanisms, which include reinforcements of the joint capsule, joint cohesion and geometry, and ligamentous support, are also described later.

The scapula (Fig. 16-1) functions as a stable base from which G-H mobility can occur. The scapula is a flat blade of bone that is oriented to contribute to stability: it lies along the thoracic cage at 30 degrees to the frontal plane (Fig. 16-2), 3 degrees superiorly relative to the transverse plane to augment functional reaching motions above shoulder height,[18] and 20 degrees forward in the sagittal plane.[19–21] This orientation results in arm elevation occurring in a plane that is 30–45 degrees anterior to the frontal plane. When elevation of the arm occurs in this plane, the motion is referred to as scapular plane abduction or scaption.

CLiNiCAL PeArL

It has been recommended that many strengthening exercises for the shoulder joint complex be performed in the scapular plane. Reasons for this include:

- When the limb is positioned in the plane of the scapula, the mechanical axis of the glenohumeral joint is in line with the mechanical axis of the scapula, and movement of the humerus in this plane is less limiting than in the frontal or sagittal planes because the glenohumeral capsule is not twisted.[22,23]
- Because the rotator cuff muscles originate on the scapula and attach to the humerus, the length–tension relationship of these muscles is improved in this position.

The scapula's wide and thin configuration allows for its smooth gliding along the thoracic wall and provides a large surface area for muscle attachments both distally and proximally.[24] In all, 16 muscles gain attachment to the scapula (Table 16-1). Six of these muscles, including the trapezius, rhomboids, levator scapulae, and serratus anterior, support and move the scapula, while nine of the other ten (the omohyoid is not included) are concerned with G-H motion.[25–27]

Posteriorly, the scapula is divided by the elevated scapula spine into two unequally sized muscle compartments. The supraspinous fossa is small and serves as the site of origin for the supraspinatus muscle (see Fig. 16-4). The infraspinous fossa gives attachment for the downward-acting infraspinatus and teres minor muscles (see Fig. 16-4), important muscles for the stabilization of the humeral head (see "Muscles of the Shoulder Complex" section). The spine of the scapula (see Fig. 16-1) provides a continuous line of attachments for the supporting trapezius muscle along its upper border, whereas the deltoid muscle, which suspends the humerus, gains origin from its lower border. The undersurface of the scapula is covered by the subscapularis muscle (see Fig. 16-4), which also assists in stabilizing the humeral head against the glenoid fossa.

A prominent feature of the scapula is the large overhanging acromion (see Fig. 16-3), which, along with the coracoacromial ligament and the previously mentioned labrum, functionally enlarges the G-H socket. The position of the acromion also places the deltoid muscle in a dominant position to provide

TABLE 16-1 Muscles of the Scapula

muscular support during elevation of the arm. Bigliani et al.[21,28] introduced the following acromion types:

- Type I has a relatively flat undersurface
- Type II is slightly convex
- Type III is hooked

The distance, or angle, between the scapula and the clavicle is variable and depends on function. While the shoulder is protracted, the angle is 50 degrees. At rest, the angle is approximately 60 degrees, and with retraction the angle increases to 70 degrees.[3]

Along the medial border of the scapula arise three muscles: the two rhomboid muscles and the serratus anterior (Fig. 16-5),

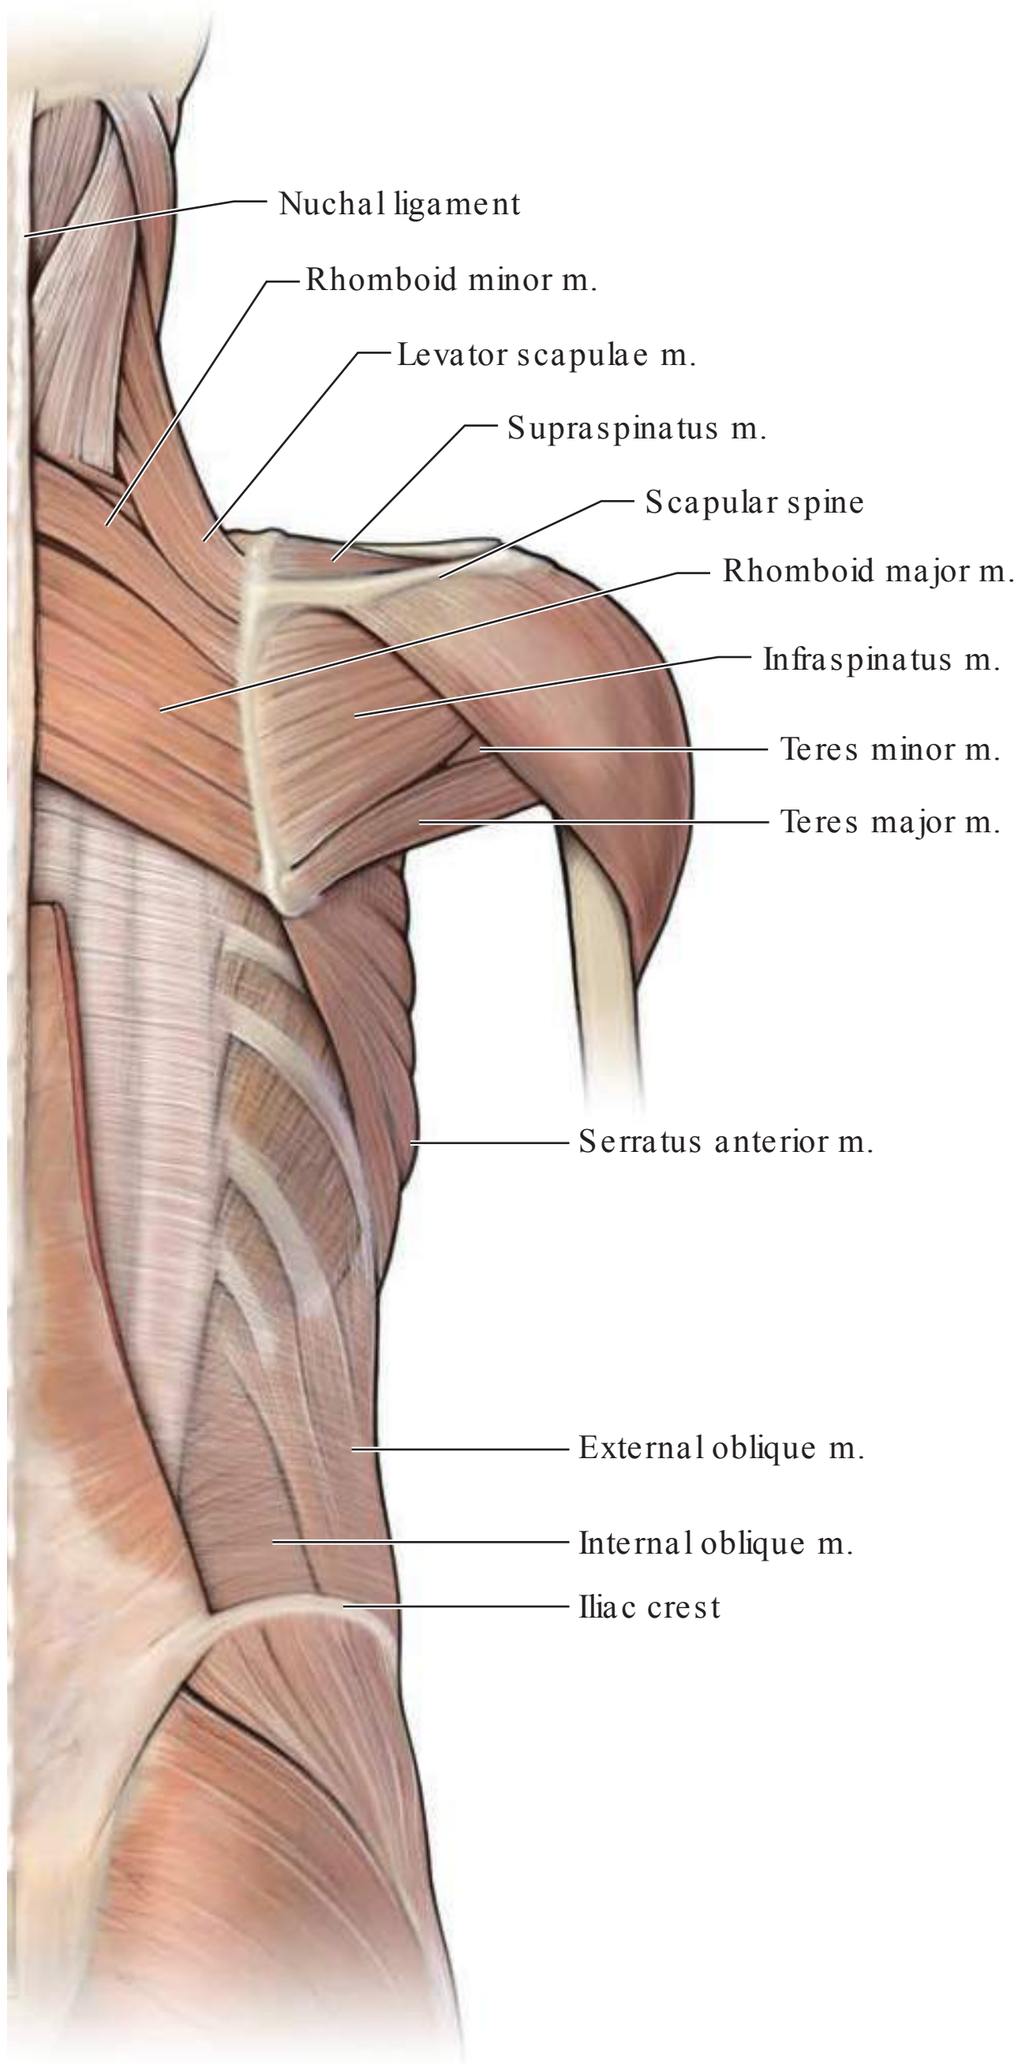

FIGURE 16-5 Rhomboid muscles and serratus anterior. (Reproduced, with permission, from Chapter 1. Back. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

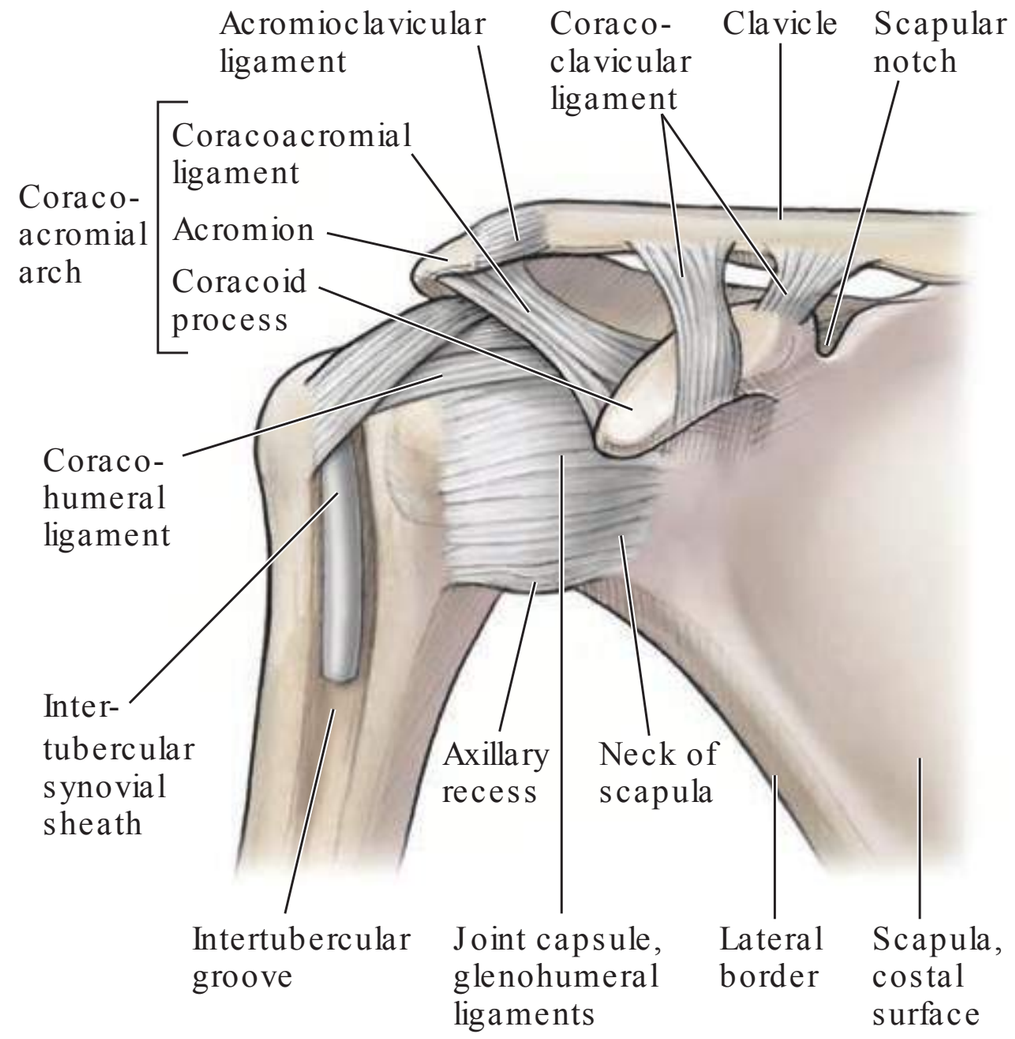

FIGURE 16-6 Glenohumeral joint and ligaments. (Reproduced, with permission, from Chapter 30. Shoulder and Axilla. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

all of which aid with scapular stability during arm elevation (see later). The coracoid process (see Fig. 16-3) projects forward like a crow's beak, for which it is named. This forward position provides an efficient lever whereby the small pectoralis muscle can help to stabilize the scapula. In addition, the process serves as a point of origin for the coracobrachialis and the short head of the biceps muscle.

The lateral attachment of the voluminous joint capsule of the G-H joint attaches to the anatomical neck of the humerus (Fig. 16-6).[6] Medially, the capsule is attached to the periphery of the glenoid and its labrum. The overall strength of the joint capsule bears an inverse relationship with the patient's age; the older the patient, the weaker the joint capsule. The fibrous portion of the capsule is very lax and has several recesses, depending on the position of the arm. At its inferior aspect, the capsule forms an axillary recess, which is both loose and redundant. The recess permits normal elevation of the arm, although it can also be the site of adhesions when the shoulder is immobilized in adduction. The anterior aspect of the joint capsule is reinforced by three ligaments (Z ligaments), which are described in the next section. The tendons of the rotator cuff (supraspinatus, infraspinatus, teres minor, and subscapularis) reinforce the superior, posterior, and anterior aspects of the capsule, as does the LHB tendon.

An inner synovial membrane lines the fibrous capsule and secretes synovial fluid into the joint cavity. The synovium typically lines the joint capsule and extends from the glenoid labrum down to the neck of the humerus. It also forms variously sized bursae, the largest of which, the subacromial or subdeltoid bursa, lies on the superior aspect of the joint (see later).

The greater and lesser tuberosities (see Fig. 16-1), which serve as attachment sites for the tendons of the rotator cuff muscles, are located on the lateral aspect of the anatomical neck of the humerus, an imaginary line that separates

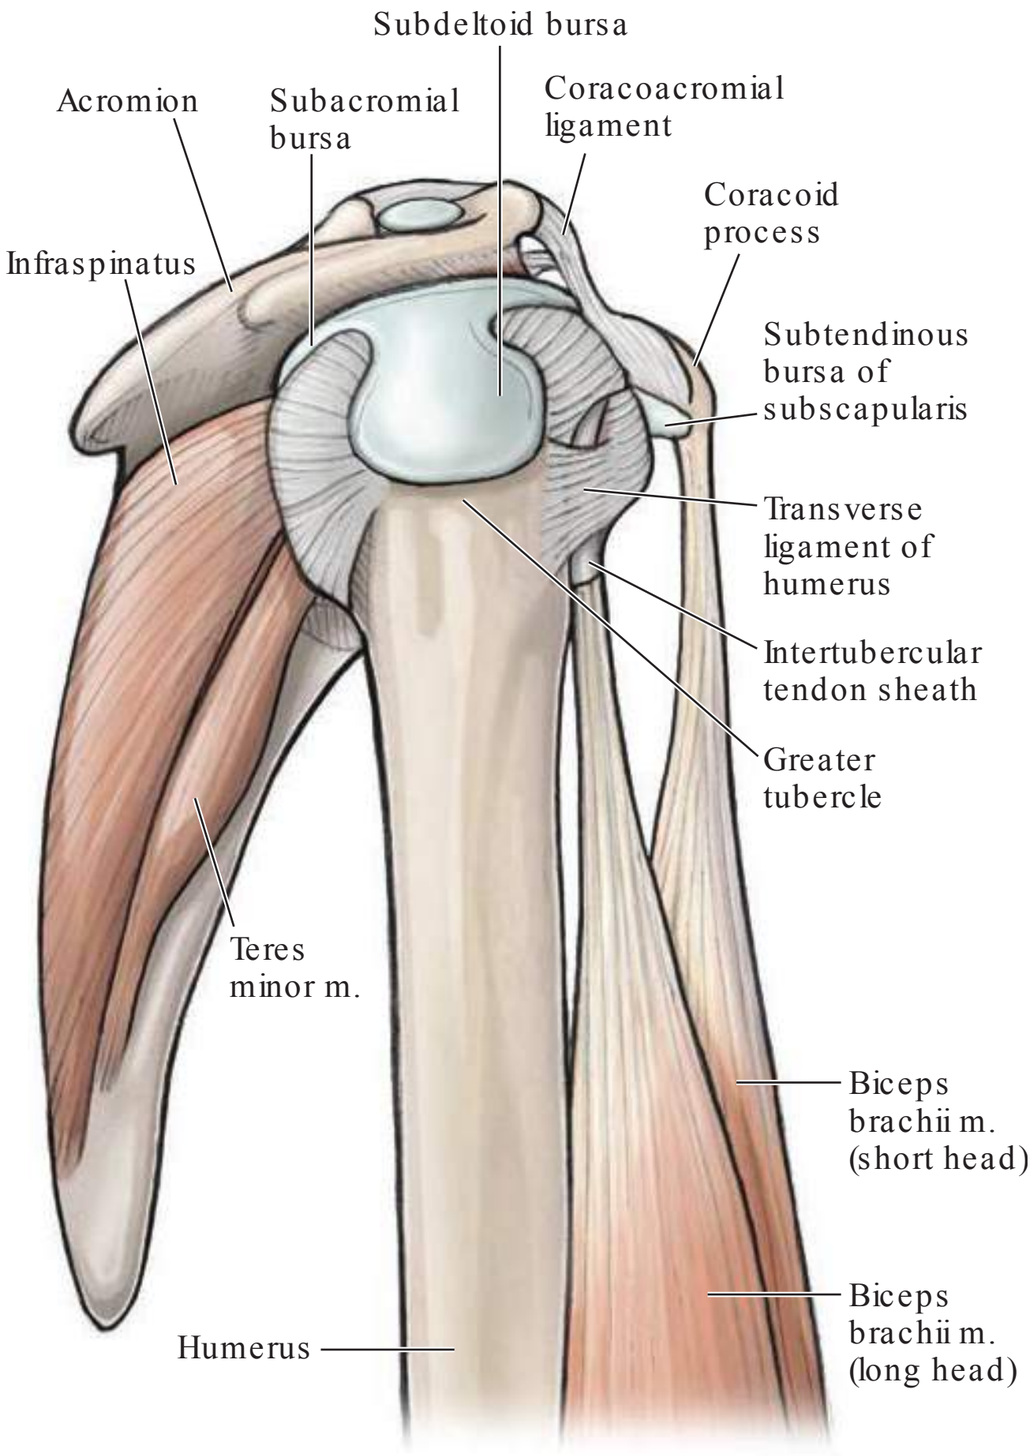

FIGURE 16-7 Soft-tissue structures of the shoulder. (Reproduced, with permission, from Chapter 30. Shoulder and Axilla. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

the humeral head from the rest of the humerus. The lesser tuberosity serves as the attachment for the subscapularis. The greater tuberosity serves as the attachment for the supraspinatus, infraspinatus, and teres minor. The greater and lesser tuberosities are separated by the intertubercular groove (see Fig. 16-1), through which passes the tendon of the LHB on its route to attach to the superior rim of the glenoid fossa. This groove has wide variance in the angle of its walls, but 70% fall within a 60–75-degree range.[29] Certain shoulder disorders, including rotator cuff and bicipital tendinopathy, have been associated with anomalies of this groove.[30] As the tendon of the LHB (Fig. 16-7) passes over the humeral head from its origin, it makes a right-angle turn to lie in the anterior aspect of the humerus. This abrupt turn may permit abnormal wearing of the tendon at this point. The roof of this groove is formed by the transverse ligament. The transverse humeral ligament (Fig. 16-7), which runs perpendicular over the biceps tendon, was once thought to function as a restraint to the biceps tendon within the intertubercular groove. However, this appears to be the role of the coracohumeral ligament.[30]

The region below the greater and lesser tuberosities, where the upper margin of the humerus joins the shaft of the humerus, is referred to as the surgical neck (Fig. 16-1). The axillary nerve and posterior humeral circumflex artery lie in close proximity to the medial aspect of the surgical neck.

CLiNiCAL PeArL

Fractures of the surgical neck of the humerus occur more frequently than fractures of the anatomical neck, and are most likely to cause damage to the axillary nerve.

Ligaments

A number of structures function as static stabilizers during motion of the arm to reciprocally tighten and loosen, thereby limiting translation and rotation of the G-H joint surfaces in a load-sharing fashion.[31] These include the G-H ligaments and the posterior capsule. Further static stabilization is provided by the glenoid labrum. The posterior capsule is under tension when the shoulder is in flexion, abduction, IR (in particular, the superior and middle segments), or in any combination of these.

At the anterior portion of the outer fibers of the joint capsule, three local reinforcements are present: the superior, middle, and inferior G-H ligaments. Together with the coracohumeral ligament, these ligaments form a Z-pattern on the anterior aspect of the shoulder.[32] In the midrange of rotation, the G-H ligaments are relatively lax and stability is maintained primarily by the action of the rotator cuff muscle group compressing the humeral head into the conforming glenoid articulation.[31] The G-H ligaments appear to produce a major restraint during shoulder flexion, extension, and rotation[33]:

- The anterior G-H ligament is under tension when the shoulder is in extension, abduction, and/or external rotation (ER).
- The posterior G-H ligament is under tension in flexion and ER.
- The inferior G-H ligament is the most important of the G-H ligaments. It is under tension when the shoulder is abducted, extended, and/or externally rotated. In addition, this ligament is a primary restraint against both anterior and posterior dislocations of the humeral head, and is the most important stabilizing structure of the shoulder in the overhead athlete.[34] At 0-degree abduction, the subscapularis muscle, the labrum, and the superior G-H ligament are the primary restraints against anterior translation. At 45-degree abduction, the subscapularis muscle and the middle and inferior G-H ligaments, along with labrum, prevent anterior translation. When the arm is abducted more than 90 degrees, which is the most common position of anterior dislocation, the anterior fibers of the inferior G-H ligament are the primary restraint against anterior movement.[9,35]
- The middle G-H ligament is under tension when the shoulder is flexed and externally rotated. In addition, the middle G-H ligament and the subscapularis tendon limit ER from 45–75 degrees of abduction, and are important anterior stabilizers.

Other ligaments help provide stability to the G-H joint. These include the following:

- **The coracohumeral ligament.** The coracohumeral ligament (see Fig. 16-6) arises from the lateral end of

the coracoid process and runs laterally, where it is split into two bands by the presence of the biceps tendon. The posterior band blends with the supraspinatus tendon to insert near the greater tuberosity, and the anterior band blends with the subscapularis tendon to insert near the lesser tuberosity. The coracohumeral ligament covers the superior G-H ligament anterosuperiorly and fills the space between the tendons of the supraspinatus and subscapularis muscles, uniting these tendons to complete the rotator cuff in this area. Tears of the cuff usually extend longitudinally between the supraspinatus and coracohumeral ligament so that the hood action of the cuff is lost. It is generally agreed that the posterior band of the coracohumeral ligament limits flexion, whereas the anterior band limits extension of the G-H joint.[36] Both the bands also limit inferior and posterior translation of the humeral head, strengthening the superoanterior aspect of the capsule.[36,37]

- *The coracoacromial ligament.* The coracoacromial ligament (see Fig. 16-6) is often described as the roof of the shoulder. It is a very thick structure that runs from the coracoid process to the anteroinferior aspect of the acromion, with some of its fibers extending to the A-C joint. The ligament consists of two bands that join near the acromion, and it is ideally suited, both anatomically and morphologically, to prevent separation of the A-C joint surfaces. The coracoclavicular ligaments and the costoclavicular ligaments are described in the A-C joint section and the S-C joint section, respectively.

Coracoacromial Arch

The coracoacromial arch (Fig. 16-6) is formed by the anteroinferior aspect of the acromion process, and the coracoacromial ligament, which connects the coracoid to the acromion and the inferior surface of the A-C joint.[38–40] A number of structures are located in the subacromial or suprahumeral, space (Fig. 16-7) between the coracoacromial arch superiorly and the humeral head inferiorly, and the coracoid process, anteromedially. These include (from inferior to superior) the following:

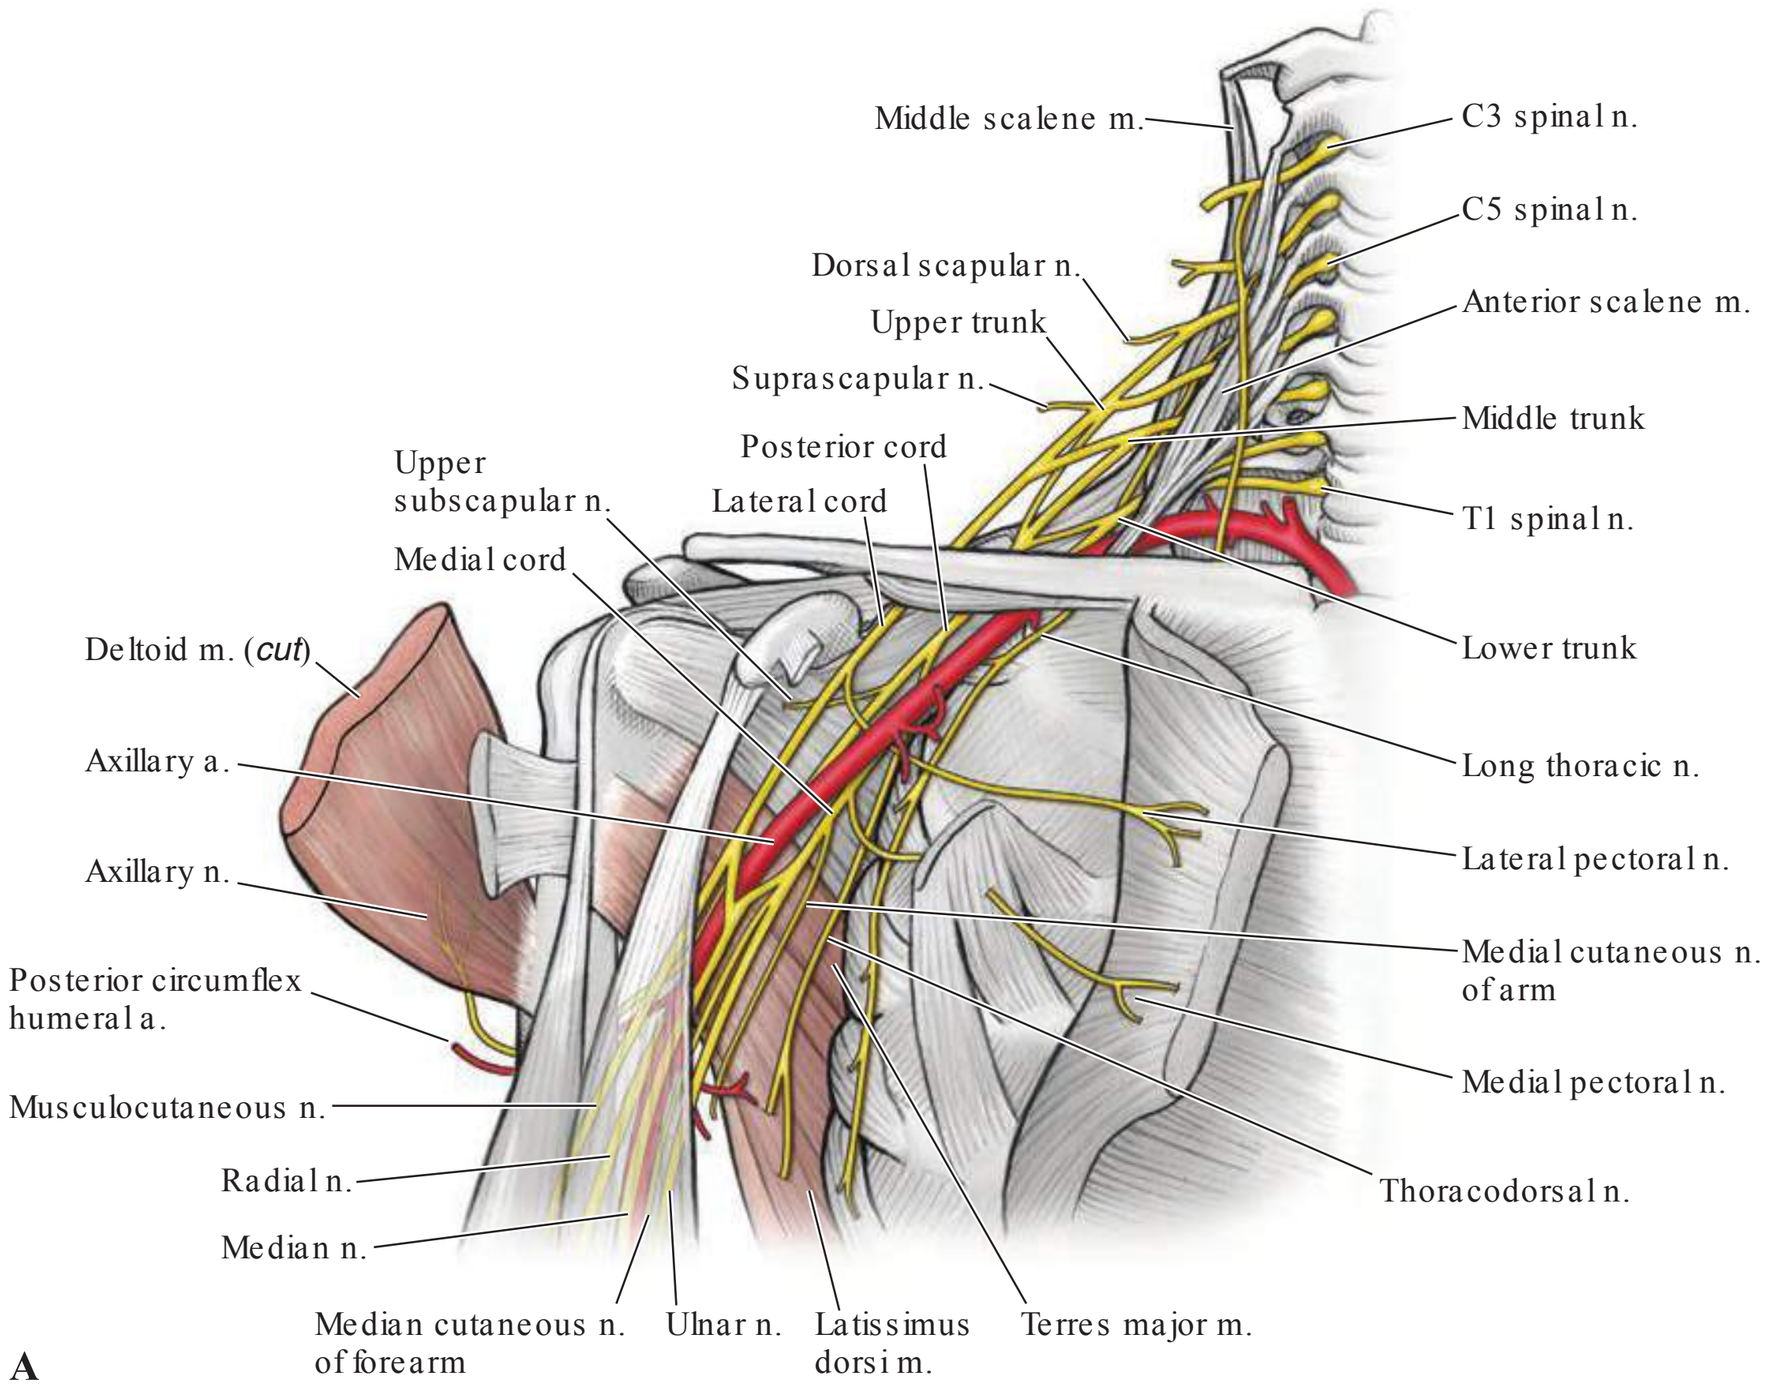
- the head of the humerus,
- the long head of biceps tendon (intra-articular portion),
- the superior aspect of the joint capsule,
- the supraspinatus and upper margins of subscapularis and infraspinatus,
- the subdeltoid–subacromial bursae,
- the inferior surface of coracoacromial arch.

In normal individuals, the subacromial space averages 10–11 mm in height with the arm adducted to the side.[41,42] Elevating the arm in the plane of the scapula decreases this space, and the space is at its narrowest between 60 and 120 degrees of scaption.[43] During overhead motion in the plane of the scapula, the supraspinatus tendon, the region of the cuff most involved in overuse syndromes of the shoulder, can pass directly underneath the coracoacromial arch. If the arm is elevated while internally rotated, the supraspinatus tendon passes under the coracoacromial ligament, whereas if the arm is externally rotated, the tendon passes under the acromion itself.[44]

Muscle imbalances or capsular contractures can cause an increase in superior translation of the humeral head, narrowing the subacromial space. For example, if the rotator cuff muscles are weak or injured, increased translation occurs between the humeral head and the glenoid labrum.[45] This increase in translation may lead to increased wear on the labrum, increased reliance on the static restraints (e.g., ligaments, capsule), and eccentric overloading of the dynamic (muscle) restraints, which in turn can result in instability and/or a condition termed "subacromial impingement syndrome (SIS)."[46,47]

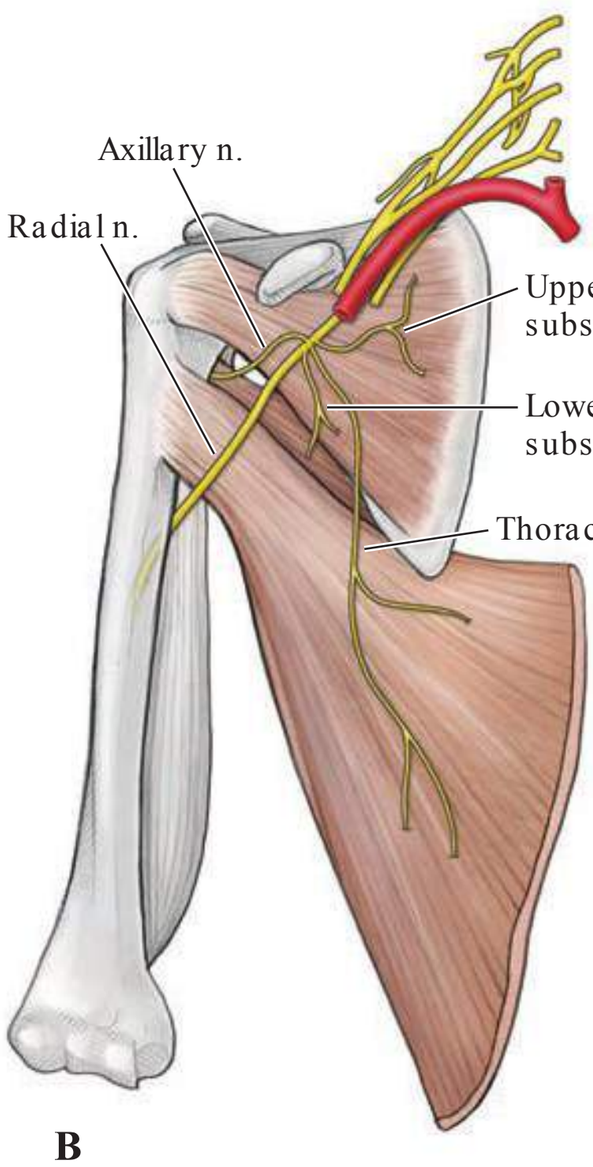
Bursae

Approximately eight bursae are distributed throughout the shoulder complex. The subdeltoid–subacromial bursae (see Fig. 16-7) are usually collectively referred to as the subdeltoid bursa because they are often continuous in nature. The subdeltoid bursa is one of the largest bursae in the body and provides two smooth serosal layers, one of which adheres to the overlying deltoid muscle and the other to the rotator cuff lying beneath. This bursa is also connected to the acromion, greater tuberosity, and coracoacromial ligament. As the humerus elevates, it permits the rotator cuff to slide easily beneath the deltoid muscle. There are also smaller bursae interposed between most of the muscles in contact with the joint capsule:



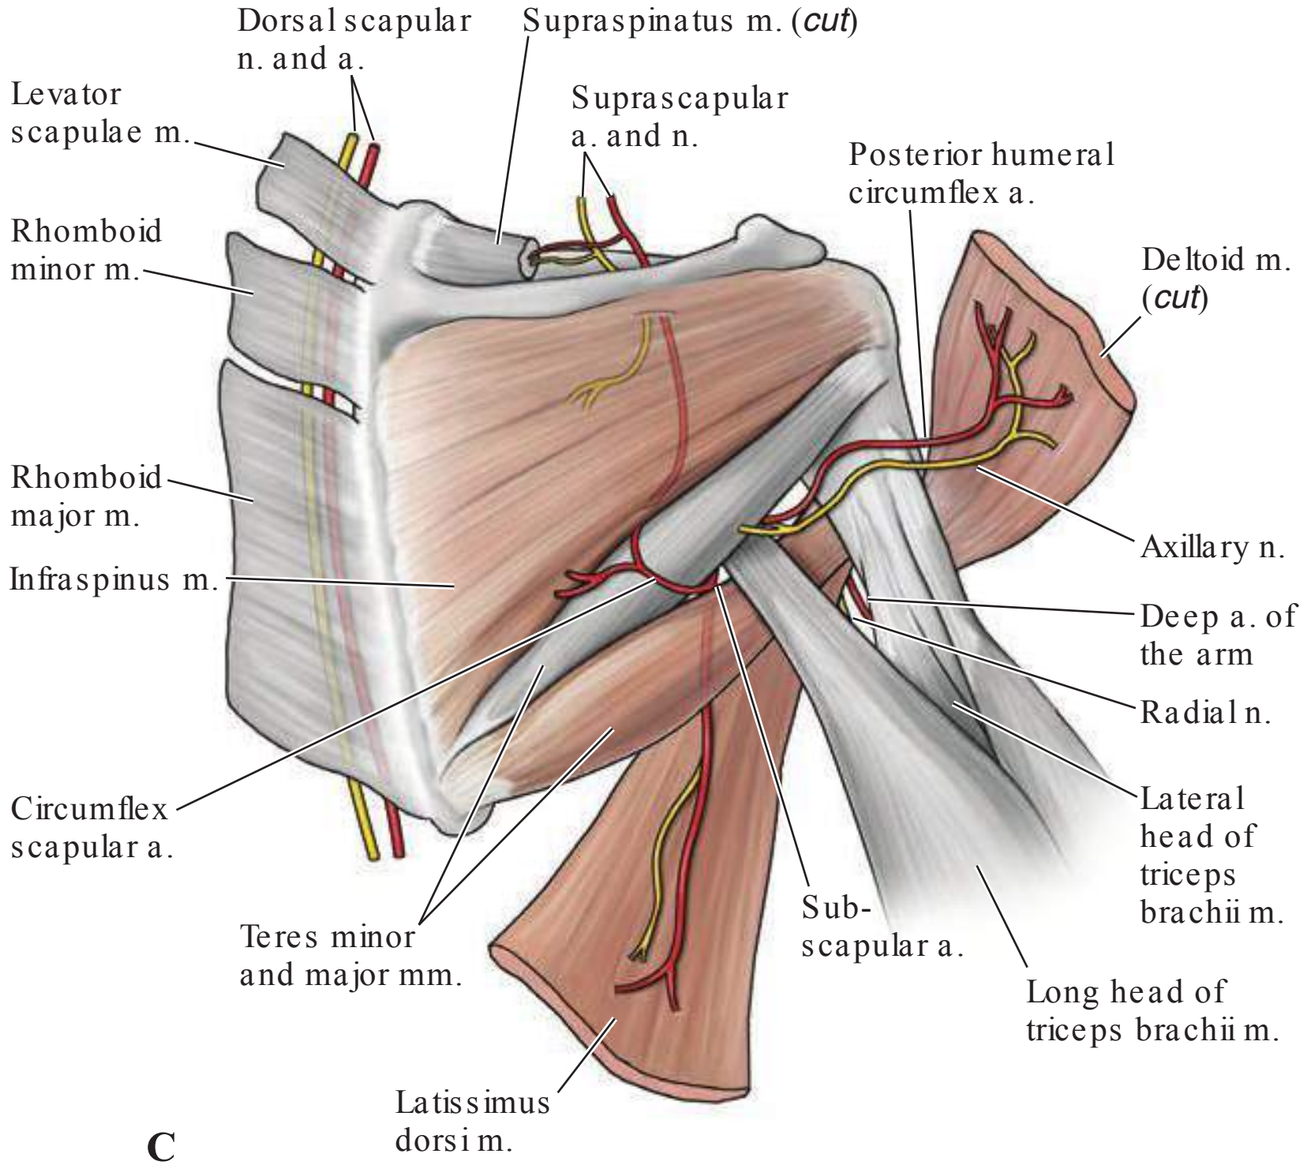
- *The subcoracoid bursa.* This bursa is located under the coracoid process.
- *The subscapular bursa.* This bursa is located between the subscapular muscle tendon and the anterior neck of the scapula and protects the tendon as it passes under the coracoid process.

Neurology



The shoulder complex is embryologically derived from C5 to C8, except the A-C joint, which is derived from C4 (Fig. 16-8). The sympathetic nerve supply to the shoulder originates primarily in the thoracic region from T2 down as far as T8.[48]

One study[49] attempted to determine the variability of the course and the pattern of these nerves and found that the peripheral nerves contributing to the anterior shoulder joint included the axillary (C5–6), subscapular (C5–6), and lateral pectoral (C5–6). The same study found that the nerves contributing articular branches to the posterior joint structures are the suprascapular nerve (C5–6) and small branches of the axillary nerve.[49] The pathways of these nerves are described in Chapter 3.



Other nerves innervate the muscles that act upon the shoulder. These include the long thoracic nerve (C5–7) (Fig. 16-8), which innervates the serratus anterior, the spinal accessory nerve (cranial nerve XI and C3–4), which innervates the sternocleidomastoid (SCM) and trapezius muscles, and the musculocutaneous nerve (C5–7) (Fig. 16-8), which innervates the coracobrachialis, biceps brachii, and brachialis, before dividing into its cutaneous branches.

CLiNiCAL PeArL

Shoulder pain that persists despite extensive conservative approaches could be of neural origin, as the peripheral nerves that innervate the ligaments, capsule, and bursae of the shoulder joint may have been subject to damage, either at the time of initial trauma or through subsequent surgical intervention.[49–51]

Vascularization

The vascular supply to the shoulder complex is primarily provided by branches off the axillary artery (Fig. 16-9A), which begins at the outer border of the first rib as a continuation of the subclavian artery. The axillary artery is commonly divided into three parts: above, behind, and below the pectoralis minor muscle. The axillary artery meets the more deeply placed brachial plexus in the neck, and here they are encased in the axillary sheath, together with the axillary vein.[52] The lateral, posterior, and medial cords of the brachial plexus descend behind the first portion of the artery and then take up their respective locations at the second portion of the artery (behind the pectoralis minor muscle). The branches of these cords also maintain their respective positions. Compression of the axillary artery (or, to a lesser degree, the axillary vein) can result in shoulder dysfunction and most commonly occurs in the posterior fossa around the shoulder and against the humerus with shoulder elevation.[52] The G-H joint receives its blood supply from the anterior and posterior circumflex humeral as well as the suprascapular and circumflex scapular vessels (Fig. 16-9B-C).[53] The vascular supply to the labrum arises mostly from its peripheral attachment to the capsule and is from a combination of the suprascapular circumflex scapular branch of the subscapular and posterior humeral circumflex arteries (Fig. 16-9C).[8]

The brachial artery (Fig. 16-9A) provides the dominant arterial supply to each of the two heads of the biceps brachii. The artery travels in the medial intermuscular septum and is bordered by the biceps muscle anteriorly, the brachialis muscle medially, and the medial head of the triceps muscle posteriorly.[54]

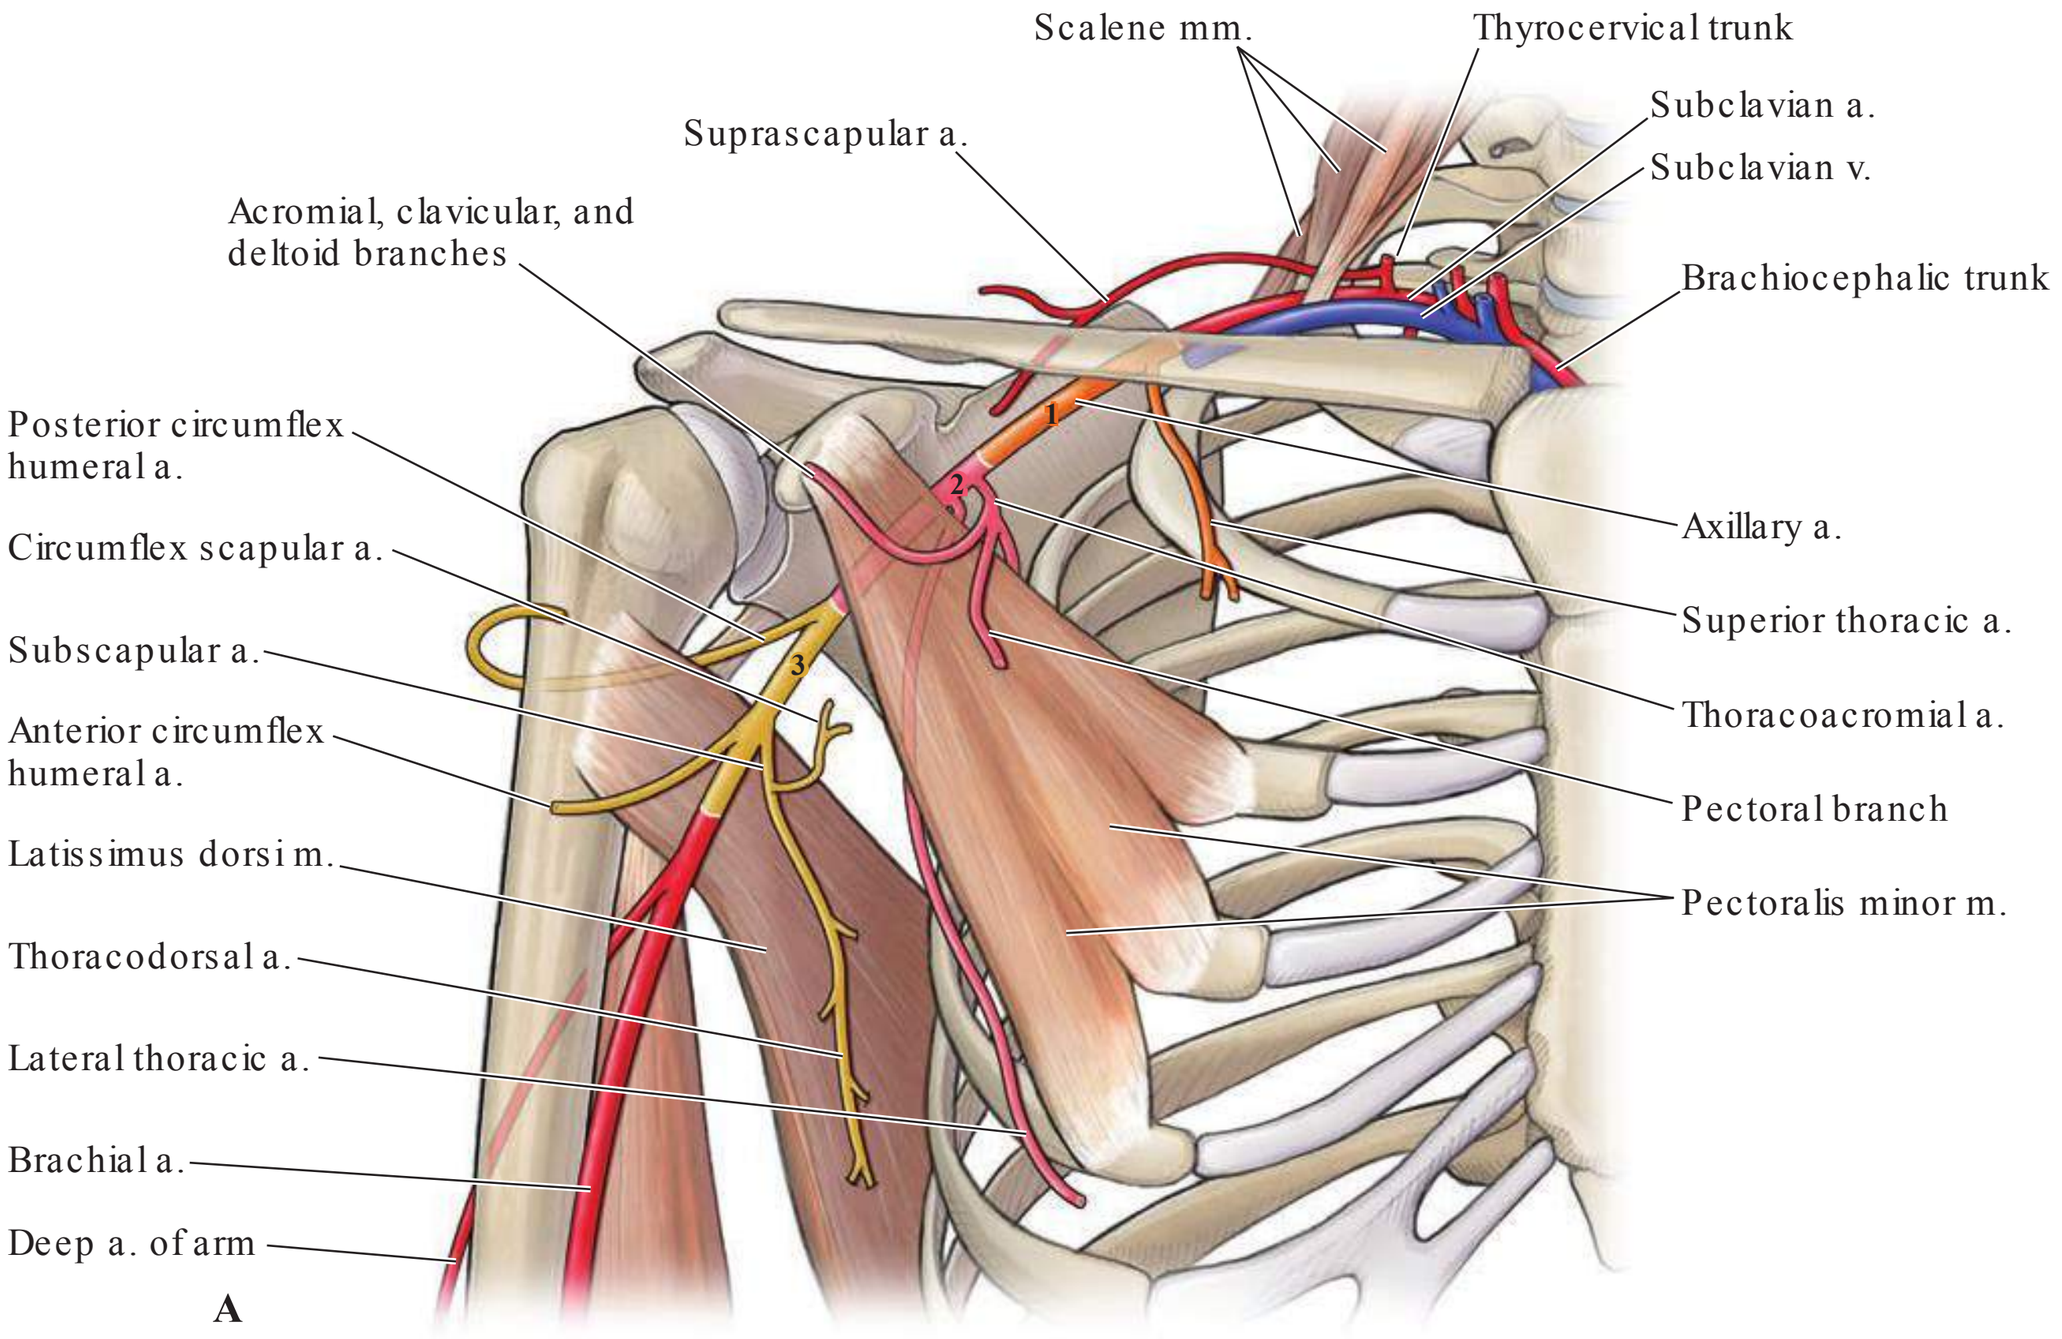
The microvasculature of the rotator cuff has been the subject of much discussion and consists of three main sources: the thoracoacromial, suprahumeral, and subscapular arteries.[53] The supraspinatus receives its primary supply from the thoracoacromial arteries. The subscapularis receives its supply from the anterior humeral circumflex (Fig. 16-9A) and the thoracoacromial arteries (Fig. 16-9A). The posterior rotator cuff muscles, the infraspinatus and teres minor, receive their blood supply from the posterior humeral circumflex and suprascapular artery (Fig. 16-9C). The circulation of the rotator cuff is unidirectional with no flow traversing the tide mark at the insertion of the supraspinatus.[55] The supraspinatus and biceps tendons appear to be particularly vulnerable to areas of relative avascularity, referred to as critical zones. The vascular compromise of the supraspinatus is thought to be due to a number of factors:

- It can be directly compressed by the subacromial structures. With the arm adducted to the side, the vessels within the supraspinatus tendon are poorly perfused.[56] Other arm positions, such as raising the arm above 30 degrees, have been shown to increase intramuscular pressure in the supraspinatus muscle to an extent that may impair normal blood perfusion.[56,57]
- Its blood vessels travel parallel to the tendon fibers, which make them vulnerable to stretch.[58] Avascularity appears to increase with age beginning as early as 20 years.[59]
- The presence of a critical zone just proximal to the supraspinatus insertion point.[56] Two early studies noted a critical zone that lies slightly proximal to the supraspinatus insertion point.[60,61] Since then, it has been determined that the critical zone is more likely a zone of anastomoses between the vessels supplying the bone and the tendon and is not less vascular except in certain positions.[56,62,63]

Although it is possible that sustained isometric contractions, prolonged adduction of the arm or increases in subacromial pressure[64] may reduce the microcirculation, it is unlikely that frequent abduction or elevation of the arm would produce selective avascularity of the supraspinatus or biceps tendon.

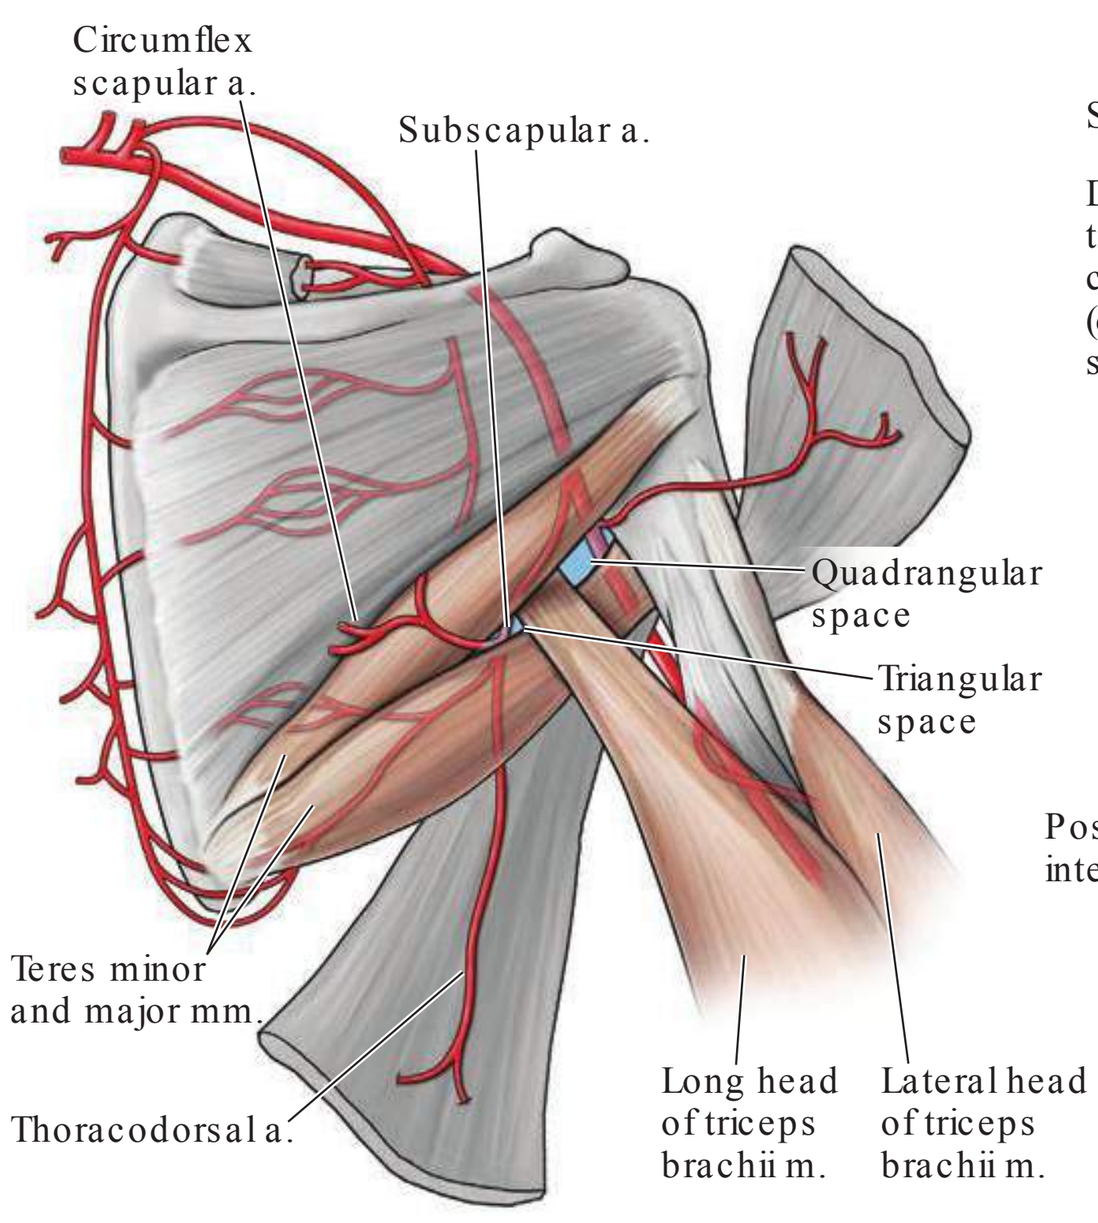
Close-Packed Position

The close-packed position for the G-H joint is 90 degrees of G-H abduction and full ER or full abduction and ER, depending on the source.



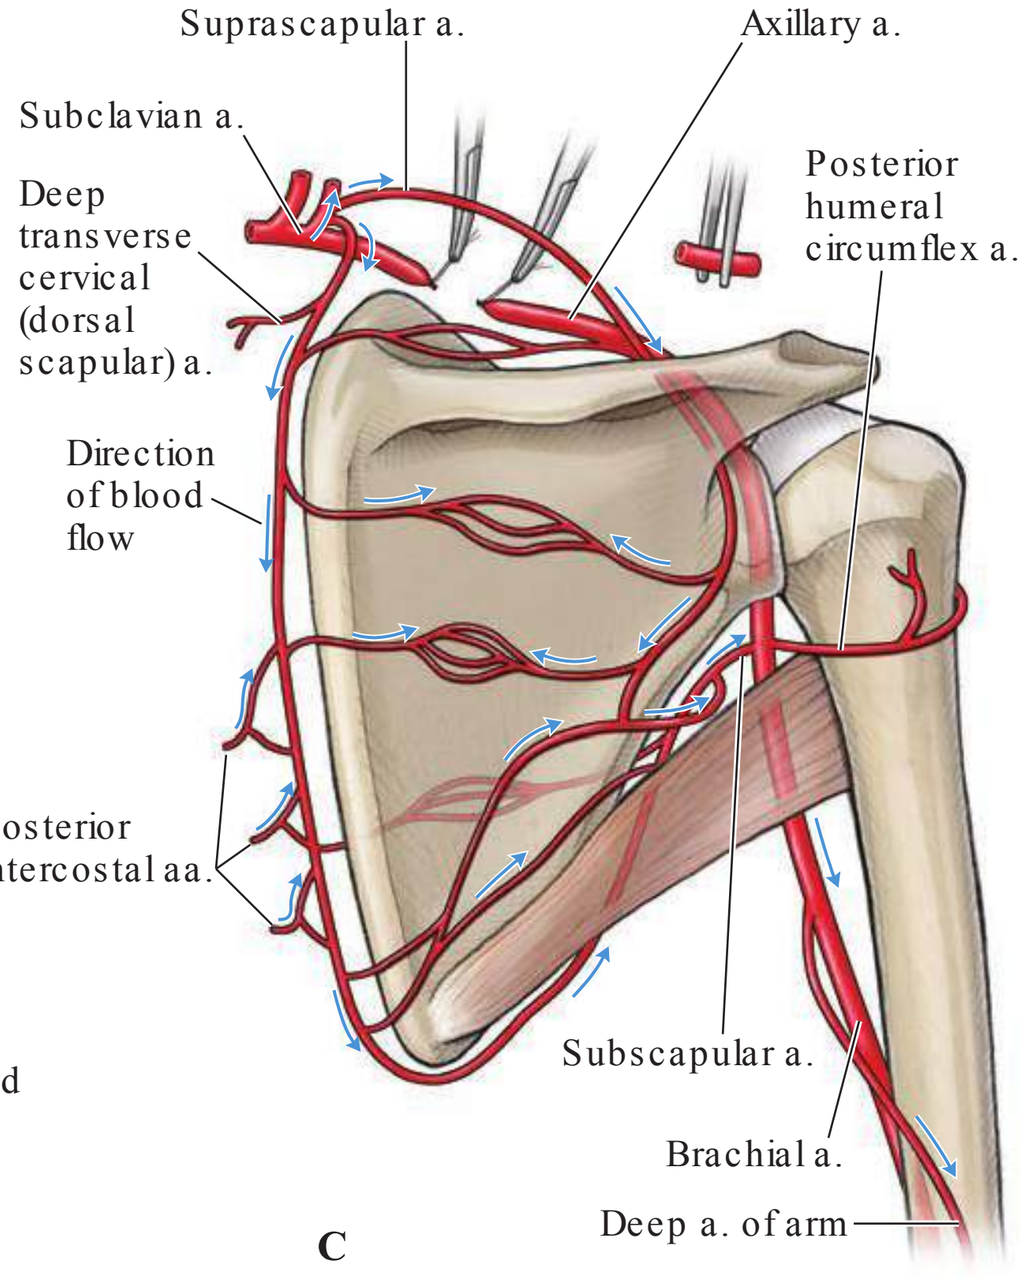
Open-Packed Position

Without IR or ER occurring, the open-packed position of the G-H joint has traditionally been cited as 55 degrees of semi-abduction and 30 degrees of horizontal adduction.[65] More recently, a cadaver study, which examined the point in the range at which maximal capsular laxity occurred in seven subjects, determined the open-packed position to be 39 degrees of abduction in the scapular plane or at the point which is 45% of the maximal available abduction range of motion (ROM).[66] This finding suggests that the open-packed position may be closer to neutral and that joint mobility testing and joint mobilizations of the G-H joint should be initiated according to a smaller angle of abduction than the traditionally cited open-packed position.[66]



The zero position for the G-H joint is the arm relaxed by the side, which, relative to the scapula, averages approximately 0 degrees of abduction, 12 degrees of flexion, and 10 degrees of ER.[67]

Capsular Pattern



According to Cyriax,[68] the capsular pattern for the G-H joint is that ER is the most limited, abduction the next most limited, and IR the least limited in a 3:2:1 ratio, respectively. However, this pattern only appears to be consistent with adhesive capsulitis of the shoulder. IR, rather than ER or abduction, appears to be the most limited motion in conditions with selected capsular hypomobility.[69]

The ACromioCLAViCULAr JOiNT

The A-C joint is a synovial joint, formed by the medial margin of the acromion and the lateral end of the clavicle. The A-C joint is most often described as a gliding or plane joint, but the joint surfaces can vary from flat to slightly convex or concave, corresponding with the articulating surface of the acromion. In the early stages of development, the articular surfaces of the A-C joint are lined with hyaline cartilage, which changes to fibrocartilage at approximately 17 years of age on the acromial side of the joint, and until approximately 24 years of age on the clavicular side.[70] Within the A-C joint, there is variable presence of a thumbtack-shaped intra-articular fibrous disk that projects superiorly into, and incompletely divides, the A-C joint. This disk is subject to tearing.[70] When viewed from above, the clavicle is convex anteriorly in the medial two-thirds and convex posteriorly in the lateral one-third (see Fig. 16-1). Variability in the inclination of the joint is common and can be anywhere from 10 to 50 degrees, but the anteromedial border of the acromion usually faces anteriorly, medially, and superiorly.[71] This variability may account for the differences in vulnerability to separation seen among people.[72]

The A-C joint serves as the main articulation that suspends the upper extremity from the trunk, and it is at this joint about which the scapula moves. Specifically, the A-C joint provides the scapula with additional range of rotation on the thorax, which allows the scapula to adjust outside of its initial plane (posterior tipping and IR) to follow the changing shape of the thorax as movement occurs.[73,74] The clavicle serves as the lever by which the upper extremity acts on the torso and as an attachment site for many soft tissues.[70,75] The thin joint capsule is lined with synovium, which is strengthened anteriorly, posteriorly, inferiorly, and superiorly by A-C ligaments (see Fig. 16-6). The superior A-C ligament (see Fig. 16-6) gives support to the capsule and serves as the primary restraint to posterior translation and posterior axial rotation at the joint.[70] Other support structures for the joint include the costoclavicular, coracoclavicular (conoid and trapezoid) ligament, the pectoralis major, SCM, deltoid, and trapezius muscles (see Fig. 16-10).[75,76]

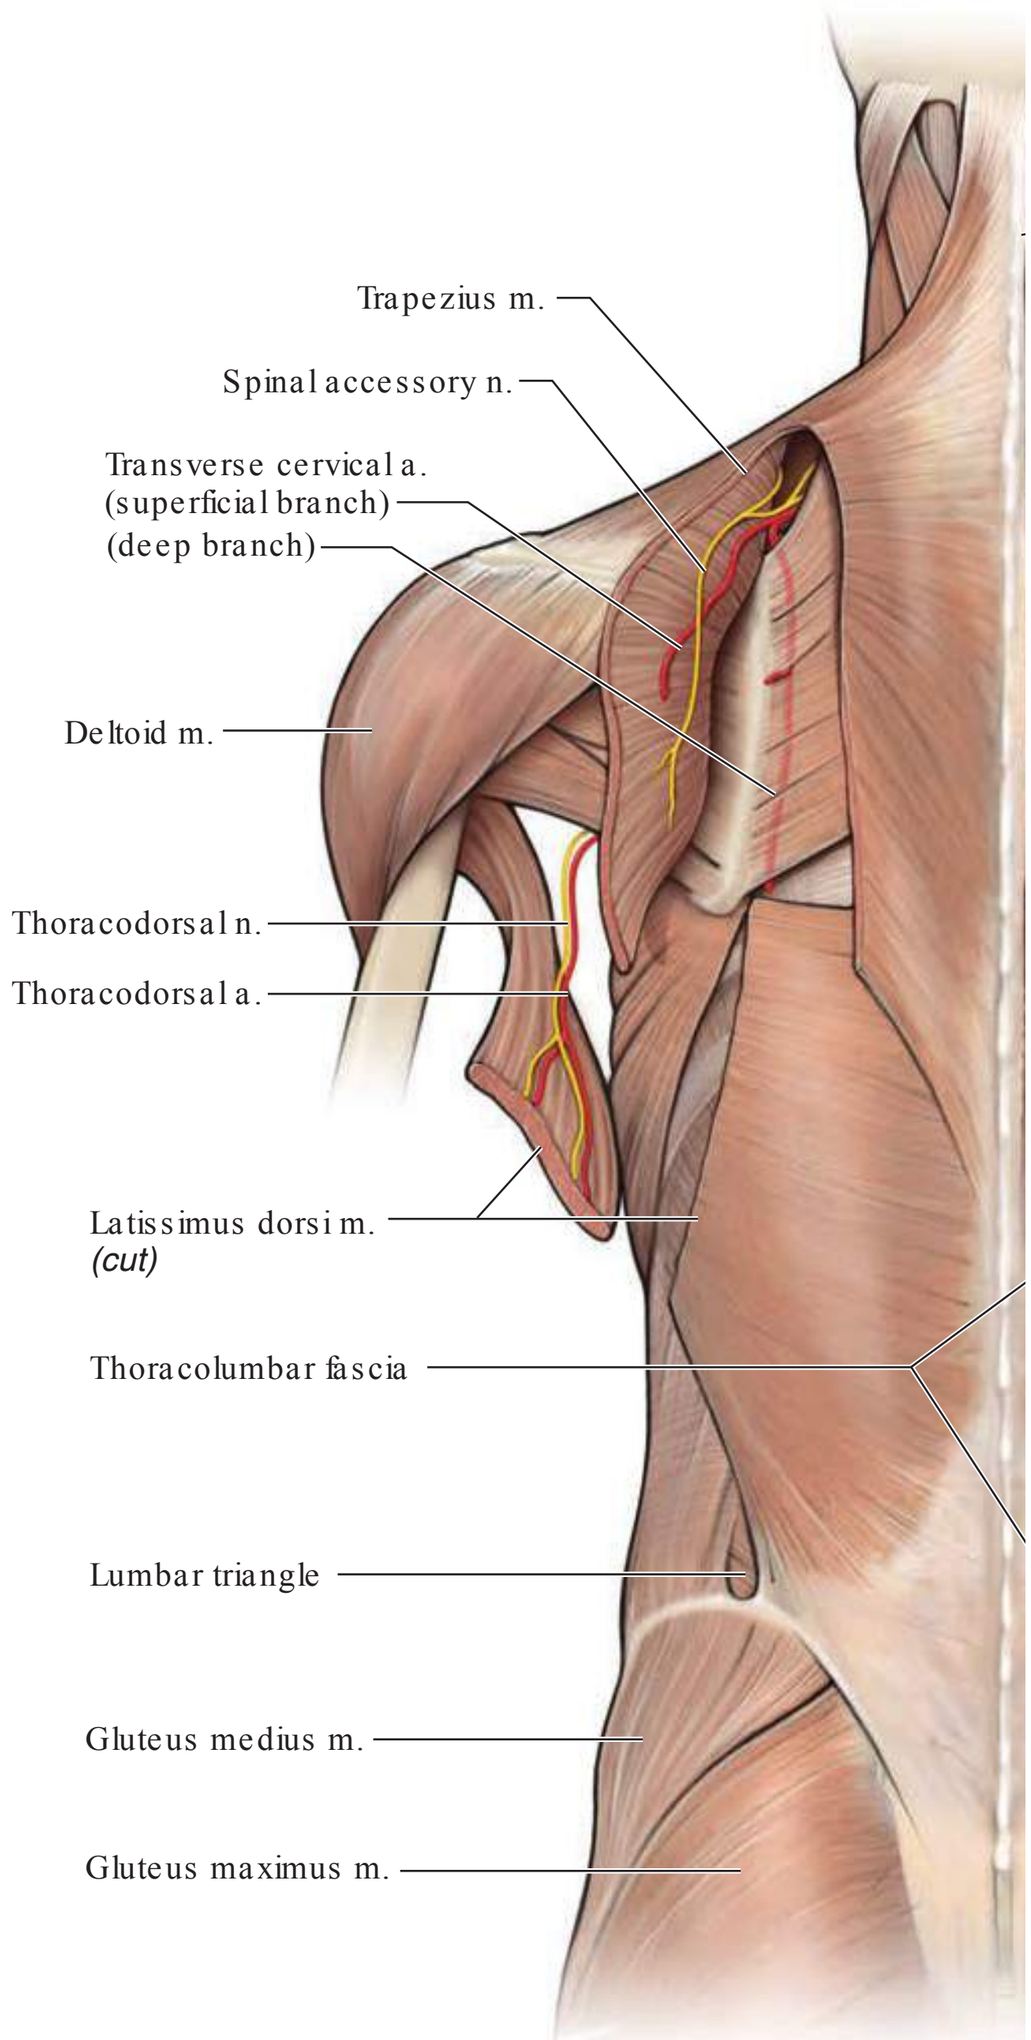

FIGURE 16-10 Muscles of the shoulder. (Reproduced, with permission, from Chapter 1. Back. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

CLiNiCAL PeArL

Degenerative changes of the A-C joint, including narrowing of the joint space and the formation of inferior osteophytes, can predispose an individual to SIS.[40,77,78]

Ligaments

The coracoclavicular ligament (see Fig. 16-6), which is typically described as having conoid and trapezoid portions, is the primary support for the A-C joint and runs from the coracoid process to the inferior surface of the clavicle. The conoid ligament is the more fan shaped with its apex pointing inferiorly. It lies in the frontal plane and is the more medial of the two ligaments. This ligament functions to block coracoid movement away from the clavicle inferiorly.[79] The trapezoid ligament arises from the medial border of the upper surface of the coracoid process and runs superiorly and laterally to insert into the inferior surface of the clavicle. It is larger, longer, and stronger than the conoid and forms a quadrilateral sheet that lies in a plane that is at right angles to the plane formed by the conoid ligament. The function of this ligament is unclear, although its orientation suggests that it may block medial movement of the coracoid,[79] or act as a restraint to superior or posterior displacement of the clavicle.[80] In addition, as the clavicle rotates upward, the coracoclavicular ligament dictates scapulothoracic rotation by virtue of its attachment to the scapula.[81]

CLiNiCAL PeAr L

The conoid and trapezoid ligaments provide mainly vertical stability, with control of superior and anterior translation as well as anterior axial rotation.[70,79,82]

Neurology

Innervation to this joint is provided by the suprascapular, lateral pectoral, and axillary nerves (Fig. 16-8).[83]

Vascularization

The A-C joint receives its blood supply from branches of the suprascapular and thoracoacromial arteries (Fig. 16-9).

Capsular Pattern

Joints such as the A-C joint, which are not controlled by muscles, lack true capsular patterns. However, anecdotal clinical evidence suggests that the capsular pattern for the A-C joint is pain at the extremes of ROM, especially horizontal adduction and full elevation.

Close-Packed Position

The close-packed position for this joint seems to correspond to 90 degrees of G-H joint abduction.

Open-Packed Position

The open-packed position for this joint is undetermined, although it is likely to be when the arm is by the side. This positions the clavicle in approximately 15–20 degrees of retraction relative to the coronal plane and elevated approximately 2 degrees from the horizontal plane.[84]

STERNOCLAVICULAR JOINT

The S-C joint, which is the only joint that connects the shoulder girdle to the axial skeleton, represents the articulation between the enlarged medial end of the clavicle, the clavicular notch of the manubrium of the sternum, and the cartilage of the first rib, which forms the floor of the joint. The articulating surfaces of the S-C joint are covered with fibrocartilage. The S-C joint is angulated slightly upward approximately 20 degrees in a posterior and lateral direction. If held vertically, the proximal end of the clavicle is convex whereas the manubrium surface is concave (see Fig. 16-1). If held anteroposteriorly, the proximal end of the clavicle is concave and the manubrium is convex. A very thick meniscus or disk is the key to the joint curvature. The clavicle presents with an irregularly shaped surface to the disk, and this lateral part of the joint acts as an ovoid. The disk is attached to the upper and posterior margin of the clavicle, and to the cartilage of the first rib by an intra-articular disk ligament, which functions to help prevent medial displacement of the clavicle, and completely divides the joint into two cavities: a larger one that is above and lateral to the disk, and a smaller one that is medial and below the disk. Greater movement occurs between the clavicle and the disk than between the disk and the manubrium. The S-C joint has very little bony stability and relies heavily on support from the surrounding capsule and ligaments.

Some confusion seems to exist about classification of the S-C joint—it has been classified as a ball and socket joint,[83] a plane joint, and as a saddle joint.[83] These classifications depend on whether anatomy or function is being considered. For example, when its function is considered, the S-C joint acts similar to a ball and socket joint, allowing for motion in almost all planes, including rotation.

CLiNiCAL PeAr L

During normal shoulder motion, the S-C joint permits 30–35 degrees of upward elevation, 35 degrees of combined forward and backward movement, and 45–50 degrees of rotation about the long axis of the clavicle.[3,85]

Ligaments

Because of its bony arrangement, the S-C joint itself is extremely weak, but is held securely by strong ligaments that hold the sternal end of the clavicle downward and toward the sternum. These ligaments include the following:

Capsular-Ligamentous structures

Capsular Ligament. This ligament represents the inner aspect of the joint capsule. The anterior portion is heavier and stronger, and it covers the anterior aspect of the joint running obliquely from the proximal end of the clavicle to the sternum in an inferior and medial direction. The posterior component, which covers the posterior aspect of the joint, also runs obliquely from the proximal end of the clavicle to the sternum in an inferior and medial direction. The capsular ligament is considered the most important and strongest ligaments of the S-C joint and is most responsible for preventing upward displacement of the medial clavicle in the presence of a downward force on the distal end of the shoulder.[86]

Interclavicular. This ligament connects the superomedial sternal ends of each clavicle with the capsular ligaments and the upper sternum. Together, these structures help to hold up the shoulder when the upper extremities are resting by the side. This function can be demonstrated by placing a finger in the superior sternal notch; the ligament is lax with elevation of the arm but becomes taut when both arms are hanging by the sides.

Costoclavicular (Rhomboid Ligament). This is short and strong ligament, which runs from the upper border of the first rib to the inferior surface of the clavicle, consists of two laminae: fibers of the anterior lamina run superiorly and laterally and check elevation and lateral movement (upward rotation) of the clavicle.[86] The posterior lamina fibers run superiorly and medially and check downward rotation of the clavicle.[86]

Due to the support provided by the ligaments, the S-C joint is very stable and trauma to the clavicle usually results in a fracture rather than a joint dislocation.[87] Gross motions

occur here as with the A-C joint. The SCM, which can be seen clearly with rotation of the head, has a tendinous sternal and clavicular insertion. The subclavius (C5–6) has a questionable function but may function as a dynamic ligament, which contracts and pulls the clavicle toward the manubrium.

Close-Packed Position

The close-packed position for the S-C joint is maximum arm elevation and protraction.

Open-Packed Position

The open-packed position for the S-C joint has yet to be determined, but is likely to be when the arm is by the side.

Capsular Pattern

Similar to the A-C joint, the S-C joint is not controlled by muscles and therefore lacks a specific capsular pattern. One possibility, seen clinically, is pain at the extreme ranges of motion, especially full arm elevation and horizontal adduction.

Neurology

Pain can be referred from this joint to the throat, anterior chest, and axillae. The neural supply to this joint is primarily from the following:

- The anterior supraclavicular nerve
- The nerve to the subclavius (medial accessory phrenic) C5–6
- The T1 spinal nerve root

Vascularization

The S-C joint receives its blood supply from the internal thoracic and suprascapular arteries.[88]

SCAPULOTHORACIC JOINT

This articulation is functionally a joint, but it lacks the anatomic characteristics of a true synovial joint. However, the movement of the scapula on the wall of the thoracic cage is critical to shoulder joint motion. A lack of ligamentous support at this "joint" delegates the function of stability fully to the muscles that attach the scapula to the thorax.

An altered position of the scapula, or an abnormal motion at this joint due to muscle imbalances, have both been linked with shoulder complex dysfunction.[24,89,90] Motions at this joint are described according to the movement of the scapula relative to the thorax. Available motion consists of approximately 60 degrees of upward rotation of the scapula, 40–60 degrees of IR/ER, and 30–40 degrees of anterior and posterior tipping of the scapula.[91] Other motions occurring here include elevation and depression and retraction (adduction) and protraction (abduction) of the scapula (Fig. 16-11).

Close-Packed and Capsular Pattern

Since the scapulothoracic joint is not a true joint, it is difficult to determine its close-packed position or capsular pattern.

Open-Packed Position

Relative to the thorax, when the arm is by the side, the scapula is in an average of 30–45 degrees of IR, and slight upward rotation, and approximately 5–20 degrees of anterior tipping.[67,91]

Bursae

There are a number of bursae located in and around the scapulothoracic articulation. The scapulothoracic bursa is located between the thoracic cage and the deep surface of the serratus anterior.[92] The subscapular bursa is most often located between the superficial surface of the serratus anterior and the subscapularis.[92]

The scapulotrapezial bursa lies between the middle and lower trapezius fibers and the superomedial scapula.[92] The purpose and clinical significance of the scapulotrapezial bursa are not known. It may encourage smooth gliding of the superomedial angle of the scapula against the undersurface of the trapezius during scapular rotation in the same manner that the scapulothoracic bursa (between the serratus attachment at the anteromedial surface of the superior angle) encourages smooth gliding against the underlying ribs.[92] It is possible that inflammation of either of these bursae, directly or as a consequence of injury, may result in painful clicking at the superomedial angle of the scapula.[92]

The relationship of the spinal accessory nerve to the scapulotrapezial bursa may also have clinical importance, especially as it is closely applied to the superficial wall of the scapulotrapezial bursa.[92] The spinal accessory nerve receives afferent fibers from C3 and C4, which are thought to be proprioceptive, before reaching the deep surface of the trapezius.[92,93] As a consequence of their proximity, inflammation and fibrosis within the bursa may cause irritation and pain of the nerve, or interference with the normal proprioceptive feedback mechanism provided by the nerve.[92]

MUSCLES OF THE SHOULDER COMPLEX

A number of significant muscles control motion at the shoulder and provide dynamic stabilization. Rarely does a single muscle act in isolation at the shoulder. For simplicity, the muscles acting at the shoulder may be described in terms of their functional roles: scapular pivoters, humeral propellers, humeral positioners, and shoulder protectors (Table 16-2).[94]

Scapular Pivoters

The scapular pivoters comprise the trapezius, serratus anterior, levator scapulae, rhomboid major, and rhomboid minor.[94] As a group, these muscles are involved with motions

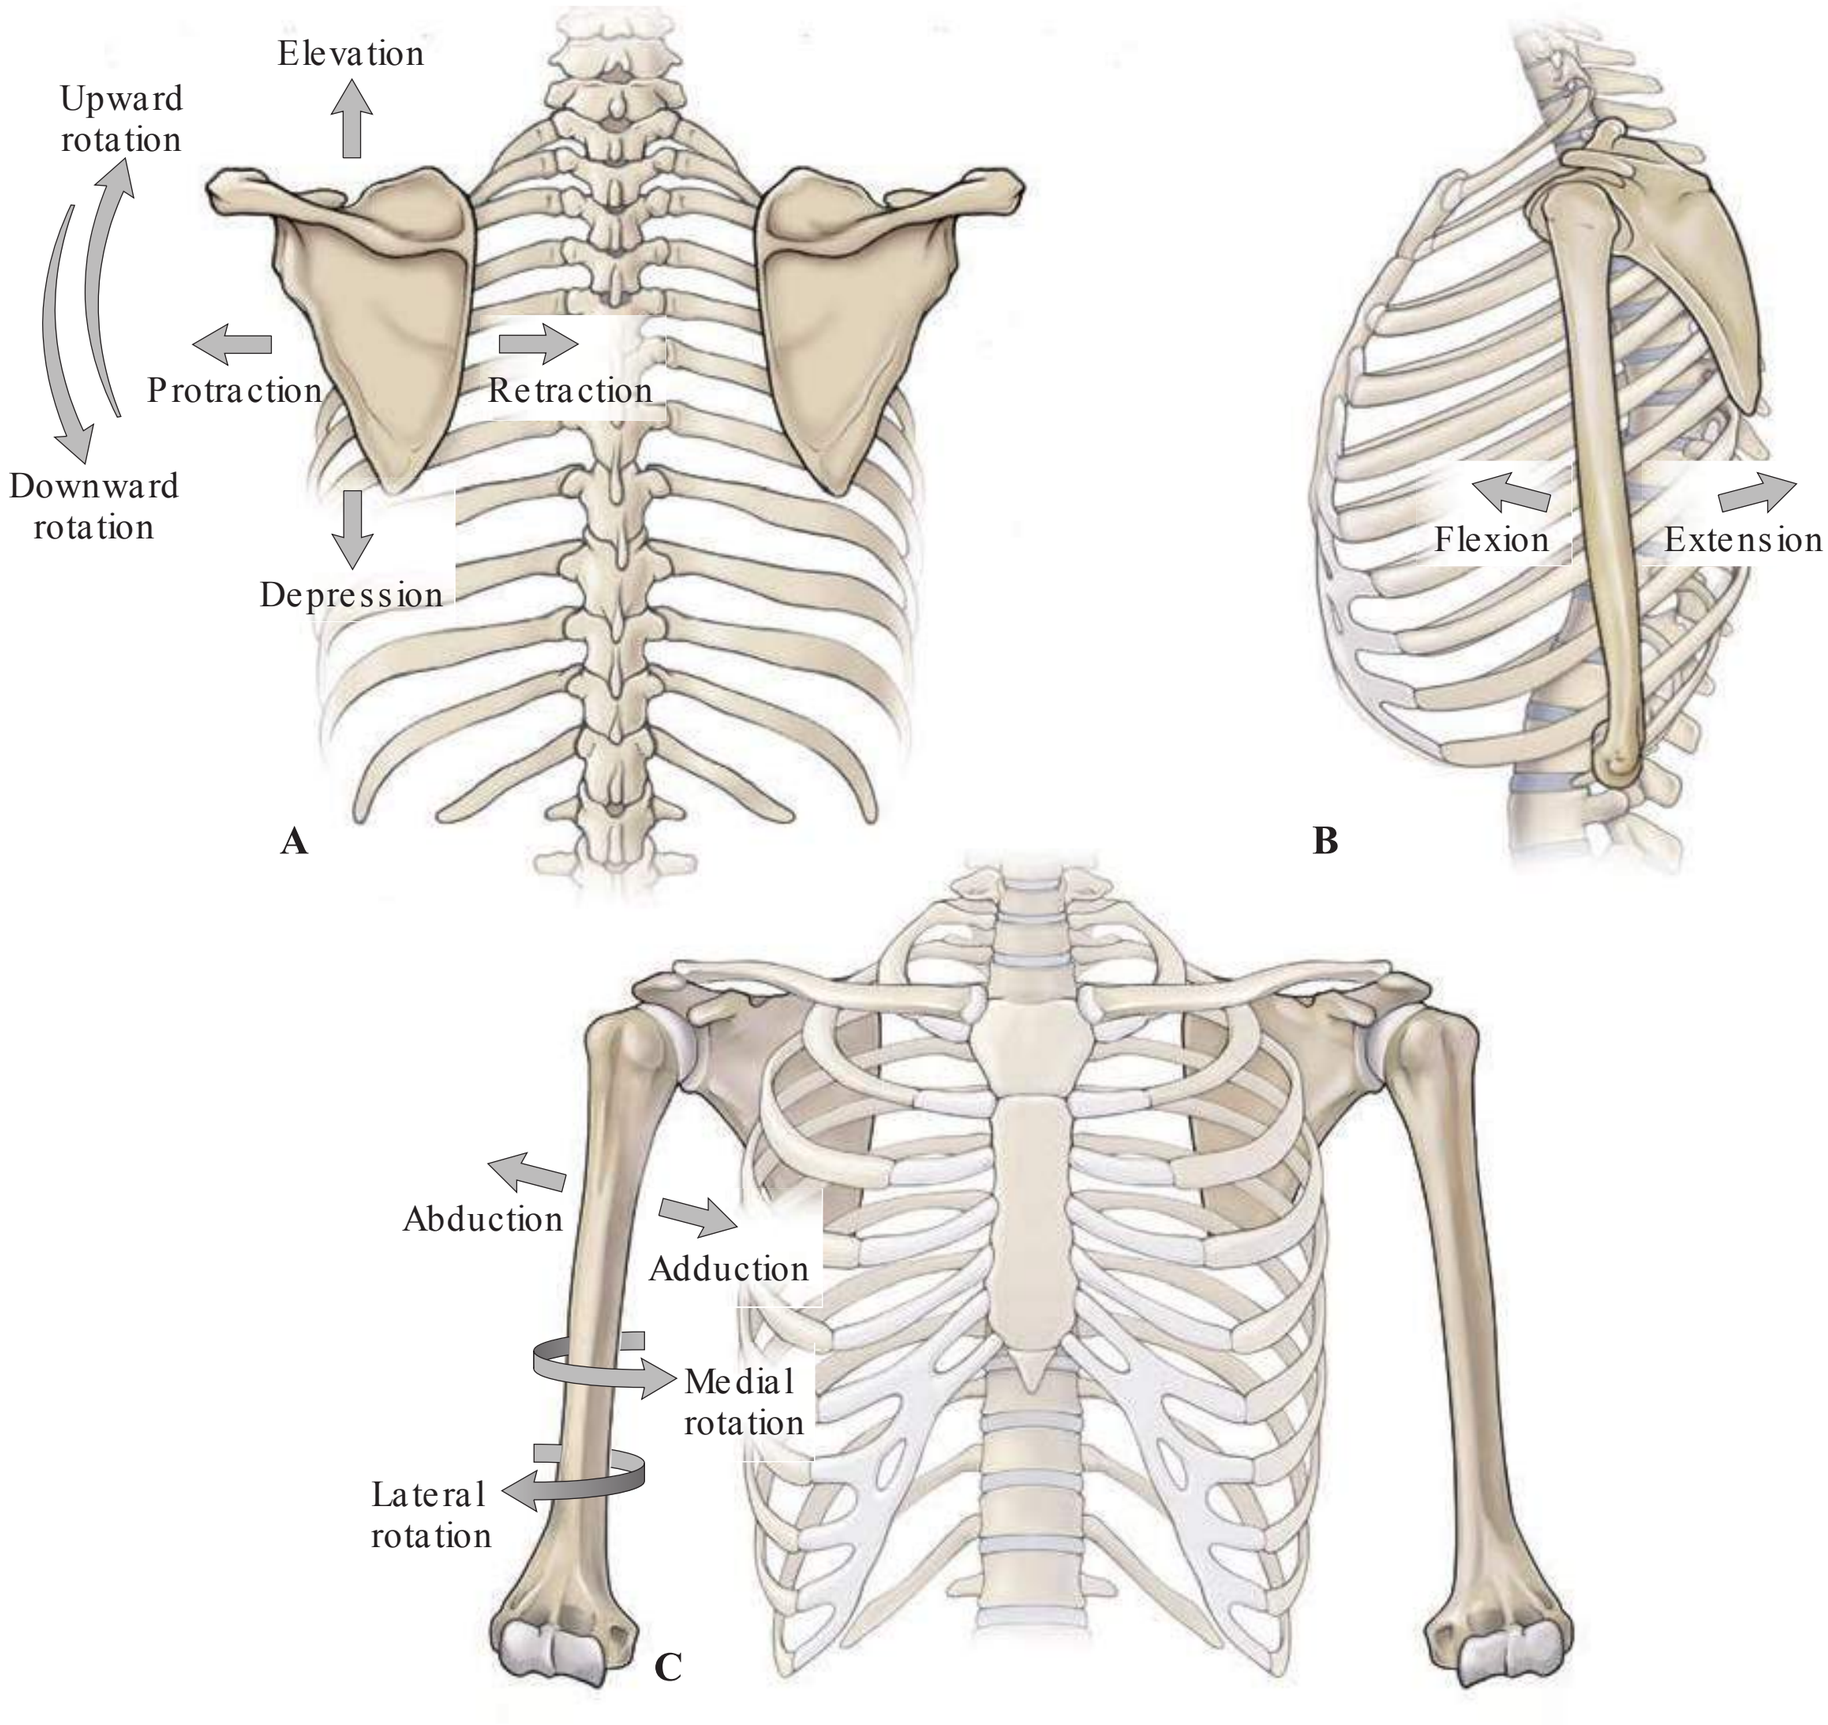

FIGURE 16-11 Movements of the scapula and upper extremity. (Reproduced, with permission, from Chapter 30. Shoulder and Axilla. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

at the scapulothoracic articulation, and their proper function is vital to the normal biomechanics of the whole shoulder complex. The scapular muscles can contract isometrically, concentrically, or eccentrically, depending on the desired action and whether the action involves stabilization, acceleration, or deceleration. To varying degrees, the serratus anterior and all parts of the trapezius cooperate during the upward rotation of the scapula.

Trapezius

The trapezius muscle (Fig. 16-10) originates from the medial third of the superior nuchal line, the external occipital protuberance, the ligamentum nuchae, the apices of the seventh cervical vertebra, all the thoracic spinous processes, and the supraspinous ligaments of the cervical and thoracic vertebrae. The upper fibers descend to attach to the lateral third of the posterior border of the clavicle. The middle fibers of the trapezius run horizontally to the medial acromial margin and superior lip of the spine of the scapula. The inferior fibers ascend to attach to an aponeurosis gliding over a smooth triangular surface at the medial

end of the spine of the scapula to a tubercle at the scapular lateral apex.

It has been suggested that the upper fibers of this muscle have a different motor supply than that to the middle and lower portions.[95,96] Recent clinical and anatomical evidence seems to suggest that the spinal accessory nerve provides the most important and consistent motor supply to all portions of the trapezius muscle, and although the C2–4 branches of the cervical plexus are present, no particular elements of innervation within the trapezius have been determined.[97]

One of the functions of the trapezius is to produce shoulder girdle elevation on a fixed cervical spine. For the trapezius to perform its actions, the cervical spine must first be stabilized by the anterior neck flexors to prevent simultaneous occipital extension from occurring. Failure to prevent this occipital extension would allow the head to translate anteriorly, resulting in a decrease in the length, and therefore the efficiency, of the trapezius,[98] and an increase in the cervical lordosis.

CLiNiCAL PeArL

Complete paralysis of the trapezius usually causes moderate to marked difficulty in elevating the arm over the head. The task, however, can usually be completed through full range as long as the serratus anterior remains totally innervated.[99]

serratus Anterior

The muscular digitations of the serratus anterior (see Fig. 16-5) originate from the upper eight to ten ribs and fascia over the intercostals. The muscle is composed of three functional components:[100,101]

- The upper component originates from the first and second ribs and inserts into the superior angle of the scapula.
- The middle component arises from the second, third, and fourth ribs and inserts into the anterior aspect of the medial scapular border.
- The lower component is the largest and most powerful, originating from the fifth through ninth ribs. It runs anterior to the scapula and inserts into the medial border of the scapula.

The serratus anterior is activated with all shoulder movements, but especially during shoulder flexion and abduction.[101] Working in synergy with the trapezius, as part of a force couple (see later), the main function of the serratus anterior is to protract and upwardly rotate the scapula,[102,103] while providing a strong, mobile base of support to position the glenoid optimally for maximum efficiency of the upper extremity.[104] Its lower fibers draw the lower angle of the scapula forward to rotate the scapula upward while maintaining the scapula on the thorax during arm elevation.[105] This moves the coracoacromial arch out of the path of the advancing greater tuberosity and opposes the excessive elevation of the scapula by the levator scapulae and trapezius muscles.[106] Without upward rotation and protraction of the scapula by the serratus anterior, full G-H elevation is not possible. In fact, in patients with complete paralysis of the serratus anterior, Gregg et al.[104] reported that abduction is limited to 110 degrees.

Dysfunction of the serratus anterior muscle causes winging of the scapula as the patient attempts to elevate the arm.[4,107] Scapulothoracic dysfunction can also contribute to G-H instability, as the normal stable base of the scapula is destabilized during abduction or flexion.[4,108,109]

The serratus anterior muscle is innervated by the long thoracic nerve (C5–7).

CLiNiCAL PeArL

Paralysis or weakness of the serratus anterior muscle results in disruption of normal shoulder kinesiology. The disability may be slight with partial paralysis, or profound with complete paralysis. As a rule, persons with complete or marked paralysis of the serratus anterior cannot elevate the arms above 110 degrees of abduction.[99]

Levator scapulae

The levator scapulae muscle (see Fig. 16-10) originates by tendinous strips from the transverse processes of the atlas, axis, and C3 and C4 vertebrae, and descends diagonally to insert into the medial superior angle of the scapula.

The levator scapulae can act on the cervical spine (see Chapter 23) and on the scapula. If it acts on the cervical spine, it can produce extension, side flexion, and rotation of the cervical spine to the same side.[110] When acting on the scapula during upper extremity flexion or abduction, the levator scapula muscle acts as an antagonist to the trapezius muscle, and provides eccentric control of scapular upward rotation in the higher ranges of motion (see later).[111]

Both the trapezius and levator scapulae muscles are activated with increased upper extremity loads.[98,101,112]

The levator scapulae muscle is innervated by the posterior (dorsal) scapular nerve (C3–5).

rhomboids

The rhomboid major muscle (Fig. 16-10) originates from the second to fifth thoracic spinous processes and the overlying supraspinous ligaments. The fibers descend to insert into the medial scapular border between the root of the scapular spine and the inferior angle of the scapula.

The rhomboid minor muscle (see Fig. 16-10) originates from the lower aspect of the ligamentum nuchae, and the seventh cervical and first thoracic spinous processes, and attaches to the medial border of the scapula at the root of the spine of the scapula.

The rhomboid muscles help control scapular positioning, particularly with horizontal flexion and extension of the shoulder complex.[111]

The rhomboid muscles are innervated by the posterior (dorsal) scapular nerve (C4–5).

humeral Propellers

The total muscle mass of the shoulder's internal rotators (subscapularis, anterior deltoid, pectoralis major, latissimus dorsi, and teres major) is much greater than that of the external

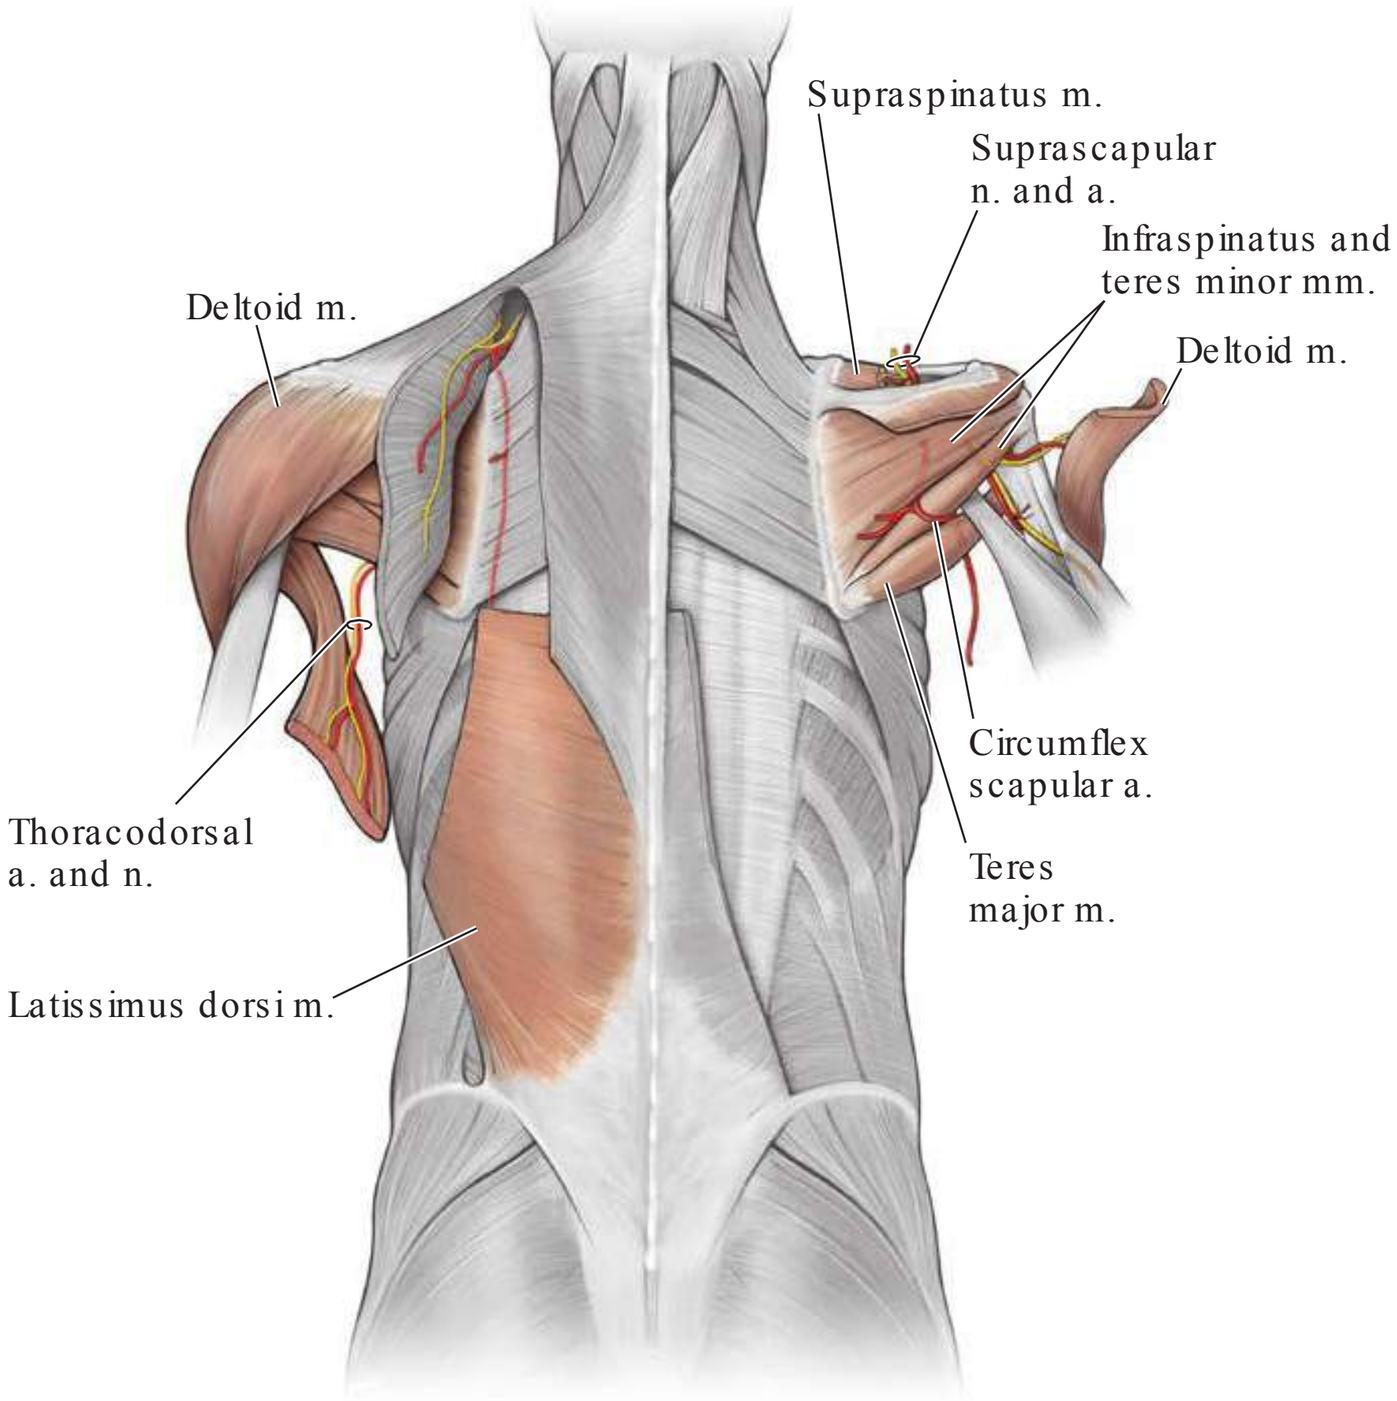

FIGURE 16-12 Latissimus dorsi. (Reproduced, with permission, from Chapter 30. Shoulder and Axilla. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

rotators (infraspinatus, teres minor, and posterior deltoid).[99] This fact explains why the shoulder internal rotators produce approximately 1.75 times greater isometric torque than the external rotators.[113] Peak torques of the internal rotators also exceed the external rotators when measured isokinetically, under both concentric and eccentric conditions.[99,114]

Latissimus Dorsi

The latissimus dorsi muscle (see Fig. 16-12) originates from the spinous processes of the last six thoracic vertebrae, the lower three or four ribs, the lumbar and sacral spinous processes through the thoracolumbar fascia, the posterior third of the external lip of the iliac crest, and a slip from the inferior scapular angle. The scapular slip allows the latissimus dorsi to act at the scapulothoracic articulation. The latissimus dorsi inserts into the intertubercular sulcus of the humerus. The muscle functions as an extensor, adductor, and powerful internal rotator of the humerus, and also assists in scapular depression, retraction, and downward rotation.[115] It is innervated by the thoracodorsal nerve (C6–8).

Teres major

The teres major (see Fig. 16-12) originates from the inferior third of the lateral border of the scapula and just superior to the inferior angle. The teres major tendon inserts into the medial lip of the intertubercular groove of the humerus. The teres major functions to complement the actions of the latissimus dorsi in that it extends, adducts, and internally rotates the G-H joint. It is innervated by the lower subscapular nerve (C5, C6).

Pectoralis major

The pectoralis major (see Fig. 16-13) originates from the sternal half of the clavicle, half of the anterior surface of the sternum to the level of the sixth or seventh costal cartilage, the sternal end of the sixth rib, and the aponeurosis of the obliquus externus abdominis. The fibers of the pectoralis major converge to form a tendon that inserts into the lateral lip of the intertubercular sulcus of the humerus. Although this muscle does not insert into the scapula, it does act upon the scapulothoracic articulation through its insertion on the humerus. The function of the pectoralis muscle depends on which fibers are activated:

- Upper fibers (clavicular head)—IR, horizontal adduction, flexion, abduction (once the humerus is abducted 90 degrees, the upper fibers assist in further abduction), and adduction (with the humerus below 90 degrees of abduction) of the G-H joint.
- Lower fibers (sternal head)—IR, horizontal adduction, extension, and adduction of the G-H joint.
- The pectoralis major is innervated by the medial (lower fibers) and lateral (upper fibers) pectoral nerves (C8–T1 and C5–7, respectively).

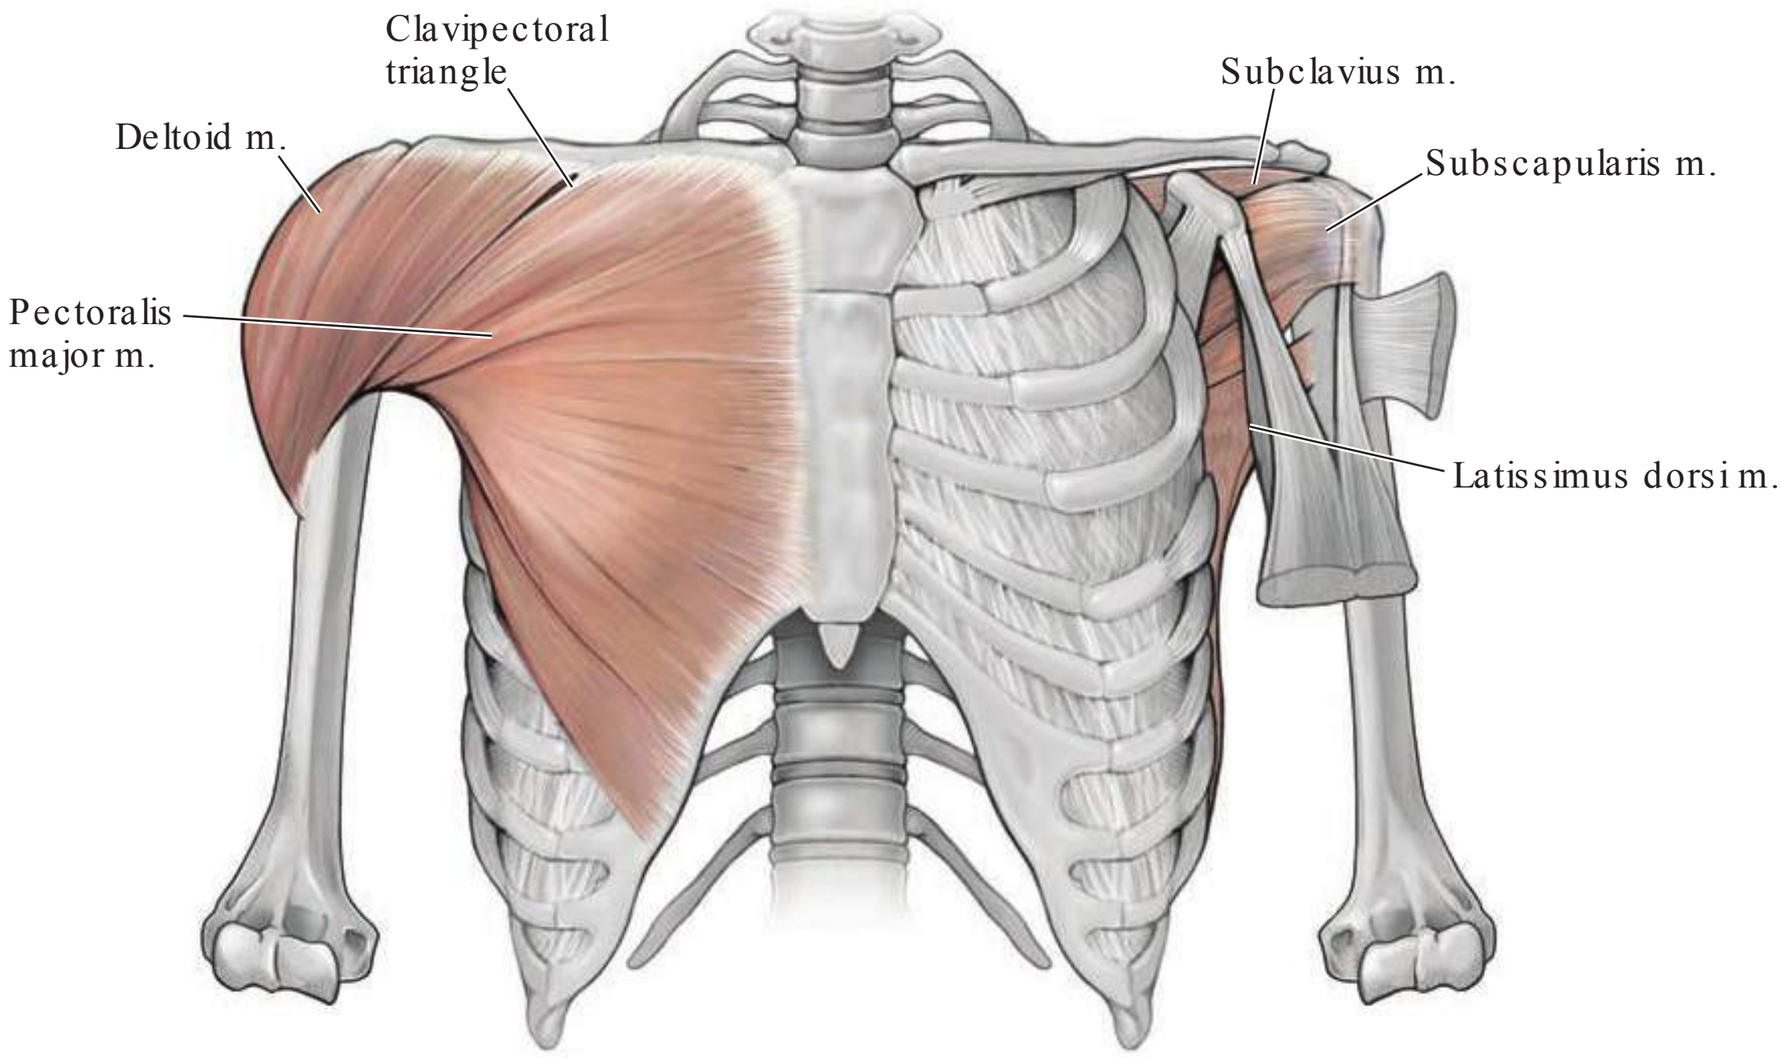

FIGURE 16-13 Pectoralis major muscle.

CLiNiCAL PeArL

The pectoralis major and latissimus dorsi muscles are referred to as humeral propeller muscles as they have been shown to be the only muscles in the upper extremity to have a positive correlation between peak torque and pitching velocity, and during the propulsive phase of the swim stroke.

Pectoralis minor

The pectoralis minor (see Fig. 16-9) originates from the outer surface of the upper margins of the third to fifth ribs near their cartilage. The fibers of the pectoralis minor ascend laterally, converging to a tendon that inserts into the coracoid process of the scapula.

The pectoralis minor muscle is innervated by the medial pectoral nerve (C6–8).

humeral Positioners

Deltoid

The deltoid muscle originates from the lateral third of the clavicle, the superior surface of the acromion, and the spine of the scapula (Fig. 16-13). It inserts into the deltoid tuberosity of the humerus. The deltoid can be described as three separate muscles—anterior, middle, and posterior—all of which function as humeral positioners, positioning the humerus in space.[94]

The deltoid muscle is innervated by the axillary nerve (C5–6).

shoulder Protectors

rotator Cuff

The rotator cuff muscles (Fig. 16-4), which consist of the supraspinatus, infraspinatus, teres minor, and subscapularis, are commonly implicated with shoulder pathology. The anatomy of these muscles was described previously (see "Glenohumeral Joint" section). These muscles are referred to as the protectors of the shoulder since, in addition to actively moving the humerus, they fine-tune the humeral head position during arm elevation.[94] Compared with most joints that have a single axis on which torques are generated, the shoulder is very different, because it has no fixed axis. As a result, each muscle activation creates a unique set of rotational moments, which necessitates precise coordination in the timing and magnitude of muscle contractions.[72] Jenp et al.[116] used electromyography (EMG) to detect the most specific positions of the highest activation for the individual rotator cuff muscles. The greatest activation of the subscapularis was with the arm in the scapular plane at 90 degrees of elevation and neutral humeral rotation. The subscapularis has also been shown to be an effective humeral head depressor in ER, whereas it produces almost no A-P translation in abduction and ER. The infraspinatus–teres minor muscles are very effective humeral head depressors with the arm in the sagittal plane and the humerus elevated to 90 degrees in the midrange of external/IR (the so-called "hornblower's" position). The supraspinatus has yet to be effectively isolated.

The rotator cuff muscles have an important role in the function of the shoulder and serve the following:

- Assist in the rotation of the shoulder and arm. At the G-H joint, elevation through abduction of the arm (Table 16-3) requires that the greater tuberosity of the humerus pass under the coracoacromial arch. For this to occur, the humerus must externally rotate, and the acromion must elevate.[117] ER of the humerus is produced actively by a contraction of the infraspinatus and teres minor, and by a twisting of the joint capsule. A force couple exists in the transverse plane between the subscapularis anteriorly and the infraspinatus and teres minor

TABLE 16-3 Contributors to Glenohumeral Abduction

Degree of Abduction	Biomechanics Involved
0–90	The concerted action of the active stabilizers (deltoid, biceps, and rotator cuff muscles) and the passive restraints (articular surfaces, osseous structures, and ligaments) is necessary for purposeful function. The supraspinatus contracts to initiate abduction of the glenohumeral joint.[a] The remaining rotator cuff muscles also contract to pull the humeral head into the glenoid fossa. At approximately 20 degrees of humeral abduction, scapular upward rotation begins with concurrent clavicular elevation and axial rotation.[b,c] At approximately 90 degrees, or a little more in females, the upper extreme of G-H abduction is reached, and clavicular elevation ceases due to tension of the costoclavicular ligament.[d] Continued abduction of the humerus requires continued upward rotation of the scapula, which by this point has rotated through a range of approximately 30 degrees.[e]
90–150	As the scapula continues to upwardly rotate, the glenoid fossa faces superiorly and laterally, and its inferior angle moves laterally through approximately 60 degrees. The scapular contribution peaks between 90 and 140 degrees.[f] The scapular upward rotation is accommodated at both the S-C and A-C joints by a posterior axial rotation of the clavicle of 30–40 degrees and a clavicular elevation of approximately 30–36 degrees.[c] The muscles producing this movement are the serratus anterior and trapezius, acting as a force couple on the scapulothoracic joint. The movement is limited by the acromion and S-C joint, and by the scapular and humeral adductors (notably the latissimus dorsi and pectoralis major).
150–180	Abduction beyond 150 degrees requires adequate motion at the vertebral joints of the upper thorax and cervical spine.[g] Bilateral abduction demands that the thoracic spine extends and the lumbar lordosis increases.

posteriorly in which cocontraction of the infraspinatus, teres minor, and subscapularis muscles both depresses and compresses the humeral head during overhead movements.

CLiNiCAL PeArL

The importance of the external rotation during humeral elevation can be demonstrated clinically. If the humerus is held in full IR, only about 60 degrees of G-H abduction is passively possible before the greater tuberosity impinges against the coracoacromial arch and blocks further abduction. This helps explain why individuals with marked IR contractures cannot abduct fully, but can elevate the arm in the sagittal plane.

However, in clinical practice, shoulders having large rotator cuff tears and good function are frequently encountered. In the coronal plane, there is another force couple between the deltoid and the inferior rotator cuff muscles (infraspinatus, subscapularis, and teres minor). With the arm fully adducted, contraction of the deltoid produces a vertical force in a superior direction, resulting in an upward translation of the humeral head relative to the glenoid. Cocontraction of the inferior rotator cuff muscles produces both a compressive force and a downward translation of the humerus that counterbalances the force of the deltoid, thereby stabilizing the humeral head.

EMG studies have shown that during casual elevation of the arm in normal shoulders, the deltoid and the rotator cuff act continuously throughout the motion of abduction, each reaching a peak of activity between 120 and 140 degrees of abduction.[13,118] However, during more rapid and precise movements, such as those involved with throwing, a more selective pattern emerges with specific periods of great intensity.[119] Weakening of the rotator cuff appears to allow the deltoid to elevate the proximal part of the humerus in the absence of an adequate depressor and compression effect from the rotator cuff, resulting in a decrease in the subacromial space and impingement of the rotator cuff on the anterior aspect of the acromion.[120,121]

- Reinforce the G-H capsule. The rotator cuff muscles, together with the coracohumeral ligament, and the LHB (often referred to as the fifth rotator cuff muscle) function as contractile ligaments. For example, firing of the rotator cuff muscles increases the tension of the middle G-H ligament when the arm is abducted to 45 degrees and externally rotated.[36]
- Control much of the active arthrokinematics of the G-H joint. Contraction of the horizontally oriented supraspinatus produces a compression force directly into the glenoid fossa.[120] This compression force holds the humeral head securely in the glenoid cavity during its superior roll, which provides stability to the joint and also maintains a mechanically efficient fulcrum for elevation of the arm.[120] In the shoulder midrange position,

when all of the passive restraints are lax, joint stability is achieved almost entirely by the rotator cuff. In addition, as previously mentioned, without adequate supraspinatus force, the near vertical line of force of a contracting deltoid tends to jam or impinge the humeral head superiorly against the coracoacromial arch.[99]

Long head of the Biceps Brachii

The biceps brachii muscle is a large fusiform muscle in the anterior compartment of the upper extremity, which has two tendinous origins from the scapula (Fig. 16-7). The medial head and LHB normally originate from the coracoid process and supraglenoid tubercle of the scapula, respectively. However, a great deal of research has noted that the origin of the biceps tendon varies, not only in its type of insertion (single, bifurcated, or trifurcated), but also in the specific anatomical location of where it inserts.[11,72] The proximal LHB tendon receives an arterial supply from labral branches of the suprascapular artery.[122] As it leaves its origin, the LHB tendon is surrounded by a synovial sheath, which ends at the distal end of the bicipital groove, making the tendon an intra-articular but extrasynovial structure.[72] As the LHB tendon moves between the greater and lesser tuberosities, it is stabilized in position by the tendoligamentous sling comprising the coracohumeral ligament, superior G-H ligament, and fibers from the supraspinatus and the subscapularis.[72,123] Once in the bicipital groove, the LHB tendon passes under the transverse humeral ligament, which bridges the groove.[124] After coursing through the groove, the two heads join to form the biceps muscle belly at the level of the deltoid insertion.[125] The medial tendon is interarticular, lying inside the G-H capsule.[126] This tendon is not as common a source of shoulder pain as the long tendon, and it rarely ruptures.[38–40]

The function of the biceps as a forearm supinator and secondarily as an elbow flexor is well known.[127] At the shoulder joint, however, the function of the LHB tendon is less clear, with most references regarding it as a week flexor of the shoulder.[128] Cadaveric studies have suggested that the LHB tendon functions as a humeral head depressor (in full ER), an anterior stabilizer, a posterior stabilizer, a limiter of ER, a lifter of the glenoid labrum, and a humeral head compressor at the G-H joint.[129–132] The muscle has also been described as having an important role in decelerating the rapidly moving arm during activities such as forceful overhand throwing.[72] In the anatomical position, the biceps has no ability to elevate the humerus. If the arm is rotated 90 degrees externally, the tendon of the long head lines up with the muscle belly to form a straight line across the humeral head. As the biceps contracts in this position, the humeral head rotates beneath the tendon, resisting ER of the humeral head and increasing the anterior stability of the G-H joint.[133,134] Contraction of the LHB in this position fixes the humeral head snugly against the glenoid cavity, as the resultant force passes obliquely through the center of rotation of the humeral head and at right angles to the glenoid.[133] The humeral head is prevented from moving upward by the hood-like action of the biceps tendon (Fig. 16-7), which exerts a downward force and assists the depressor function of the cuff.[135–137] Interestingly, the biceps tendon was found to be wider in cuff-deficient shoulders in one study.[138]

The biceps brachii muscle is innervated by the musculocutaneous nerve.

CLiNiCAL PeArL

A number of pathological conditions have been associated with the LHB tendon including LHB tendon degeneration, SLAP lesions, LHB tendon anchor abnormalities, and LHB tendon instability.[124]

BiOmeChANiCs

The G-H joint accounts for approximately two-thirds of most shoulder motions, with the remainder provided by the scapulothoracic joint.[85] For full motion to occur, a complex interaction between the deltoid muscle, rotator cuff muscles, LHB, G-H capsule, glenoid articulating cartilage, and scapular pivoters (trapezius, serratus anterior, levator scapulae, and rhomboids) is required.[139] Complete movement at the shoulder girdle also involves a complex interaction between the G-H, A-C, S-C, scapulothoracic, upper thoracic, costal, and sternomanubrial joints, the upper thorax, and the lower cervical spine. Within the joints of the shoulder complex, there appear to be no well-defined points within the range where one joint's motion ends and another begins. Rather, they all blend into a smooth harmonious movement during normal arm raising (see Tables 16-3 and 16-4).

The majority of functional shoulder motions involve a series of sequentially activated links in a kinetic chain of body segments.[140,141] For those motions requiring more force, the number of links in the kinetic chain increases—the sequence of activation starts as a ground reaction force (GRF) and moves up through the ankles, knees and hips to the trunk, and into the shoulder. Approximately 50% of the total kinetic energy and force occurring at the G-H joint originate from a combination of the GRF and the forces from the legs and hips.[140–142] At the shoulder, G-H, A-C, S-C, and scapulothoracic joints, motion occurs simultaneously as a result of muscle action and ligamentous tension in these joints. The specific sequence of muscle activation in the upper extremity depends on the activity, although the direction of activation is usually from proximal to distal as this is the most efficient method for producing large forces and accelerations to the arm. As part of this activation sequence, specific joint positions are developed depending on the activity. Any changes to this sequence of activation can produce an abnormal movement pattern, involving substitution or compensation from the more distal links.[46,143] For example, a throwing athlete with decreased trunk rotation due to stiffness has to rely more on the shoulder to provide the force for the throw. These adaptive patterns eventually result in either decreased performance or increased injury risk.

During shoulder rotation and arm activities, the scapula invariably acts as a platform upon which the activities are based. It is worth noting that the supporting structures of the G-H joint are only effective if the scapula can maintain its correct relationship with the humerus (see "The Dynamic Scapula" section).

TABLE 16-4 Contributors to Glenohumeral Elevation

Degree of Elevation and Main Contributor	Biomechanics Involved
0–60 degrees: glenohumeral elevation	A combined motion of flexion, abduction, and external rotation occurs at the glenohumeral joint, produced by the anterior deltoid, coracobrachialis, and the clavicular fibers of pectoralis major. Motion is limited by the increasing tension in the posterior coracohumeral ligament and the stretching of the shoulder extensors, adductors, and external rotators.[a]
60–120 degrees: sternoclavicular and acromioclavicular elevation	The scapula depresses, protracts, and abducts on the posterior thoracic wall, such that the glenoid fossa faces anteriorly and superiorly and its inferior angle faces laterally and anteriorly. This motion is accommodated by the S-C and A-C joints. The scapulothoracic motion is produced in the same manner as with abduction, by the serratus anterior and trapezius, and is limited by the ligaments of the two joints, and the tension in the shoulder extensor and adductor musculature.[a]
120–180 degrees—costospinal elevation	Kapandji[b] states that the extreme of flexion is the same as the extreme of abduction. That is, during unilateral elevation, the lateral displacement is produced by the contralateral spinal muscles while bilateral abduction requires an exaggeration of the lumbar lordosis to bring the arms vertical. In addition, the medial attachments of the first and second ribs descend while those of the fourth to sixth ascend and the third acts as the axis. Bilateral abduction demands that the thoracic spine extends.

Glenohumeral Joint

The G-H joint has three degrees of freedom (DOF): flexion/extension, abduction/adduction, and internal/ER. Available ranges of motion at the G-H joint are approximately as follows:

- **Flexion and abduction.** Approximately 100–120 degrees are available (approximately 180 degrees if scapular motion is included), with females demonstrating slightly more motion than males.
- **External rotation.** Approximately 60–80 degrees are available, with females demonstrating slightly more motion than males.
- **Internal rotation.** Approximately 80–90 degrees are available, with females demonstrating slightly more motion than males.
- **Extension.** Great variability exists with extension, with ranges existing from 10 to 90 degrees.

G-H motions consist of a combination of glides and rolls based on the concave–convex rule (see Chapter 10). At the G-H joint, the concave–convex rule dictates that the articulating surface moves in the opposite direction of the shoulder motion (Table 16-5). Motions at this joint do not occur in isolation, but rather as coupled motions.[144] For example, ER and abduction occur with flexion, and ER and adduction accompany extension.[76]

The G-H joint has been described as being similar to a golf ball on a tee due to the size relationships. A more accurate biomechanical description is that the G-H joint is like a ball on a seal's nose.[145] As the ball or humeral socket moves, the seal's nose, or the scapula, needs to move to maintain the position of the ball on the glenoid. The orientation of the G-H joint causes motions at this joint to occur in the scapular plane. The shoulder has the greatest ROM of any joint, with a vast array of muscles producing those motions.[1] The correct function of these muscles is dependent on appropriate length–tension relationships and coordinated activation.[47] Over 1,600 different positions in three-dimensional space can be assumed by the shoulder.[141,146] Due to this wide ROM, the G-H joint is faced with the task of maintaining equilibrium between the functional mobility and adequate stability during normal activities of daily living (ADL).[147] When sport is added to the equation, extremely high forces can be generated at the shoulder. For example, the angular velocity of an overhead throw reaches over 7,000 degrees per second, which is the fastest recorded human movement.[148]

CLINICAL PEARL

It has been estimated that the anterior translation forces generated with pitching are equal to one-half body weight during the late cocking phase, and there is a distraction force equal to body weight during the deceleration phase.[149]

The complex kinematics of this region probably account for the fact that strains and sprains may remain symptomatic for much longer than in other joints.[1]

TABLE 16-5 Glenohumeral Joint Motions and Their Appropriate Axis and Accessory Motions

Plane/Axis of Motion	Physiologic Motion	Accessory Motion
Sagittal/mediolateral	Flexion/extension	Spin (minimal roll and slide)
Coronal/anteroposterior	Abduction	Superior roll, inferior slide
Transverse/longitudinal	Horizontal adduction	Posterior roll, anterior slide
	Internal rotation at 0 degrees abduction	Anterior roll, posterior glide
	External rotation at 0 degrees abduction	Posterior roll, anterior slide

TABLE 16-6	Static Restraints to Inferior Translation (Dependent on the Position of the Arm)
Degrees of Glenohumeral Abduction	**Restraining Structures**
0	Superior G-H and coracohumeral ligaments
90	Inferior G-H ligament (posterior band in external rotation, anterior band in IR)

Data from Warner JJP, Deng XH, Warren RF, et al. Static capsuloligamentous restraints to superior-inferior translation of the glenohumeral joint. Am J Sports Med. 1992;20:675–685.; Turkel SJ, Panio MW, Marshall JL, et al. Stabilizing mechanisms preventing anterior dislocation of the glenohumeral joint. J Bone Joint Surg Am. 1981;63:1208–1217.

Full elevation of the arm occurs through an arc of approximately 180 degrees and can occur in an infinite number of body planes.[150] Locally, this motion is a result of abduction of the G-H joint and upward rotation of the scapulothoracic joint. During abduction of the shoulder, the G-H joint is reported to contribute up to 120 degrees of the total arc of motion, with the remaining 60 degrees occurring at the scapulothoracic joint. Arm elevation beyond 90 degrees requires motion in other, more distal joints such as the A-C and S-C joints (see "The Dynamic Scapula" section) and the vertebral joints of the upper thorax and lower cervical spine, in addition to various static restraints (Tables 16-6 and 16-7).

Flexion at the G-H joint involves a pure spin if it occurs strictly in the sagittal plane; no roll or slide is necessary. Tension within the surrounding capsular structures, particularly the posterior structures, may cause a slight anterior translation of the humerus at the extremes of flexion.[45] However, although flexion in the sagittal plane involves a pure spin, elevation of the arm in the scapular plane involves a combination of flexion, abduction, and ER. Thus, at the joint surface of the G-H joint during arm elevation in the scapular plane, the head of the humerus spins (flexion component), glides inferiorly (abduction component), and glides anteriorly (ER component) (Table 16-5).

The synchronized motions that occur between the scapula and the humerus during elevation are a combination of

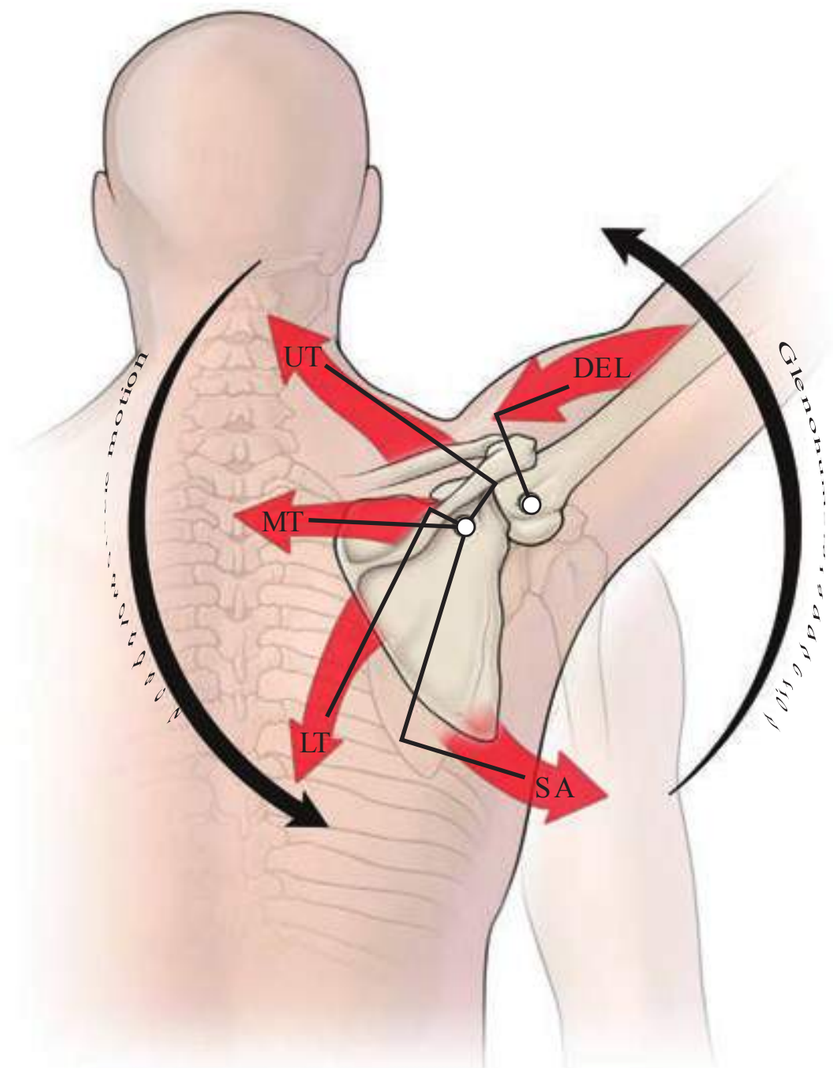

FIGURE 16-14 The scapulohumeral rhythm.

scapulothoracic motion and scapulohumeral motion. During arm elevation, the scapula generally upwardly rotates, tilts posteriorly, and either moves toward internal or external rotation. The angle between the glenoid and the moving humeral head has to be maintained within a safe zone of 30 degrees of angulation during activities to decrease shear and translatory forces.[151] For this to occur, the scapula must be positioned muscularly in relation to the moving humerus and must also act as a stable base of muscle origin for the rotator cuff muscles. If the scapula cannot be controlled, the glenoid cannot be positioned correctly to allow for the optimal length–tension relationships within the shoulder complex.[106,152] The synchronized motion between the glenoid cavity and the humerus is referred to as scapulohumeral rhythm (Fig. 16-14). Proper rhythm involves a rotation of the scapula during arm elevation. By allowing the glenoid to stay centered under the humeral head, the strong tendency for a downward dislocation of the humerus is resisted and the glenoid is maintained within a physiologically tolerable range (Fig. 16-14). At full abduction, the glenoid completely supports the humerus.

Several studies have examined the scapulohumeral rhythm three dimensionally.[25,26,85,153,154] An early study by Inman et al.[85] determined that a 2:1 ratio existed between the motion occurring at the G-H joint and scapula, respectively. However, more recent studies have shown that this ratio is not consistent throughout the ROM.[21,107,153] As the humerus elevates to 30 degrees (setting phase), there is minimal movement of the scapula. In this initial portion of abduction, G-H motion predominates and the ratio has been found to be 4.4 degrees of G-H motion for every degree of scapular motion (4.4:1 ratio). From 30 to 90 degrees, the scapula abducts and upwardly rotates, and the ratio becomes 5 degrees of G-H motion to 4 degrees of scapular motion (5:4 ratio). As the shoulder moves above 90 degrees of abduction to full abduction, the scapula

Data from Warner JJP, Deng XH, Warren RF, et al. Static capsuloligamentous restraints to superior-inferior translation of the glenohumeral joint. Am J Sports Med. 1992;20:675–685; Turkel SJ, Panio MW, Marshall JL, et al. Stabilizing mechanisms preventing anterior dislocation of the glenohumeral joint. J Bone Joint Surg Am. 1981;63:1208–1217.

abducts and upwardly rotates 1 degree for every 1 degree of humeral elevation (1:1 ratio) .[25,111,153] However, it must be kept in mind that these ratios are based on two-dimensional radiographic projections of angular rotations taken at discrete positions of elevation, whereas in reality, the arm moves in three dimensions, and that the scapulohumeral rhythm has also been found to change with external loading of the arm.[154]

CLiNiCAL PeArL

A reverse scapulohumeral rhythm, in which the scapula moves more than the humerus, occurs in conditions such as adhesive capsulitis.

scapulothoracic Joint

Scapulothoracic motion is a vital component of shoulder function and consists of rotation and translation around approximately three axes of motion. T ese axes are considered to be embedded in the scapula.[155]

- Anterior and posterior tipping occurs around an axis parallel to the scapula.
- Protraction and retraction of the scapula occur through protraction and retraction of the clavicle at the S-C joint.
- IR and ER occur around an axis running through the scapula from superior to inferior.
- Elevation and depression of the scapula occurs through elevation and depression of the clavicle at the S-C joint. T roughout the 180 degrees of arm elevation, a total of 30–35 degrees of clavicle elevation occurs, in addition to rotation of the clavicle (38–55 degrees) around its longitudinal axis.[73] T is clavicular elevation and rotation occur in two main phases of shoulder abduction. Assuming a 2:1 scapulohumeral rhythm, shoulder abduction up to 90 degrees occurs as a summation of 60 degrees of G-H abduction, and 30 degrees of scapulothoracic upward rotation. T e 30 degrees of upward rotation occurs predominantly through a synchronous 20–25 degrees of clavicular elevation at the S-C joint and 5–10 degrees of upward rotation at the A-C joint.[99] T e elevation of the clavicle raises the acromion during arm elevation allowing for the subacromial structures to pass under the coracoacromial arch.[24] Shoulder abduction from 90 to 180 degrees occurs as a summation of an additional 60 degrees of G-H joint abduction and an additional 30 degrees of scapulothoracic upward rotation.[99] During this late phase, the clavicle elevates only an additional 5 degrees at the S-C joint, whereas, at the A-C joint, the scapula upwardly rotates 20–25 degrees. T us, by the end of 180 degrees of abduction, the 60 degrees of scapulothoracic upward rotation can be accounted for by 30 degrees of elevation at the S-C joint and 30 degrees of upward rotation at the A-C joint.[99] T e motion at the A-C joint is controlled by tension in the coracoclavicular ligaments. Finally, the clavicle has been demonstrated in vivo to posteriorly rotate around its long axis during the late phase of shoulder abduction.[24] It is, as yet, unclear whether this posterior rotation occurs at the S-C or at the A-C joint. T e rotation of the clavicle, though, is controlled by tension in the coracoclavicular ligaments and the clavipectoral fascia.

Elevation of the arm in the scapular plane in healthy subjects is accompanied by posterior tipping and upward rotation of the scapula.[155] T e upward rotation of the scapula occurs about an axis that passes through the base of the spine of the scapula and occurs in various phases (see Tables 16-3 and 16-4). Rotation of the scapula about the vertical axis shows a somewhat more variable pattern,[155] with some studies showing ER occurring predominantly at higher elevation angles,[67,156,157] while others demonstrate IR.[158–160]

- Upward and downward rotation occurs around an axis perpendicular to the plane of the scapula that travels through the A-C joint and S-C joint.[70] T e upward rotation of the scapula during shoulder abduction helps to maintain an effective length–tension relationship between the three groups (force couples) of muscles that attach to the scapula. A force couple can be defined as two forces that act in opposite directions to rotate a segment around its axis of motion.

During the first 30 degrees of upward rotation of the scapula, the serratus anterior muscle and the upper and lower divisions of the trapezius muscle are considered the principal upward rotators of the scapula. Together these muscles form two force couples; one formed by the upper trapezius and the upper serratus anterior muscles (Fig. 16-14) and the other by the lower trapezius and lower serratus anterior muscles.[6,85,161]

T e prime muscles that abduct the G-H joint are the middle deltoid and the supraspinatus muscles.[99] Elevation of the arm through flexion is performed primarily by the anterior deltoid, coracobrachialis, and LHB brachii.[99] T e trapezius appears to be more critical for controlling the scapula during the initial phases of abduction, whereas the serratus has been found to be the most effective upward rotator of the scapula.[85,162] T e lower trapezius contributes during the later phase of shoulder abduction by preventing tipping of the scapula and assisting in the stabilization of the scapula through eccentric control of the scapula during scapular upward rotation.[111,153]

CLiNiCAL PeArL

During approximately the first 150 degrees of arm elevation through flexion

- the upper and lower fibers of the trapezius contract concentrically,
- the fibers of the lower serratus anterior contract concentrically,
- the levator scapulae contracts eccentrically,
- the rhomboids contract eccentrically.

From approximately 150–180 degrees

- the lower fibers of the serratus anterior contract isometrically,
- the lower fibers of the trapezius contract concentrically,
- the pectoralis minor contracts eccentrically,
- the upper fibers of the serratus anterior contract eccentrically.

The middle trapezius and rhomboids may also contribute to the scapular motions involved during arm elevation.[163] The antagonists are the pectoralis major, teres major, latissimus dorsi, and coracobrachialis, all working eccentrically. Normal motion of the scapula on the thorax is believed to include consistent contact between the thoracic wall, the medial border, and inferior angle of the scapula.[161,163] Loss of this contact has been clinically implicated as evidence of abnormal scapular kinematics. These abnormal scapular kinematics may result in additional stress on the anterior shoulder stabilizers.[164–166]

The appropriate force couples for the acromial elevation that occurs during G-H abduction are the lower trapezius and serratus muscles working together, paired with the upper trapezius and rhomboid muscles (Fig. 16-14).[24]

The EMG activity of the levator scapula muscle, upper and lower trapezius muscles, and serratus anterior muscle during arm elevation increases progressively as the humeral angle increases.[67] Activities that maintain an upwardly rotated scapula while accentuating scapular protraction, such as a push-up plus, elicit the greatest serratus anterior EMG activity.[76]

CLiNiCAL PeArL

A number of investigations have aimed to determine if adaptations in scapular movement occur in individuals with impingement or rotator cuff disease.[156,167–169] Specifically noted are a decreased scapular movement toward upward rotation, posterior tilt, and external rotation during humeral elevation.[67,170,171]

The last few degrees of shoulder elevation consist of upper thoracic movement once full G-H joint and shoulder girdle motion have been completed. Movement of the thoracic spine during unilateral and bilateral arm elevation has been examined in a number of studies.[172,173] In young, asymptomatic individuals, the total range of thoracic spine extension motion has been reported to be between 2 and 19 degrees, with slightly greater mobility in men.[174] The fact that a decrease in thoracic spine extension mobility has been reported in asymptomatic individuals older than 60 years,[175] would tend to indicate that the sagittal curvature of the spine in the region (kyphosis) must influence the amount of available thoracic spine extension.

The scapula also functions during retraction and protraction along the thoracic wall (see Fig. 16-11).[24] Protraction occurs as the serratus anterior at the scapula and the pectoralis major at the humerus contract simultaneously. Retraction is produced by the combined action of the trapezius and rhomboids.[176] A 15–18-cm translation of the scapula around the thoracic wall occurs during retraction and protraction, depending on the size of the individual and the vigorousness of the activity.[24,142] This is retraction and protraction is used during activities such as reaching and pulling, respectively.[24]

Finally, the scapula functions to transfer the large forces and energy from the legs, hips, back, and trunk to the actual delivery mechanism, the arm and hand.[24,140,177,178]

Acromioclavicular Joint

The motions available at the A-C joint occur around three axes:

- Rotation in an anteroposterior (A-P) direction around a longitudinal axis that projects through the A-C and S-C joints, and rotation in a superoinferior (vertical) direction. The A-P rotation occurs during arm elevation. The superoinferior rotation, which occurs around the costoclavicular ligament, is involved during protraction (anterior movement of the acromial end of the clavicle) and retraction (posterior motion of the acromial end). The A-P rotation of the clavicle on the scapula is three times greater than that of the superoinferior rotation. The clavicle can rotate in the A-P direction with contributions from the mobile S-C joint.[179] The type of glide and rotation that occurs with clavicular motion depends on the shoulder motion and the shape of the articular surfaces. If the lateral end of the clavicle presents a concave surface, an anterior glide is combined with an anterior rotation. If the lateral end presents a convex surface, an anterior glide is combined with a posterior rotation.

CLiNiCAL PeArL

The clavicle must be able to fully rotate for full elevation to occur; otherwise elevation would be limited to approximately 110 degrees.[179]

- Pure spin/rotation. A pure spin occurs during abduction/adduction (lateral and medial rotation of inferior scapula angle) motions.
- Glides. Glides of the clavicle can occur in an A-P and superoinferior direction.
- The A-C joint is predisposed to chronic stress injury, especially in the situations in which it is subjected to repetitive high demand.[70,180] The joint can also be affected by direct trauma and by nontraumatic factors such as degenerative arthritis and inflammatory arthropathies.[75] Table 16-8 contains the pathologies and dysfunctions that may affect the A-C joint.

TABLE 16-8 Pathologies and Dysfunctions that May Affect the A-C Joint

Traumatic conditions	Separation/dislocation (types I–VI), and fracture
Infectious conditions	Septic arthritis
Inflammatory conditions	Rheumatoid arthritis Systemic lupus erythematosus Ankylosing spondylitis Subacromial bursitis Rotator cuff pathology
Degenerative joint disease	Osteoarthritis Osteolysis
Metabolic conditions	Gout

Data from Powell JW, Huijbregts PA. Concurrent criterion-related validity of acromioclavicular joint physical examination tests: A systematic review. J Man Manip Ther. 2006;14:E19–E29.

sternoclavicular Joint

Two types of translation also occur at the S-C joint: anterior to posterior and superior to inferior, with the former exceeding the latter motion by 2:1.[181] T ese translations allow for three DOF: the movements of elevation, depression; protraction, retraction; and upward (backward) and downward (forward) motion.

- Protraction/retraction. Approximately 15–20 degrees of protraction and retraction of the clavicle are available. With protraction, the concave surface of the medial clavicle moves on the convex sternum, producing an anterior glide of the clavicle, and an anterior rotation of the lateral clavicle.[181] With retraction to the neutral position, the medial clavicle articulates with a flat surface and tilts/swings, causing an anterolateral gapping, and a posterior rotation at the lateral end.[181]
- Elevation/depression of the clavicle. T ere are 35–40 degrees of elevation and approximately 15 degrees of depression available,[3,85,181] involving the convex clavicle gliding on the concave sternum.

As the clavicle elevates and rolls upward on the manubrium, an inferior glide is produced, with the reverse occurring with depression. Elevation and depression movements at the S-C joint are associated with reciprocal motions of the scapula because of the lateral attachment of the clavicle to the scapula at the A-C joint.[76]

Rotation around the long axis produces a spin of the clavicle on the manubrium. Approximately 40 degrees of upward rotation and 5 degrees of downward rotation are available and are necessary to allow upward scapular rotation.[3,85]

CLiNiCAL PeAr L

For the scapular to abduct and upwardly rotate throughout 180 degrees of humeral abduction, clavicular movement must occur at both the S-C and A-C joints.

stabilization of the static shoulder

T e glenohumeral joint at rest requires very little muscular support. Its vertical stability is a result of the inferior lateral projection and upward inclination of the glenoid fossa, which is maintained by a mild contraction of the fibers of the trapezius. It was traditionally theorized that the humeral head was prevented from rolling off of this lateral projection by a moderate contraction of the supraspinatus and the deltoid.[131,182] More recent studies have demonstrated that the muscle tone of the rotator cuff is not a significant contributor to the static inferior stability of the dependent shoulder with light loads, but that maintenance of the intra-articular pressure and the adhesion and cohesion properties of the articular surfaces are far more significant.[183,184] However, the rotator cuff does provide a passive restraint to translation, especially to posterior translation, during the early-to-midranges of elevation.[185]

During the mid and end ranges of motion, a combination of several different static restraints create a vector that keeps the humeral head securely seated in the glenoid, through concavity compression—negative articular pressure.[139,146,183,186–188]

TABLE 16-9 Dynamic and Static Restraints to External Rotation (Dependent on the Position of the Arm)

Degrees of Glenohumeral Abduction	Restraining Structures
0	Subscapularis, superior G-H, and coracohumeral ligaments
45	Subscapularis, middle G-H ligament, superior fibers of the inferior G-H ligament
90	Inferior G-H ligament

Data from Warner JJP, Caborn DN, Berger RA, et al. Dynamic capsuloligamentous anatomy of the glenohumeral joint. J Shoulder Elbow Surg. 1993;2:115–133; Turkel SJ, Panio MW, Marshall JL, et al. Stabilizing mechanisms preventing anterior dislocation of the glenohumeral joint. J Bone Joint Surg Am. 1981;63:1208–1217.

Static restraint is also provided by the anatomic curvature of the humerus and glenoid, the extra depth of the labrum, and ligamentous restraints.[189] (see Tables 16-6, 16.7 and 16-9).[161] T e ligamentous restraints contribute especially at the end ranges of motion[190] and are assisted with concomitant muscle activity (see Table 16-9).

stabilization of the Dynamic shoulder

Dynamic stability of the shoulder complex is dependent on a variety of mechanisms including the optimal alignment of the scapula, correct G-H orientation, and the quality of the length–tension relationship of the involved muscles, and correct functioning of the static restraints.

T e deltoid, pectoralis major, latissimus dorsi, and teres major muscles are prime movers of the G-H joint. EMG studies have shown that these muscles function along the line of pull, creating the potential for infinite lines of pull that may allow an almost 360 degrees arc of motion.[13,26] Indeed, like the temporomandibular joint, the G-H joint enjoys the benefit that all of its prime movers compress the joint surface, thus optimizing joint stability. T e secondary movers of the G-H joint are the LHB, and the triceps.

CLiNiCAL PeAr L

The long head of the biceps and the triceps muscles are major dynamic stabilizers of the G-H joint, predominately functioning as "shunt" muscles (muscles that produce a compression at the joint surfaces of the joints they cross) during high-velocity activities.

As motion occurs at the G-H joint, the glenoid cavity of the scapula adopts a diverse number of reciprocal positions. It is likely that these scapular positions are based on both the functional task and the placement of the hand. Dysfunction or inhibition of any of the scapular stabilizers (serratus anterior, latissimus dorsi, trapezius, rhomboids, levator scapulae, and the pectoralis minor) can alter the position of the glenoid significantly, resulting in abnormal centering of the humeral head within the glenoid.[24,191,192]

Until recently, EMG or cadaver studies have been the primary method of evaluating the contribution of each rotator cuff and shoulder muscle to a particular motion or exercise. For example, using cadavers, Kibler et al.[146] determined that the subscapularis contributes 53% of the cuff moment and believed it to be the most important muscle in humeral head stabilization.

Magnetic resonance imaging (MRI) is now being used to show increases in muscle signal intensity detected immediately following exercise.[147–149] On the basis of the level of signal intensity, this so-called exercise-induced enhancement seen on MRI can determine which muscles are used for a given exercise.[140,147,148,150–152] For example, one study of the shoulder[149] demonstrated that sidelying abduction produced the greatest signal intensity in the supraspinatus, infraspinatus, and subscapularis muscles. Surprisingly, scaption with internal rotation (SIR), previously associated with isolation of the supraspinatus muscle, did not provide the highest increase in any muscle of the rotator cuff.[149] However, caution must be used in drawing conclusions from single studies, and further research is certainly warranted in this area.

As previously mentioned, the role of the capsuloligamentous complex in stabilizing the G-H joint during dynamic activities is complex and varies with both shoulder position and the direction of the translation force.[193] The posterior capsule is the main restraint against posterior translation of the humerus on the glenoid fossa with the arm below 90 degrees of abduction.[194] With the arm at 90 degrees of abduction, the inferior G-H ligament and the posteroinferior capsule become the main restraint.[194] The posterior band of the inferior G-H ligament resists inferior translation when the arm is at 90 degrees of abduction.

examination

The intervention strategies for the common pathologies of the shoulder complex are detailed after the examination section. An understanding of both is necessary. As mention of the various pathologies occurs with reference to the examination and vice versa, the reader is encouraged to alternate between the two. Shoulder complex conditions are often multifaceted, and patients with the same shoulder condition often present with diverse physical findings. It is critical that the clinician consider the shoulder girdle as a whole, rather than as a series of isolated articulations, and as a part of the whole kinetic chain. In the presence of shoulder complex dysfunction (assuming systemic or serious causes have been ruled out) there are three likely causes:

- Compromise of the passive restraint components of the shoulder girdle.
- Compromise of the neuromuscular system's production or control of shoulder girdle motion.
- Compromise to one or more of the neighboring joints that contribute to shoulder girdle motion, including
  - the A-C joint,
  - the S-C joint,
  - the joints of the upper thoracic spine and ribs,
  - the joints of the lower cervical spine.

Due to this complexity, all of the above-mentioned joints must be selectively tested in a specific sequence before proceeding with a more detailed examination of the suspected joint or joints.

history

A good history is the cornerstone of proper diagnosis, especially since shoulder pain has a broad spectrum of patterns and characteristics. A body chart can be used to record the patient's symptom distribution (see Chapter 4). The body chart is a symptomatic representation of a patient's complaints and can be an important element in guiding both the history and the tests and measures.

The history should begin with a brief outline of the patient's profile including age, occupation, hand dominance, recreational pursuits, work requirements, and ADL.[195] Age is occasionally significant:[196]

- Children and adolescents may have an epiphysitis of the humerus, or an osteogenic sarcoma.
- Calcific deposits in the shoulder are more common between 20 and 40 years of age.
- Chondrosarcomas usually occur after the age of 30 years.
- Rotator cuff degeneration usually occurs in the 40s and 50s.
- A frozen shoulder is more common in those aged 45–60 years and is often associated with medical conditions such as diabetes mellitus and ischemic heart disease.[195]

The exact mechanism of injury should be determined as it can help with a preliminary diagnosis:[197]

- Overhead exertion involving repetitive motions is a common mechanism for subacromial pathology, encompassing subacromial bursitis,[60] SIS,[39] rotator cuff tendinopathy,[39,198] and rotator cuff tear.[199] It is also a common cause of bicipital tendinopathy.
- A fall on an outstretched hand ("FOOSH" injury) can result in a sprain or strain injury to the wrist, elbow, and shoulder. More serious injuries from such a fall include fractures of the wrist and elbow, A-C separations, clavicular fractures, and G-H fractures and dislocations.
- A fall on the tip of the shoulder is a common mechanism for A-C separation. In addition, this mechanism can result in a compression periostitis (bone contusion) or a cervical spine injury, both of which appear remarkably similar to an A-C separation especially in the early stages.
- Forced horizontal extension of the abducted, externally rotated arm is a common mechanism for anterior dislocation.
- Shoulder pain is the most frequent orthopedic injury in swimmers (see Chapter 30), with a reported prevalence between 40% and 91%.[200] This is due in part to the fact that, unlike most other sports where the legs initiate the propulsive force, swimming athletes primarily use their arms to generate forward thrust.[201] It is thought that muscle fatigue of the upper back, rotator cuff, and pectoral

muscles caused by the repetitive movements involved in swimming can result in microtrauma due to decreased dynamic stabilization of the humeral head.[202,203]

It is important to establish the patient's chief presenting complaint (which is not always pain) as well as defining their other symptoms. The most common complaints associated with shoulder pathology include pain, instability, stiffness, deformity, locking, and swelling.[195] However, patients sometimes complain of catching, clunking, grinding, or popping of the shoulder with various movements. These sounds and sensations may be asymptomatic and nonpathologic but they may also indicate pathology including labral disorders, rotator cuff tears, snapping scapular, subacromial bursitis, or biceps tendon disorders, especially if the sound or sensation is associated with pain or instability.[195] Periscapular pain is often associated with local muscle strain but may be referred.[1]

The quality of the pain is also important. Radicular pain tends to be sharp, burning, and radiating. Bone pain is deep, boring, and localized. Muscle pain can be dull, aching, and hard to localize. Tendon pain tends to be hot and burning. Vascular pain can be diffused, aching, and poorly localized and may be referred to other areas of the body. The intensity of pain may wax and wane with particular motions associated with specific activities. For example, common complaints with a rotator cuff tear include difficulty with elevation of the arm in abduction, as well as ER, and when the patient attempts to put his or her hand behind the head or back (combing the hair, or reaching into a back pocket respectively).[204] Patients who report difficulty tucking in their shirts may have limited IR from posterior capsular stiffness.[205] The hallmark of posterior capsular contracture is symmetric loss of active and passive IR. Posterior capsular stiffness may occur independent of rotator cuff disease. Stiffness or loss of motion at the shoulder may be the chief complaint in conditions such as adhesive capsulitis.[195] A-C joint pain tends to occur with arm motion above 90 degrees of abduction and with horizontal abduction. Pain associated with an idiopathic frozen shoulder tends to be constant, but is particularly bad at night and frequently awakens the patient.[52]

Weakness may be the chief complaint, leading to some diagnostic confusion. It is important to distinguish true weakness from weakness secondary to pain, both in terms of history and examination findings.[206] Painless weakness is usually due to neurological problems or myopathies, although peripheral nerve injuries can be painful (Table 16-10). Shoulder weakness may be caused by a rotator cuff tear or nerve injury (suprascapular, axillary, long thoracic, or thoracodorsal nerves, or cervical nerve root injury) (see Table 16-10).[107]

Symptoms that are not associated with movement should alert the clinician to a more serious condition (see "Systems Review" section). Pain that is worse at night, but increased when rolling onto the shoulder, points to a periarticular mechanical problem.[204]

Determining the location of pain is important. Pain that radiates beyond the elbow is far less likely to be due to shoulder pathology, particularly if it is associated with any sensory disturbance in the limb such as distal radiation of pain, numbness, or paresthesias.[195] In such cases the clinician should rule out thoracic outlet syndrome (TOS), cervical radiculopathy,

TABLE 16-10 Peripheral Nerve Lesions

Spinal accessory nerve	Inability to abduct the arm beyond 90 degrees Pain in the shoulder with abduction
Musculocutaneous nerve	Weak elbow flexion with forearm supinated
Long thoracic nerve	Pain on flexing a fully extended arm Inability to fully flex an extended arm Winging of the scapula at 90 degrees of forward shoulder flexion
Suprascapular nerve	Increased pain on forward shoulder flexion Pain increased with scapular abduction Pain increased with cervical rotation to the opposite side
Axillary nerve	Inability to abduct the arm with neutral rotation
Thoracodorsal nerve	Marked difficulty to resist shoulder extension Marked difficulty to resist shoulder internal rotation
Cervical spinal nerve root	Varies according to the level involved, so can include various combinations of the above

or referred pain from neighboring areas. Anterior shoulder pain suggests bicipital tendinopathy, whereas posterior shoulder pain might be due to a posterior labral tear.[52]

CLINICAL PEARL

Pain due to rotator cuff pathology and impingement, which is usually felt over the anterior or lateral part of the shoulder, can be characterized by radiation down the upper arm, and is aggravated with overhead activities.[195,207]

Pain due to A-C joint pathology is usually located at the superior region of the shoulder or well localized at the A-C joint itself, and there is often a clear history of injury to this region. Severe pain on top of the shoulder with an associated deformity could indicate an A-C joint sprain. Posterior neck pain may be indicative of a cervical radiculopathy, as neither the A-C joint nor a subacromial irritation refers pain to this area.[75,208]

The clinician should determine which positions or movements relieve the pain, as these can provide helpful information:[197]

- Pain relieved with arm elevation overhead could indicate a cervicogenic cause.[209]
- Pain relieved with the elbow supported is suggestive of A-C separation and rotator cuff tears.
- Pain relieved by circumduction of the shoulder with an accompanying click or clunk could indicate an internal derangement or subluxation.

- Pain relieved with arm distraction is suggestive of bursitis or rotator cuff tendinopathy.
- Pain relieved when the arms are held in a dependent position suggests TOS.

An inquiry about general health, any existing medical conditions, medications, and allergies should be made. Corticosteroid use can cause osteoporosis and tendon atrophy and affects wound healing; therefore a history of its use may alter the differential diagnosis.[195,204] The use of anticoagulant medication should be noted. Patients who are undergoing renal dialysis are at increased risk for tendon tears, as are patients who are 80 years of age or older.[204] Bilateral shoulder involvement is not uncommon in these groups.

Past physical therapy interventions, previous injections, and previous surgery are important to document, as are previous shoulder injuries and what relationship, if any, they have with the present symptomatology.[195]

systems review

The clinician should be able to determine the suitability of the patient for physical therapy (PT). If the clinician is concerned with any signs or symptoms of a visceral, vascular, neurogenic, psychogenic, spondylogenic, or a systemic disorder (see Chapter 5) that is out of the scope of PT, the patient should be referred back to his or her physician or another appropriate healthcare provider.

Scenarios related to the shoulder that may warrant further investigation by the clinician include an insidious onset of symptoms and complaints of numbness or paresthesia in the upper extremity.

The most common causes of numbness in the shoulder and arm are due to cervical or upper thoracic involvement, with either the segmental roots involved or the brachial plexus. The patient should be questioned about recent changes in work requirements or environment, and the presence of neck pain.[38–40,210] In studies where normal cervical ligaments and muscles,[211] cervical zygapophyseal joints,[212] and disks[213] have been stimulated, subjects have reported pain in the head, anterior and posterior chest wall, shoulder girdle, and upper limb depending on the cervical level stimulated.[111]

The Cyriax scanning examination (see Chapters 4 and 5) may demonstrate subtle weakness of the cervical root innervated muscles. Depressed or absent upper extremity reflexes are also frequently noted. Finally, reproduction of the patient's pain with cervical motion and not with shoulder movement is a strong indicator of cervical origin.

In addition to the cervical and upper thoracic spine, the related joints referring symptoms to the shoulder require clearing. These include the temporomandibular joint, costosternal joint, costovertebral and costotransverse joint, thoracic spine, and the elbow and forearm.[69,207]

Systemic causes of insidious shoulder pain include rheumatoid arthritis. Rheumatoid arthritis often affects the shoulders and hips in older individuals and can be difficult to distinguish from polymyalgia rheumatica. Morning stiffness lasting for more than 1 hour, constitutional signs, and physical signs of joint inflammation are all indicative of an inflammatory disease.[204] Other systemic sources of shoulder pain include lupus erythematosus and gallbladder and liver disease.[69] These latter conditions are associated with other signs and symptoms that are not related to movement and are systemic in nature. Chronic respiratory and cardiovascular conditions must also come into consideration.[195] The shoulder is very close to the chest and its viscera; therefore reference of symptoms to the shoulder from these structures is common (see Chapter 5). It is vital that questions be asked that would reveal a relationship between the onset of symptoms and local movements versus general exercise, the latter of which could implicate the lung, heart, or diaphragm.

CLINICAL PEARL

Severe progressive pain not affected by movement, persistent throughout the day and night, and associated with systemic signs, may indicate referred pain from a malignancy. The exception to this may be adhesive capsulitis (frozen shoulder), which is often characterized by boring, unrelenting, aching pain, even at rest.[214]

Finally, a vascular examination should be performed and should include an assessment of general skin texture, color, temperature, hair growth, and alteration of sensation about and distal to the shoulder.[52] Autonomic signs and symptoms are suggestive of complex regional pain syndrome (CRPS) (refer to Chapter 18). Neurovascular compression or TOS tests are described in "Special Test" section in Chapter 25.

TESTS AND MEASURES

The physical examination of the shoulder complex should be focused and thorough, using the clinical impression gleaned from the history and systems review as a guide.

Observation

Observation of the patient begins when the patient enters the clinic. The clinician observes how the patient holds the arm, the overall position of the upper extremity, and the willingness of the patient to move the arm. During gait, an upper extremity should swing in tandem with its opposite lower extremity. Once in the examination room, the patient is appropriately disrobed and the shoulder is systematically inspected from anterior, lateral, and posterior positions. Total body alignment is examined for overall posture, the relative rotation of the humerus, structural malalignment such as kyphosis, the presence of scars, color changes, and swelling.[195] Observable swelling in the shoulder may indicate a serious problem or damage. Anterior prominence of the humeral head or a high-riding outer clavicle suggest G-H dislocation or A-C separation, respectively.[52] The relative heights of the shoulder girdles should be assessed. The height of the shoulder may or may not be significant. If the shoulders are elevated, the neck appears short. If they are depressed, the A-C joint is seen to be lower than the S-C joint.[215] Elevation of the clavicle can be due to shortness of the upper trapezius such that the lateral

end of the clavicle appears appreciably higher than its medial aspect.[215] A low shoulder can result from[197]

- adaptive laxity of the shoulder,
- leg length discrepancy,
- scoliosis,
- sof -tissue hypertonicity,
- mechanical dysfunction of the pelvis,
- hand dominance—the shoulder on the dominant side may be slightly lower and more muscular than the nondominant side; this is a normal finding.

Deformity is a common complaint with injuries of the A-C joint and fractures of the clavicle. For example, a second-degree sprain or severe first-degree sprain of the A-C joint can be seen as a high-riding lateral clavicle (elevation of the distal end) causing a step-off to form between the clavicle and acromion.[17,216] It is frequently referred to as a tent-pole deformity. T e fountain sign describes swelling that is anterior to the A-C joint that is indicative of degeneration that has caused communication between the A-C joint and a swollen subacromial bursa underneath.

Observation of muscle symmetry should be noted. Specific atrophy can imply certain diagnoses. For example, muscle weakness or atrophy, especially posttraumatic, might indicate peripheral nerve damage:[217]

- A balled-up muscle may indicate a muscle rupture, the most common of which are of the biceps and infraspinatus. Rupture of the LHB can be noticed by the change in contour of the anterior arm with bunching of the muscle (the "Popeye" appearance).[195]
- Atrophy of the deltoid from axillary nerve neuropathy can result in a squared appearance of the lateral shoulder,[216,217] which is best observed from the front.[17] Other causes of a squaring of the shoulder include an anterior dislocation of the shoulder as the deltoid is no longer rounded out over the humeral head.
- Atrophy of the posterior deltoid can occur in patients with multidirectional instability.[217]
- Atrophy at the infraspinatus or supraspinatus fossa is a hallmark of a rotator cuff tear,[16] or suprascapular nerve entrapment. Wasting of the supraspinati and infraspinati can be determined by pushing the examining finger into the respective muscle bellies.
- Atrophy of the trapezius may indicate compromise of the spinal accessory nerve. Atrophy of the trapezius is characterized by the appearance of a shoulder girdle that droops in association with a protracted inferior border of the scapula and an elevated acromion.[24,106,218]
- Atrophy of the serratus anterior muscle can create a prominent medial border of the scapula (scapular winging) (Fig. 16-15) and a depressed acromion.

T e position and attitude of the scapula, both statically and dynamically, should be noted (see later). In standing, with their arms by the sides, the patients' medial (vertebral) border of the scapula should be 5–8 cm lateral to the thoracic spinous processes,[196,219] the medial end of the spine of the scapula should be level with the T3 spinous process, and the inferior angle of the scapula should be level with the T7 spinous process. T e superior aspect of the medial border of the scapula begins at the level of the spinous process of T2 and extends to the level of the spinous process of T7. Excessive prominence of the scapular spine may indicate atrophy of the infraspinatus and supraspinatus.[217] Two conditions, which may present with deformity of the scapula as their main symptom, are Sprengel's deformity and winging of the scapula.[195]

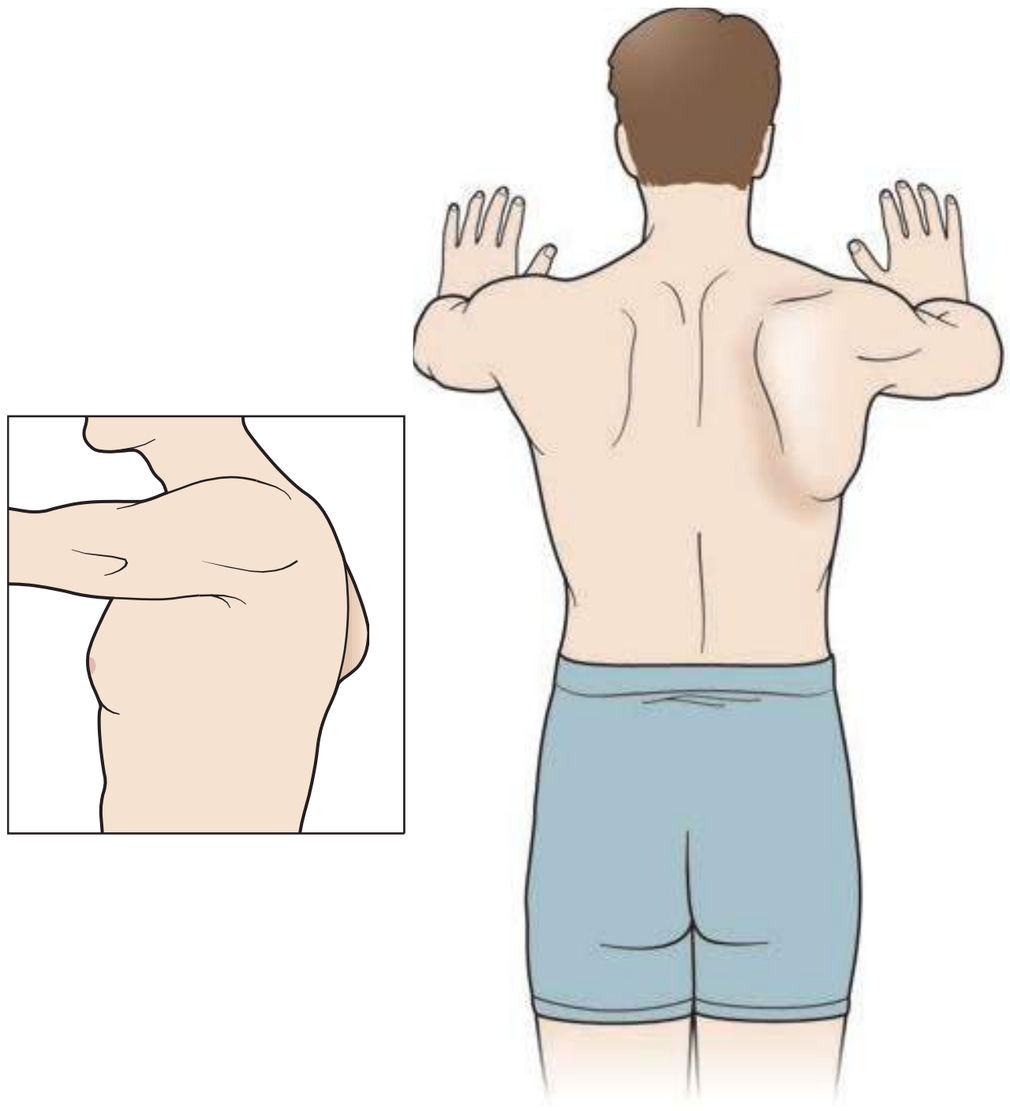

FIGURE 16-15 Scapular winging.

Sprengel's deformity is the most common congenital abnormality affecting the shoulder. It is characterized by the presence of a hypoplastic, incorrectly rotated scapula, which sits abnormally high on the posterior chest wall. T e condition results from a failure of the normal descent of the scapula, which occurs in utero, and is commonly associated with other significant musculoskeletal and visceral congenital abnormalities.[195]

Winging of the scapula (Fig. 16-15) is due to a loss of the normal scapular stability. Subtle forms of scapular winging, usually evident at the inferior border, occur commonly with many shoulder disorders such as G-H joint stiffness and shoulder instability.[108] In cases of G-H joint stiffness, there is passive limitation of G-H motion, while with instability there is evidence of excessive movements or positive apprehension signs. Scapular winging may occur as the result of serratus anterior weakness, trapezius palsy,[218] excessive shortening of the pectoralis minor muscle,[2] or myopathies.[195,220–222] Scapular winging may also be caused by G-H joint stiffness, shoulder instability, and rotator cuff disease (see "Analysis of the Static Shoulder" section).

Gait

Gait is evaluated to observe freedom of the arm swing, reciprocal upper extremity movement, position of the arms and scapulae, and motion of the trunk and lower extremities (see Chapter 6).[69,207]

Posture

An analysis of posture can prompt the clinician as to the area of movement disturbance or excessive stresses (see Chapter 6). A wide variety of structural and postural changes of the upper quarter can be a common cause of shoulder pain.[164,223,224] For example, thoracic kyphosis, scoliosis, or neck lordosis can result in excessive protraction of the scapula, producing interscapular pain.[24,225] In the older patient (aged over 50 years), an increased thoracic kyphosis may be related to a decrease in shoulder elevation.[226]

The relationship of the humeral head to the acromion should be observed. One-third of the humeral head should be anterior to the acromion. A finding of less than one-third may indicate a tight posterior capsule or adaptive shortening of the external rotators.[227]

The patient's hands and arms should also be observed in standing. Normally, the thumb faces anterior or slightly medial. If the posterior aspect of the hand faces anteriorly, there may be excessive adaptive shortening of the internal rotators.[227]

Muscle balances in the upper quadrant can cause a characteristic postural pattern of the forward head position.[228] The most common muscle imbalances are outlined in Table 16-11. The clinician should observe the trunk and neck positions in sitting and standing, as well as the relationship of the scapulae relative to the trunk and the humerus relative to the acromion. Any change in the scapular position has an impact on the A-C and S-C joint and can also alter the length–tension relationship of the scapular muscles.

The forward head and rounded shoulder posture include an abducted and elevated position of the scapula and an internally rotated humerus,[24,98,229,230] and is more common in patients presenting with shoulder pain[231] and interscapular pain.[231] Forward head posture (FHP) in the presence of abducted scapulae and protracted shoulders results in a decrease in the size of the subacromial space, which may predispose the patient to rotator cuff disorders.[232] This posture results in an adaptive shortening of the upper trapezius, levator scapulae, and pectoralis, with weakening and lengthening of the deep neck flexors and lower scapular stabilizers.[98,231,233]

If the pectoralis major is adaptively shortened or strong, the muscle will be prominent. If there is an imbalance present, it will lead to rounded and protracted shoulders and a slight IR of the humerus.[234,235] The altered position of the scapulae can distort the course of the suprascapular nerve, placing it at risk for a traction injury during upper extremity movements.[236–238]

Normally, the insertion of the SCM is barely visible. If the clavicular insertion is prominent, it may indicate adaptive shortening of the SCM.[234] A groove along the SCM is an early sign of weakness of the deep neck flexors. A weakening and atrophy of the deep neck flexors has been proposed as a sign to estimate biological age.[239] The change in the anatomical relationship of the clavicle associated with this weakness and atrophy, decreases the width of the thoracic inlet, rendering the brachial plexus vulnerable to compression (refer to Chapter 25).[236,240,241]

A loss of bulk in the interscapular muscles may indicate tightness in the trapezius and levator scapula.

Analysis of the static scapula

An abnormal position of the scapula at rest is common in patients with shoulder overuse injuries.[98,215,231,233] The scapular position is initially examined with the arms by the side. The clinician notes any signs of winging, elevation, depression, adduction, abduction, and rotation of the scapula. Abnormalities in alignment include a flattening of the interscapular area and an increase in the distance between the thoracic spinous processes and the medial border of the scapula. When the scapula is abducted (more than 8 cm from the midline of the thorax), it is also rotated more than 30 degrees anterior to the frontal plane and produces a medial rotation of the humerus.[215]

Tipping of the scapula, in which the inferior angle protrudes away from the rib cage, often results from a weakness of the lower trapezius and positions the glenoid fossa so that it faces a more inferior direction.[111] This alignment is often associated with shortness of the pectoralis minor muscle or biceps brachii muscle.[215]

Adaptive shortening of the rhomboids and levator scapulae muscles, in the presence of a lengthened upper trapezius and serratus anterior, results in an elevation of the scapulae at the superior angle, and a downward rotation of the scapula. This causes the G-H joint to move into a position of abduction.[215,242] In addition, if the levator scapula adaptively shortens, both cervical and shoulder motions occur sooner than normal because the starting position of the scapula is changed. This modification to the starting position of the scapula for shoulder-elevated tasks presumably has an effect on the timing of the scapular muscles responsible for upward rotation. This results in an end position of arm elevation that is lower than usual (see "Examination of the Dynamic Scapula" section).[111]

Extremity dominance can affect the orientation of the scapula, with the greater degree of unilateral activity producing the greater changes. A bilateral comparison should be made and allowances made for the dominance. Bilateral comparisons do not always highlight dysfunctions. For example, the symmetrical effects of an adaptive shortening of the anterior chest and shoulder musculature, and lengthening of the posterior musculature that occurs in the forward head and rounded shoulder posture, will not be confirmed until during the mobility tests.

A number of static tests for the scapular position exist. The amount of scapular protraction available can be measured clinically using the method described by Diveta et al.,[243] who advocate two linear measurements with a piece of string. The

TABLE 16-11 Common Muscle Imbalances of the Shoulder Complex

Muscles Prone to Tightness	Muscles Prone to Inactivity or Lengthening
Upper trapezius	Middle and lower trapezius
Levator scapulae	Rhomboids
Pectoralis major and minor	Serratus anterior
Upper cervical extensors	Deep neck flexors
Sternocleidomastoid	Supraspinatus
Scalenes	Infraspinatus
Teres major and minor	
Subscapularis	

distance in centimeters between the root of the scapular spine and the inferior angle of the acromion (scapular width) is divided into the distance from the third thoracic spinous process to the inferior angle of the acromion (scapular protraction). The resulting ratio provides a measurement of scapular protraction corrected for scapular size (normalized scapular protraction). This method of measurement of scapular protraction has been found to be both reliable and valid when compared with radiographic measurements.[231,243,244]

Palpation

Palpation must be performed in a systematic manner and must focus on specific anatomical structures (refer to Figs. 16-1 to 16-13). The degree and location of tenderness is often a reliable physical sign leading to an accurate diagnosis.[52] For example, tenderness over the anterior acromion and greater tuberosity is suggestive of impingement, whereas tenderness over the posterior joint line could indicate joint pathology such as G-H arthritis or a torn posterior labrum.[52] Traditionally, palpation has been viewed as a static process. However, palpation is a dynamic process and should be performed along with other aspects of the examination. The optimal methods of palpating the shoulder tendons occur in regions where there is the least amount of overlying soft tissue.[245]

It is best to divide the shoulder complex into compartments for palpation as symptoms reproduced by palpation in these compartments are frequently associated with a specific underlying pathology.

Anterior and superior Compartment

The clinician should begin anteriorly, with palpation of the contours of the clavicle. The anterior and superior aspects of the clavicle are covered by the platysma muscle. The sternal end of the clavicle, which projects cranially over the border of the manubrium, is covered by the SCM. The following areas related to the clavicle should be palpated for tenderness, swelling, or symptom reproduction:

- The supraclavicular fossa, bordered medially by the SCM and laterally by the omohyoid.
- The infraclavicular fossa, between the pectoralis major, deltoid, and clavicle. The coracoid process is located in the infraclavicular fossa, especially if the arm is placed in extension. Several palpable ligaments and muscles attach here including the coracoclavicular, on the conoid tubercle, the coracoacromial ligament, the pectoralis minor, the coracobrachialis, and the short head of the biceps. A prominent coracoid could indicate a posterior dislocation of the shoulder.
- The subclavius and costoclavicular ligament.
- The suprasternal (jugular) notch—this indentation on the superior border of the sternal manubrium is an important reference point. Three centimeters above the notch is the inferior border of the larynx, while the sternal bellies of the SCM form the sides of the notch. The interclavicular ligament is located within the notch. Disruption of the normal contours of the notch is associated with S-C dislocations.
- The S-C joint and joint line—arthrotic changes of the S-C joint are evidenced by crepitus at the joint during IR/ER of the humerus with the arm abducted to 90 degrees. The contours of the S-C joint are palpated and a comparison should be made with the contralateral side. Thickening of the S-C, or an S-C dislocation, produces an inability to abduct the arm.
- The A-C joint—injuries and arthritis of this joint are common, and focal tenderness is an important sign of A-C pathology.[195] Changes in the size and shape of the joint may indicate past or present separation, fracture, or osteoarthritis.

With the arm hanging by the side and the palm facing the body, the greater tuberosity lies laterally, and the lesser tuberosity lies anteriorly with respect to each other. They are separated by a bicipital groove. The bicipital groove is made more accessible for palpation with IR of the arm to 15–20 degrees (Fig. 16-16).[245,246] Within this groove lies the biceps tendon, which should be palpated for tenderness. If the arm at rest appears slightly abducted and externally rotated, an anterior dislocation might be present. An adducted and internally rotated arm suggests many shoulder conditions, including a posterior dislocation.

The lesser tuberosity (shaped like an inverted teardrop) is palpated during passive IR and ER of the humerus at a point lateral to the coracoid process. The subscapularis can be palpated deep in the deltopectoral triangle at its insertion into the lesser tuberosity. This is accomplished by positioning the arm by the side in neutral rotation, and palpating just lateral to the coracoid.[245]

The greater tuberosity is located directly anterior to the acromion. It is best located with the patient in sidelying, facing the clinician, with the upper arm in front in approximately 60 degrees of shoulder flexion. The clinician palpates laterally along the spine of the scapula until contact is made with the superior facet of the greater tuberosity. The supraspinatus and posterior coracohumeral ligament insert into the superior facet, the infraspinatus on its middle facet, and the teres minor on its inferior facet. The supraspinatus, located just distal to the anterolateral corner of the acromion, can be made more discernible by positioning the patient's arm behind the back in slight extension.[245,247]

The subacromial–subdeltoid bursa can be palpated by putting the patient in the prone position, and passively stretching the arm into extension before palpating anterior to the A-C joint. Tenderness reported with shoulder extension and relieved with shoulder flexion is indicative of an inflammation of this bursa.

The anterior joint capsule can be located by palpating one fingerbreadth lateral to the coracoid process with the arm by the side. Persistent tenderness at this point with IR and ER of the arm suggests capsular involvement.[248]

The muscle bellies, origins, and insertions of the upper trapezius, supraspinatus, and levator scapula should be palpated for tenderness or asymmetries.

Lateral Compartment

The deltoid muscle belly and insertion should be palpated for tenderness or atrophy.

Posterior Compartment

The spine of the scapula should be located. The clinician should be able to locate the inferior pole of the scapula, the medial border of the scapula, and the posterior angle of the

acromion. The superior angle of the scapula should be level with the second rib, the spine of the scapula with the level of T3, and the inferior border with the level of T7.

The infraspinatus can be palpated just distal to the posterolateral acromion with the arm at 90-degree flexion and 10-degree adduction.[245] The teres minor is isolated and palpated using the same patient position.[245] To help locate the teres minor, the long head of the triceps is palpated by placing the patient's arm at 90 degrees of abduction followed by extension. Once the long head of the triceps is located, the patient is repositioned and the teres minor, now superior to the long head of the triceps, can be palpated. Tenderness of the posterior capsule suggests capsular laxity.

Inferior Compartment

The lymph nodes in the axilla are palpated for swelling or tenderness. Also located in the inferior compartment are the anterior coracohumeral ligament, G-H ligament, transverse humeral ligament, and pectoralis major. The latissimus dorsi tendon can be palpated deep in the axilla.

The teres major tendon is palpated medial to the superior part of the latissimus dorsi tendon insertion. It can be differentiated from the latissimus dorsi by using a combination of isometric IR and adduction with the patient's shoulder positioned at 90 degrees of abduction and maximum ER.

The subscapularis tendon is palpable between the serratus anterior and the latissimus dorsi while the patient's arm is elevated.

Active and Passive Range of Motion

Due to the complex nature of the arthrokinematics, osteokinematics, and myokinetics of this region, the results from the active and passive movements can be misleading; therefore care must be taken with any interpretation of the findings. Goniometric measuring techniques for the shoulder joint complex are described and illustrated in Chapter 13. PROM testing should be performed when active motion is incomplete. PROM is performed if there is a deficiency in active motion to determine the end-feel.[249]

Active motion testing provides the clinician with information regarding the following:

- Willingness of the patient to move the extremity. Painful or hesitant initiation or termination of movement. Such a hesitation may be a subtle sign of instability or rotator cuff dysfunction.[250]
- Overall functional capacity of the shoulder.
- Quantity of movement (Table 16-12). Estimation of true G-H motion is performed by fixing the scapula at its inferior border.
- Developed trick movements or modifications to the movement, such as an altered plane, the use of trunk movements, or abnormal recruitment of muscles.
- Associated signs and symptoms not reproduced with nonfunctional motion testing.
- Presence of a capsular pattern (Table 16-13).
- Detection of a "painful arc."
- End-feels (see Table 16-12), if passive overpressure is applied. Pain with end-range stress is an important clinical finding. Crepitus can be soft with rotator cuff pathology or harsh with G-H arthritis.

McClure and Flowers[251] classify limited shoulder motion into two categories:

- Decreased ROM secondary to changes in the periarticular structures, including shortening of the capsule, ligaments, or muscles, as well as adhesion formation. Clinical

TABLE 16-12 Normal Ranges for Movements of the Shoulder Complex and Potential Causes of Pain

Motion	Range Norms (Degrees)	End-Feel	Potential Source of Pain
Elevation–flexion	170–180	Tissue stretch	▫ Suprahumeral impingement ▫ Stretching of G-H, A-C, S-C joint capsule ▫ Triceps tendon if elbow flexed
Extension	50–60	Tissue stretch	▫ Stretching of G-H joint capsule ▫ Severe suprahumeral impingement ▫ Biceps tendon if elbow extended
Elevation–abduction	170–180	Tissue stretch	▫ Suprahumeral impingement ▫ A-C joint arthritis at terminal abduction
External rotation	80–90	Tissue stretch	▫ Anterior G-H instability
Internal rotation	60–100	Tissue stretch	▫ Suprahumeral impingement ▫ Posterior G-H instability

TABLE 16-13 Close-Packed, Open-Packed, and Capsular Patterns of the Shoulder Complex

	Close Packed	Open Packed	Capsular Pattern
Glenohumeral	90 degrees of G-H abduction and full external rotation; or full abduction	55-degree abduction, 30-degree horizontal adduction external rotation	External rotation, abduction, internal rotation
Acromioclavicular	90-degree abduction	Arm resting by side	Pain at extremes of range, especially horizontal adduction and full elevation
Sternoclavicular	Full arm elevation and shoulder protraction	Arm resting by side	Pain at extremes of range, especially horizontal adduction and full elevation

findings for this category include a history of trauma,[252–254] immobilization,[252–254] presence of a capsular pattern,[249] capsular end-feel,[249] and no pain with the isometric testing.[249]

- Decreased ROM due to nonstructural problems, including the presence of pain, protective muscle spasm, or a loose body within the joint space.[255] Clinical findings for this patient include a history of trauma or overuse, and the presence of a noncapsular pattern of motion restriction.

Riddle et al.[256] examined the intratester and intertester reliabilities for clinical goniometric measurements of shoulder passive ROM (PROM) using two different sizes of universal goniometers. Patients were measured without controlling therapist goniometric placement technique or patient position during measurements. Repeated PROM measurements of shoulder flexion VIDEO, extension VIDEO, abduction VIDEO, shoulder horizontal abduction, horizontal adduction, external rotation VIDEO, and internal rotation VIDEO were taken for two groups of 50 subjects each. The intratester intraclass correlation coefficients (ICCs) for all motions ranged from 0.87 to 0.99. The ICCs for the intertester reliability of PROM measurements of horizontal abduction, horizontal adduction, extension, and internal rotation ranged from 0.26 to 0.55. The intertester ICCs for PROM measurements of flexion, abduction, and external rotation ranged from 0.84 to 0.90. Goniometric PROM measurements for the shoulder appear to be highly reliable when taken by the same physical therapist, regardless of the size of the goniometer used.

FIGURE 16-16 Palpation of the bicipital groove.

The patient is asked to bring the arm actively through the ranges of motion. These motions include flexion, extension, abduction, IR, ER, horizontal adduction, and shrugging of the shoulders.

Arm elevation

The clinician should view the patient carefully as he or she attempts arm elevation. Elevation in the frontal plane (Fig. 16-17) and scapular plane is assessed. Typically, 170–180 degrees of elevation is possible in both of these planes, with the upper portion of the arm being able to be placed adjacent to the head. If the patient is unable to achieve 170–180 degrees, the clinician must determine where and why movement is not occurring. The presence of pain with arm elevation can provide the clinician with valuable information (Fig. 16-18). A common cause of pain with arm elevation is rotator cuff tendinopathy. If there is an arc of pain, the point in the range where the arc of pain occurs can be diagnostic in implicating the cause.

FIGURE 16-17 Elevation in the frontal plane.

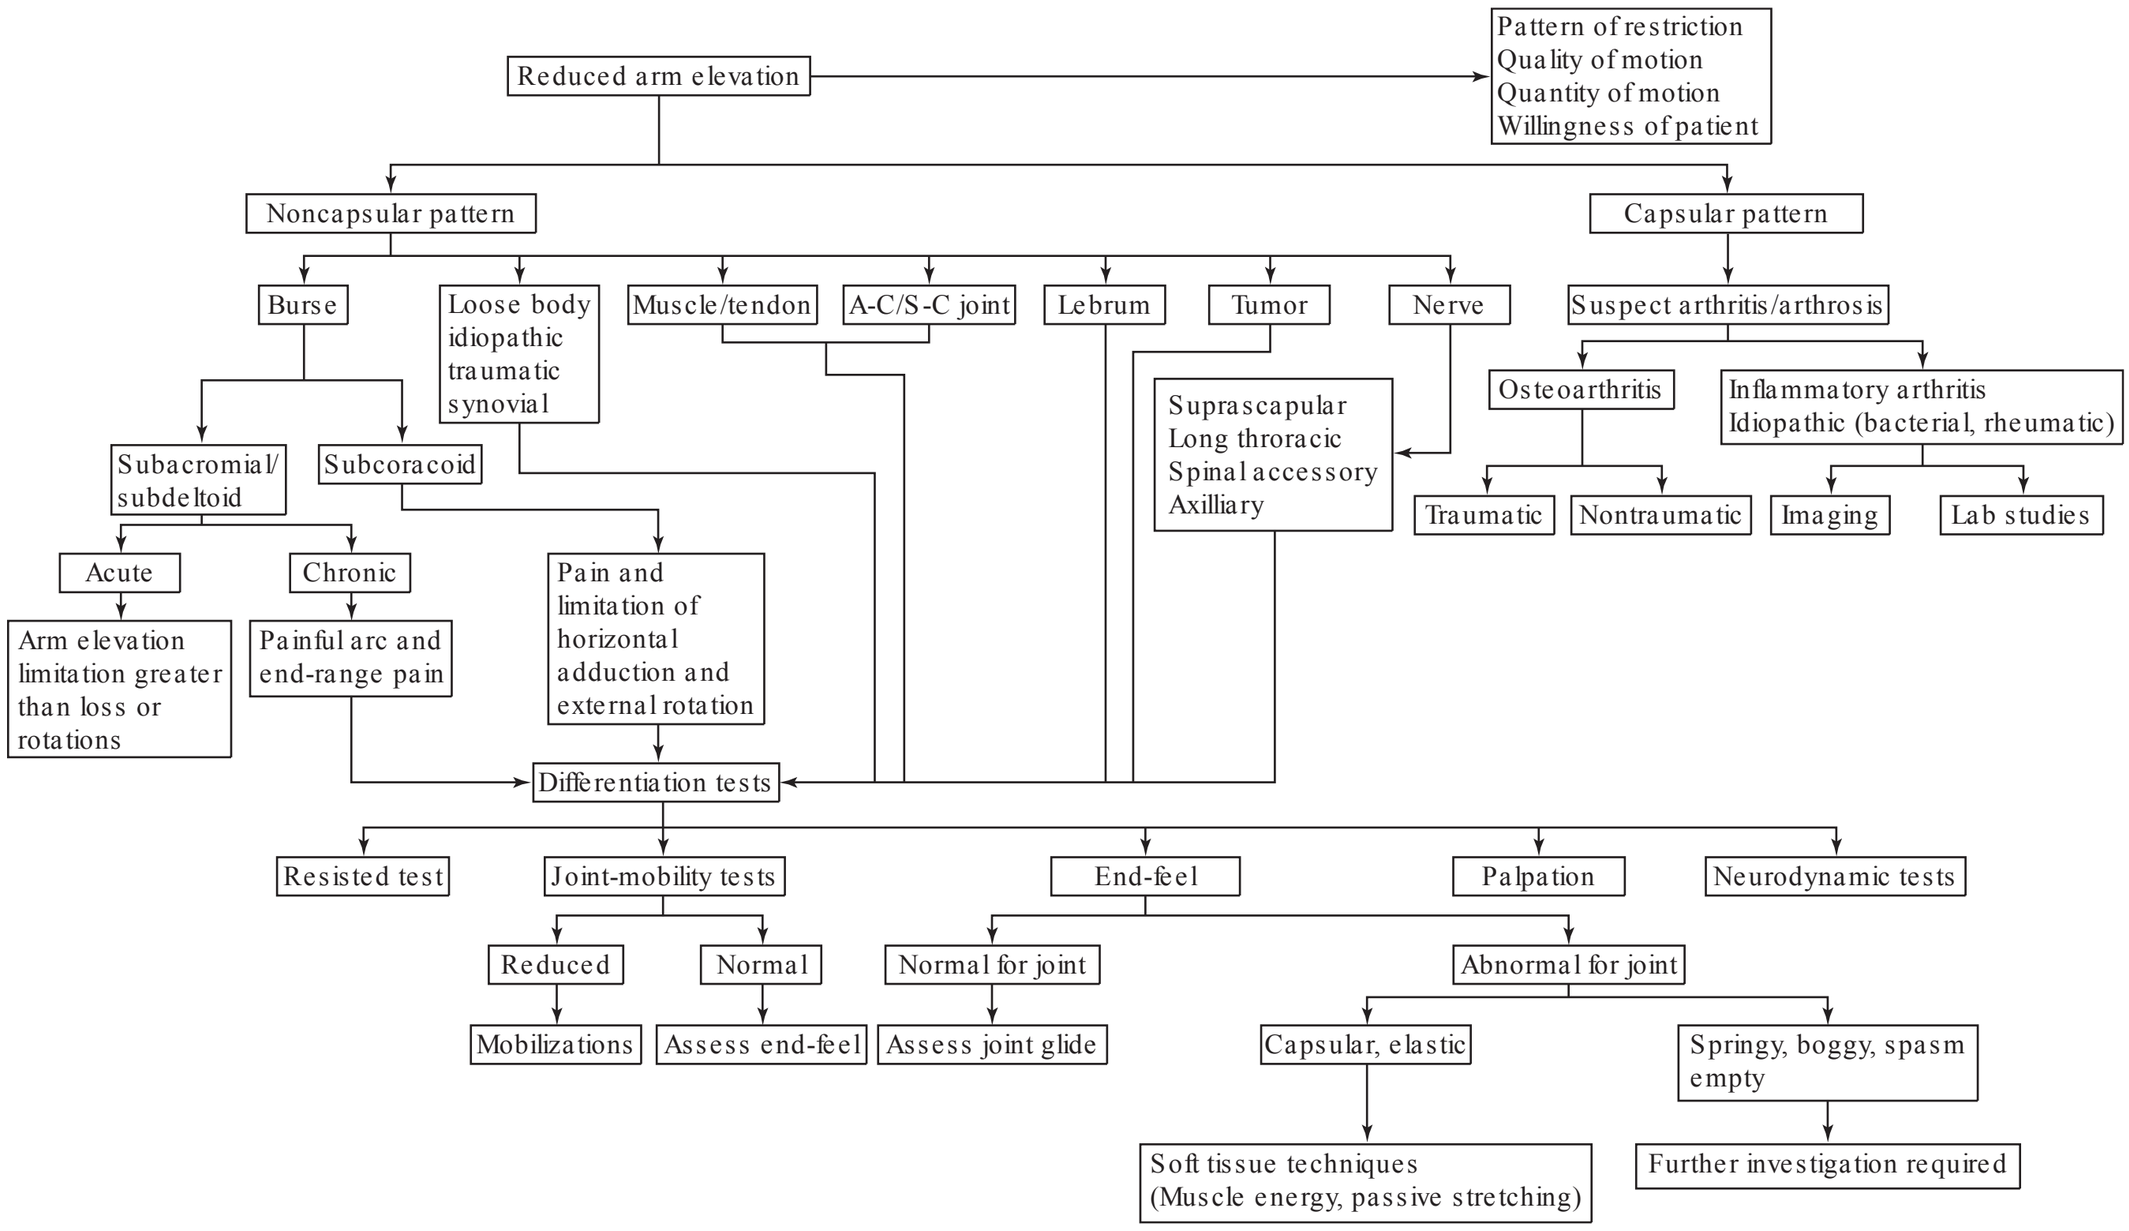

FIGURE 16-18 Causes of painful arm elevation.

- Pain that occurs between 70 and 110 degrees of abduction is deemed a "painful arc" and may indicate rotator cuff impingement, or tearing, or subacromial bursitis.[77]
- Pain which occurs in the 120–160/160–180-degree range may indicate involvement of the A-C joint.[77]

CLiNiCAL PeArL

One study[77] attempted to differentiate various types of painful arcs and proposed that adding external rotation to the painful range indicated subscapularis involvement, or possibly supraspinatus and/or infraspinatus involvement when the pain was increased. Adding IR to the painful range, the supraspinatus and/or infraspinatus was more likely the source of involvement.[77]

Kibler[24] advocates the use of the "muscle assistance" or "scapular assistance" test (SAT) to assess scapular motion and position during elevation and lowering of the arm to see if the impingement may be due to a lack of acromial elevation (Fig. 16-19). As the patient elevates the arm, the clinician pushes laterally and superiorly on the inferior medial border of the scapula to simulate the serratus anterior/lower trapezius force couple. The test is considered positive if the manual assistance diminishes or abolishes the impingement symptoms.[24] The SAT is presumed to indirectly measure the function of the scapula rotators; however, other factors, such as thoracic posture and pectoralis minor length, have also been hypothesized to affect scapular rotation, and it is possible that these could be affected by the manual pressure provided during the SAT.[155,257,258] More importantly, the SAT is used to directly assess the influence of scapular motion on shoulder pain. In a study by Rabin et al.[155] a modified version of the SAT, which included assisting posterior tipping of the scapula in addition to assisting upward rotation of the scapula, was found to possess acceptable interrater reliability for clinical use to assess the contribution of scapular motion to shoulder pain. The κ coefficient and percent agreement were 0.53 and 77%, respectively, when the test was performed in the scapular plane, and 0.62 and 91%, respectively, when the test was performed in the sagittal plane. In the modified version, the clinician places one hand on the superior aspect of the involved scapula, with the fingers over the clavicle. The other hand is placed over the inferior angle of the scapular so that the heel of the hand is just over the inferior angle and the fingers are wrapped around the lateral aspect of the thorax. The patient is asked to actively elevate his or her arm in the scapular plane, and during the movement the clinician facilitates upward rotation of the scapula by pushing upward and laterally on the inferior angle, as well as tilting the

FIGURE 16-19 Scapular assist.

scapula posteriorly by pulling backward on the superior aspect of the scapula.[24]

Weakness of the serratus anterior muscle, due to palsy or disuse, produces winging of the scapula (Fig. 16-15) as the patient attempts to elevate the arm.[4,107,109] In addition to winging, serratus anterior dysfunction presents with loss of scapular protraction during attempted shoulder elevation and the inferior tip of the scapula becomes prominent.[106]

Abduction of the shoulder requires a greater use of the upper and lower trapezius muscles, whereas shoulder flexion is more likely to recruit the serratus anterior muscle.[85,162]

Although lesions to the deltoid are rare, imbalances of the deltoid and the rotator cuff are common. When the deltoid becomes dominant, the humeral head is seen to glide superiorly during arm elevation because the downward pull of the rotator cuff muscles is insufficient to counterbalance the upward pull of the deltoid (humeral superior glide syndrome).[215] T is alteration in the G-H force couple usually occurs during the middle phase of elevation[153] (between 80 and 140 degrees), because the upward translation force of the deltoid peaks during this phase, requiring more compressive and depressive forces from the rotator cuff muscles.[259,260]

An anterior glide of the humeral head, which occurs during arm elevation (humeral anterior glide syndrome)[215] suggests that the posterior deltoid has become the dominant external rotator.[215] T is syndrome should be suspected if the pain is located in the anterior or anterior medial aspect of the shoulder and is increased by G-H IR, shoulder hyperextension, and horizontal abduction, and is decreased when the humeral head is prevented from moving anteriorly during shoulder rotation and flexion movements.[215]

When compared, the range achieved for unilateral elevation should be greater than that achieved when bilateral arm elevation is attempted. T is is because the joints of the cervicothoracic junction have to be permitted to rotate toward the elevating arm. T e clinician should observe the smoothness of the scapulohumeral rhythm during elevation and the ratio between the scapular upward rotation and G-H elevation (see "Examination of the Dynamic Scapula" section).

Compressive forces across the A-C joint occur mainly in the terminal 60 degrees of abduction. T is of en causes pain during this range if pathology exists at this joint.[195]

extension

Active extension (Fig. 16-20) is normally 50–60 degrees. Care must be taken when measuring this motion (see Chapter 13) as substitutions can occur to seemingly increase extension by bending forward at the waist or by retracting the scapula. Asymmetry of shoulder extension can indicate weakness of the posterior deltoid in one arm (swallowtail sign).

r otation

T e following arm positions can be used to assess IR and ER:

- T e arm at shoulder level (at 90 degrees of shoulder abduction, 90 degrees of elbow flexion, and with the palm parallel to the floor). Normal ER (Fig. 16-21), which is performed by rotating the hand toward the floor, is 90 degrees or beyond. Assessing ER in this position is helpful in determining the presence of a fracture of the greater tuberosity, or a decrement in the performance of a throwing athlete. IR is then carried out (Fig. 16-22), rotating the hand toward the hip, as if positioning it behind the body. Normal IR can approach 90 degrees. However, this test position is of en uncomfortable and not very functional, except for pitchers.

FIGURE 16-20 Shoulder extension AROM.

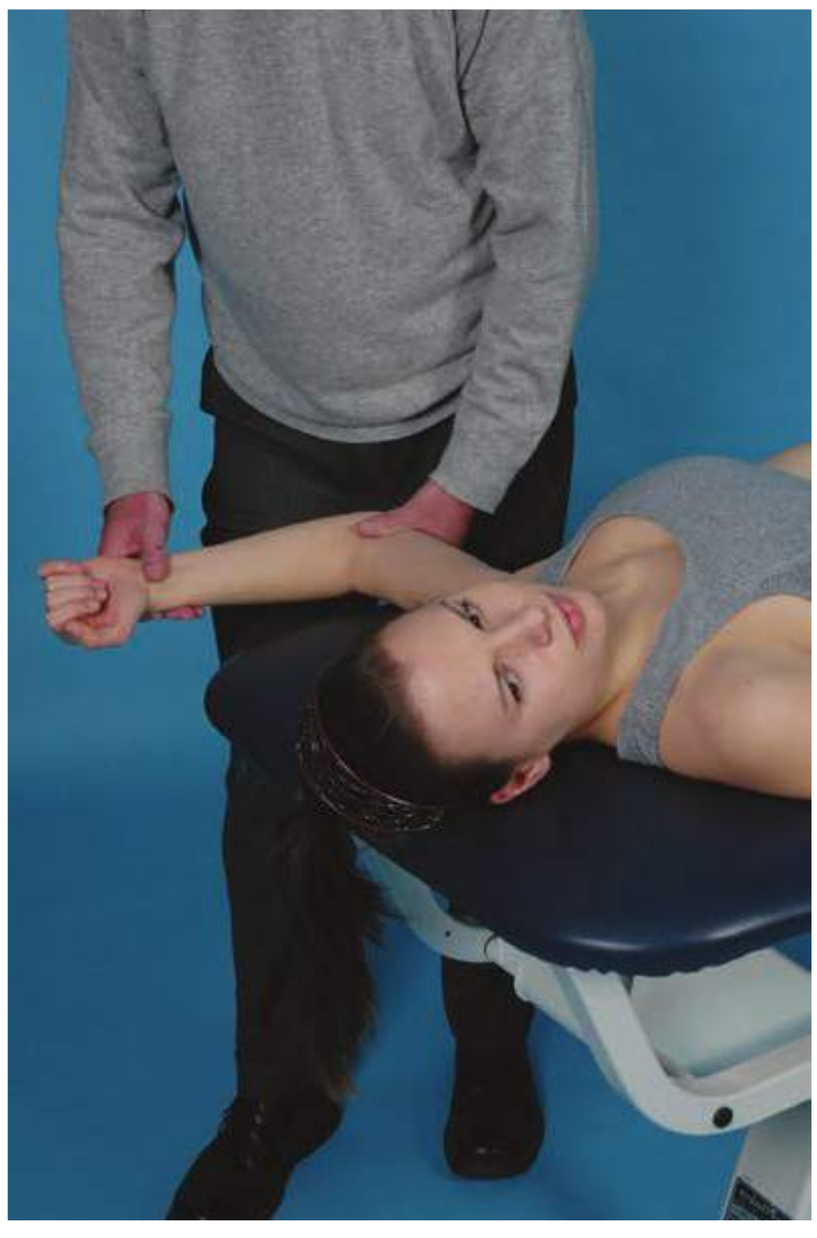

FIGURE 16-21 Shoulder external rotation in supine.

FIGURE 16-22 Shoulder IR in supine.

- The arm to the side and the elbow flexed to 90 degrees. ER is performed by moving the hand away from midline (Fig. 16-23), and IR is performed by moving the hand toward the abdomen (Fig. 16-24). Again, it is important to assess active and passive range, because a loss of active motion alone may indicate muscular weakness.

FIGURE 16-23 Shoulder external rotation in the upright position.

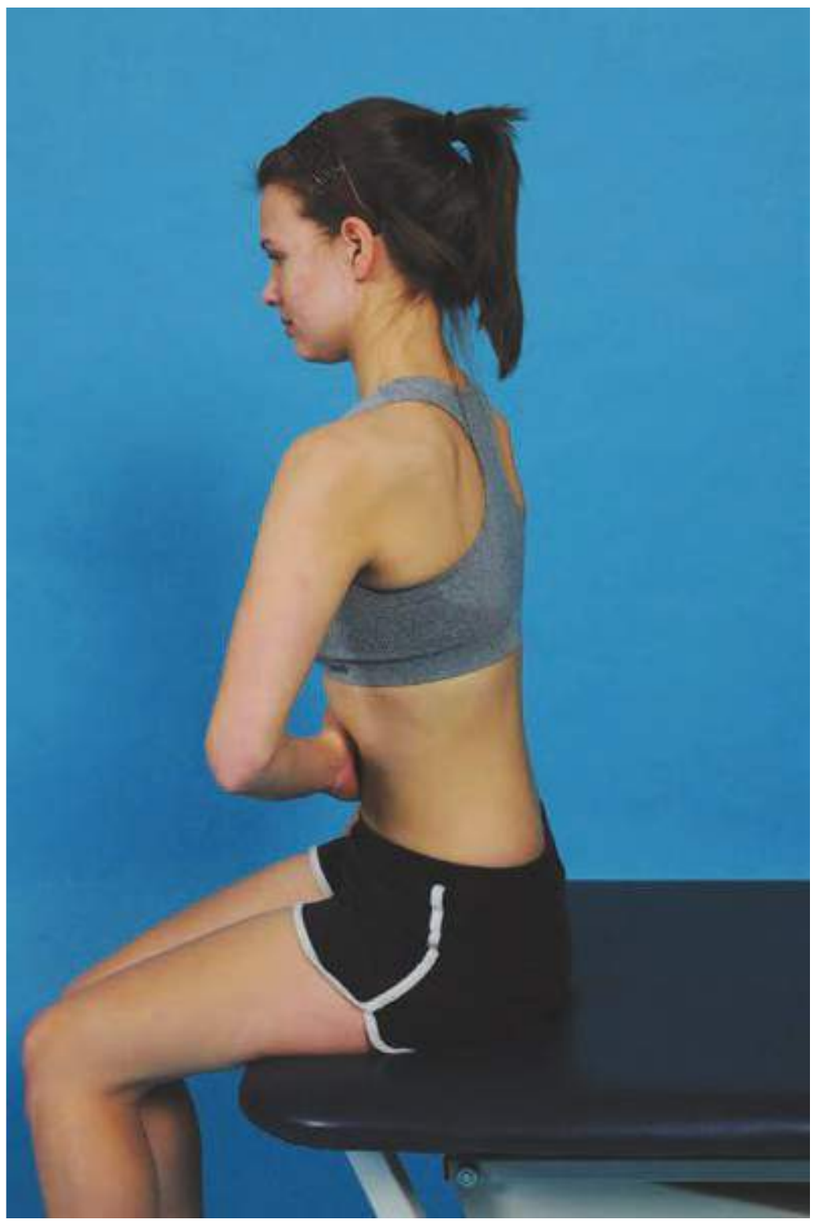

FIGURE 16-24 Shoulder IR in sitting.

- The arm at the side and the forearm behind the back (Apley scratch test). This measurement for IR is assessed by the position reached with the extended thumb up the posterior (dorsal) aspect of the spine using the spinous processes as landmarks (Fig. 16-25).[253] This is more of a functional test, and the thumb tip of normal subjects

FIGURE 16-25 Apley scratch test.

FIGURE 16-26 Shoulder ER at 45 degrees abduction.

will reach the T5–T10 level.[195] Loss of motion with this test affects the patient's ability to perform toileting duties, hook bras behind the back, reach into a back pocket, and tuck in shirts.[261] The examination is made relative to the opposite side, as there is quite a large variation in range among normal subjects. In a study by Hoving et al.,[262] which assessed the intrarater and interrater reliability among rheumatologists of a standardized protocol for measurement of shoulder movements, the movement of the hand behind the back (and total shoulder flexion) yielded the highest ICC scores for both intrarater reliability (0.91 and 0.83, respectively) and interrater reliability (0.80 and 0.72, respectively). However, in a study by Edwards et al.,[263] measurement of IR by vertebral level was not readily reproducible between observers.

- The arm at 45-degree abduction in the scapular plane (Fig. 16-26). This position is used to assess ER for overhead athletes.

Most overhead athletes exhibit excessive ER and decreased IR. The cause of this adaptation has not been established, with some authors[264–267] documenting humeral osseous retroversion as the cause, whereas others have theorized that excessive ER and limited IR are due to anterior capsular laxity and posterior capsule tightness,[268] although no clinical studies have confirmed these findings to date. G-H IR deficit (GIRD) and posterior shoulder tightness (PST) have been linked to shoulder dysfunction based on a study series by Burkhart et al.[268–270] In cadaveric studies, tightening the posterior capsule by plication has been shown to increase anterior G-H translation during flexion and cross-body adduction, cause superior G-H translation with flexion and ER of the G-H joint, and markedly decrease IR.[45,271,272] Similarly, GIRD and PST have been demonstrated in throwing athletes with internal impingement[273] and in patients with secondary impingement.[274] However, the theory of posterior capsule tightness has come into question from other researchers who have determined that ROM in baseball pitchers—specifically, a loss of IR—does not correlate with an alteration in anterior G-H translation.[275,276]

CLINICAL PEARL

Three terms can be used to describe the relationship between internal and external rotation of the glenohumeral joint[268]:

- Glenohumeral internal rotation deficit (GIRD): defined as the loss in IR between the throwing shoulder and the nonthrowing shoulder. Normally the difference should be within 18–20 degrees. The loss of shoulder IR that occurs with GIRD results from posterior capsule shortening and has been shown to predispose baseball pitchers to a higher potential for shoulder injury.
- Glenohumeral external rotation gain (GERG): defined as the difference in external rotation between two shoulders.
  - If the GIRD/GERG ratio is greater than one, the patient will likely develop shoulder problems.[269]
- Total rotational motion (TRM): determined by adding the amount of ER and IR at 90 degrees of abduction to determine the TRM arc. An asymmetry of 5 degrees is predictive of an increased injury rate.[277,278]

It is important not to disregard the effect of muscle forces on these biomechanical changes. Reinold et al.[279] recently examined the PROM of the shoulder in 31 professional baseball pitchers, before and immediately after pitching. The researchers reported that rotational range of G-H motion was immediately affected by overhead throwing and that mean IR ROM after pitching significantly decreased (73 ± 16 degrees before, 65 ± 11 degrees after) and TRM decreased (average, 9 degrees). Mean ER before throwing (133 ± 11 degrees) did not significantly change after throwing (131 ± 10 degrees). The researchers hypothesized that this decrease in IR ROM was due to large eccentric forces being generated in the external rotators during the follow-through phase of throwing that caused microscopic muscle damage in the posterior shoulder musculature. Previous studies examining the effect of repetitive eccentric contractions have shown a subsequent loss of joint ROM in the upper and lower extremities following testing.[280–282]

Wilk et al.[277] proposed the TRM concept, where the amount of ER and IR at 90 degrees of abduction are added and a TRM arc is determined. The authors reported that the TRM in the throwing shoulders of professional baseball pitchers is within 5 degrees of the nonthrowing shoulder[277] and that a TRM arc outside the 5-degree range may be a contributing factor to shoulder injuries and subsequent surgery.[278] Thus, although the dominant shoulder has greater ER and less IR, the combined total motion should be equal bilaterally.[279]

CLINICAL PEARL

It is likely that bilateral comparisons of ER and IR are useful in the assessment of the overhead athlete.

Horizontal Adduction

Horizontal adduction is performed by bringing the arm across in front of the body (Fig. 16-27). Pain with horizontal adduction may indicate A-C joint pathology (see "Crossover Impingement/Horizontal Adduction Test" section). Horizontal adduction is normally 130 degrees compared with 50–75 degrees if the arm is brought in front of the body. The loss of

FIGURE 16-27 Horizontal adduction.

horizontal adduction ROM has been identified as a predictor of increased injury rates in the throwing athlete.[273,283] Tyler et al.[283] reported an average loss in horizontal adduction of 35 degrees in subjects with pathological internal impingement, and another study that assessed changes in horizontal adduction motion by calculating the difference in horizontal adduction between the throwing in nonthrowing arm, reported a decrease of 4.2 cm in throwing athletes with internal impingement.[273]

Movement combinations are assessed.

- If pain is reproduced when internal rotation and extension are combined from a position of 90 degrees of abduction, the A-C joint, subcoracoid bursa, or subscapularis tendon may be implicated.
- If the pain is reproduced with horizontal abduction with the humerus in 90 degrees of flexion, the shoulder abductors, external rotators, and suprascapular nerve may be implicated. A jammed end-feel with this maneuver may indicate a thoracic dysfunction.
- An isolated limitation of passive external rotation may indicate subcoracoid bursitis, which is aggravated by the pectoralis major muscle being stretched over it.[259]

Traditionally, PROM has been performed with the patient positioned in supine. Given the importance of scapular motion during humeral elevation, care must be taken to not prevent the scapula from rotating during these tests.

A discrepancy between active and passive motion may indicate a painful periarticular condition.[227] Loss of active motion with preservation of passive motion is likely caused by a rotator cuff tear,[60] or rarely, suprascapular nerve injury.[210,284] A severely restricted active abduction pattern with no pain is suggestive of a rupture of the supraspinatus or deltoid. Loss of both active and passive motion is usually caused by adhesive capsulitis.[214]

A loss of PROM or active ROM (AROM) may be associated with a loss of flexibility in the passive restraints to motion. T is can occur with both single plane motions and combined motions.[36,285–288] For example, if both IR and ER are restricted and muscle tightness has been ruled out as a cause, an adhesion of the middle G-H ligament is implicated.[288]

examination of the Dynamic scapula

Given the importance of the scapulothoracic joint to overall shoulder function, it is important to examine the scapulothoracic joint arthrokinematics and muscle power.[289] Observation of the scapulohumeral rhythm and scapulothoracic motion should reveal that the scapula stops its rotation when the arm has been elevated to approximately 140 degrees. Upon completion of the elevation, the inferior angle of the scapula should be in close proximity to the midline of the thorax, and the vertebral border of the scapular should be rotated 60 degrees. Movement beyond these points may indicate excessive scapular abduction.[215] At the end range of elevation, the scapula should slightly depress, posteriorly tilt, and adduct.[215] T e motion of the scapula should be assessed carefully in patients with suspected multidirectional instability.

- A scapulothoracic dyskinesia (decrease in scapular abduction and ER with progressive arm abduction) is of en observed in patients with anteroinferior instability.[290]
- Posteroinferior instability is characterized by excessive scapular retraction.[246]
- An inferior instability is characterized by a drooping of the lateral scapula or "scapular dumping."[246]

Af er positioning the patient in prone with his or her arm abducted to 90 degrees, ER is carried out to test the ability of the scapula to remain in its correct position rather than abducting due to excessive lengthening of the thoracoscapular muscles (trapezius and rhomboids) and shortening of the scapulohumeral muscles.[215]

A number of muscles play an important role in the kinematics of the scapula, including the trapezius and serratus anterior. Increased activity of the upper trapezius muscle, or imbalances between the upper and the lower trapezius muscle, during shoulder elevation may have adverse effects on the kinematics of the scapula.[89,111,164,291]

According to Sahrmann,[215] four abnormal clinical findings exist for the scapula:

- T e scapular alignment is correct but its movement is impaired.
- T e scapular alignment is impaired and its movement is impaired.
- T e scapular alignment is impaired and its movement is of normal range, but does not correct or compensate for the impaired start position.
- T e scapular alignment is impaired but its movement is sufficient to compensate for the impaired start position.

Kibler[24] recommends the use of the isometric "scapular pinch" test to examine the strength of the medial scapular muscles. T is involves the patient squeezing his or her shoulder blades together (Fig. 16-28). Normally, the scapula can be held in this position for 15–20 seconds without difficulty. If a burning pain occurs in less than 15 seconds, Kibler suggests that scapular muscle weakness may be the cause.[24]

r esistive Tests

In addition to pain, shoulder dysfunction is of en caused or exacerbated by a loss of motion or weakness. T e resistive tests assess function in the important muscle groups of the upper kinetic chain (Tables 16-14 and 16-15).

FIGURE 16-28 Scapular pinch.

Localized, individual isometric muscle tests around the shoulder girdle can give the clinician information about patterns of pain and weakness and with information regarding weakness resulting from a spinal nerve root or peripheral nerve palsy. A general assessment of shoulder strength is initially performed, testing flexion, extension, abduction, adduction, IR, and ER. Weakness on isometric testing needs to be analyzed for the type—increasing weakness with repeated contractions of the same resistance indicating a palsy, versus consistent weakness with repeated contractions, which could suggest a deconditioned muscle or a significant muscle tear—and the pattern (spinal nerve root, nerve trunk, or peripheral nerve). A painful weakness (see Chapters 4 and 5) is invariably a sign of serious pathology and, depending on the pattern, could indicate a fracture or a tumor. However, if a single motion is painfully weak, this could indicate muscle inhibition due to pain. The various motions of shoulder can be assessed through their arcs of motion both concentrically and eccentrically against resistance, as appropriate.

CLINICAL PEARL

Pain with isometric muscle testing is generally considered a sign of first- or second-degree musculotendinous lesion (see Chapter 4). According to Cyriax,[249] pain that occurs during a muscle contraction is more likely to indicate a lesion within a muscle belly, whereas pain that occurs upon release of the contraction is more likely to indicate a lesion within a tendon.[259] However, because of the large amount of accessory joint gliding that occurs in the girdle joints with isometric contraction, the tests for inert tissue involvement must be negative before coming to the conclusion that the musculotendinous structure is at fault.

TABLE 16-15 Shoulder Girdle Muscle Function and Innervation

Muscles	Peripheral Nerve	Nerve Root	Motions
Pectoralis major	Pectoral	C5–8	Adduction, horizontal adduction, and internal rotation Clavicular fibers: forward flexion Sternocostal fibers: extension
Latissimus dorsi	Thoracodorsal	C7 (C6, C8)	Adduction, extension, and internal rotation
Teres major	Subscapular	C5–8	Adduction, extension, horizontal abduction, and internal rotation
Teres minor	Axillary	C5(C6)	Horizontal abduction (also a weak external rotator)
Deltoid	Axillary	C5(C6)	Anterior: forward flexion, horizontal adduction Middle: abduction Posterior: extension, horizontal abduction
Supraspinatus	Suprascapular	C5(C6)	Abduction
Subscapularis	Subscapular	C5–8	Adduction, and internal rotation
Infraspinatus	Suprascapular	C5(C6)	Abduction, horizontal abduction, and external rotation

FIGURE 16-29 Jobe or empty-can test for supraspinatus.

FIGURE 16-30 Full can test.

A number of resistive tests have been designed to isolate the muscles of the shoulder complex. Cyriax[275] believed that supraspinatus tendinopathy is the most common cause of a painful arc. The supraspinatus can be tested using the Jobe test or empty-can position (Fig. 16-29) VIDEO. The patient's arm is positioned in IR within the scaption plane, at approximately 90 degrees of shoulder flexion. Manual resistance is then applied by the clinician in a direction toward the floor. The Jobe test can be performed similarly with the humerus externally rotated (full-can test) (Fig. 16-30) VIDEO. One study[292] found the empty-can test to have a high sensitivity of 86% and a low specificity of 50% in diagnosing supraspinatus tendon tears in a series of 55 patients. However, in another study,[293] the full-can test had higher specificity (74% vs. 68%) and an equal sensitivity of 77% when compared with the empty-can test in a series of 136 patients.

A partial rupture of the supraspinatus tendon will result in abduction that is both weak and painful.[68] A painless weakness with abduction could indicate a complete rupture of the supraspinatus tendon, although the deltoid cannot be ruled out. The tendon of the supraspinatus can be passively stretched by positioning the humerus in adduction and IR to see if this increases the pain.[294]

It has been documented that if coracohumeral pain decreases with the addition of arm traction during resisted abduction, subacromial–subdeltoid bursitis or an A-C joint lesion should be suspected.[295] However, this was not found to be the case with ultrasonography.[296]

The test position for the infraspinatus and teres minor muscles is 90 degrees of G-H flexion and one-half full ER (Fig. 16-31).[116] If the pain is isolated to ER, then the infraspinatus is at fault. If ER and resisted adduction are painful, the teres minor is at fault, although isolated involvement of the teres minor is not common. To test the teres minor further, the muscle is placed on stretch by putting the patient in the prone position with his or her upper arms vertical, adducted, and externally rotated to approximately 20 degrees. The patient is asked to lean toward the tested side to increase the adduction.

The teres major muscle can be tested by putting the patient in the prone position with his or her hand resting on his or her lower back (Fig. 16-32) VIDEO. The patient is asked to adduct and extend the humerus while the clinician applies resistance at the elbow into shoulder abduction.

CLiNiCAL PeArL

A proper balance between agonist and antagonist muscle groups are necessary to provide dynamic stabilization to the shoulder joint.[297] For example to provide proper muscle balance, the glenohumeral joint external rotator muscles should be at the 65% of the strength of the internal rotator muscles.[298] Ultimately the external–internal rotation muscle strength ratio should be 66–75%.[298]

FIGURE 16-31 Resisted test for infraspinatus and teres minor.

FIGURE 16-32 Resisted test for teres major.

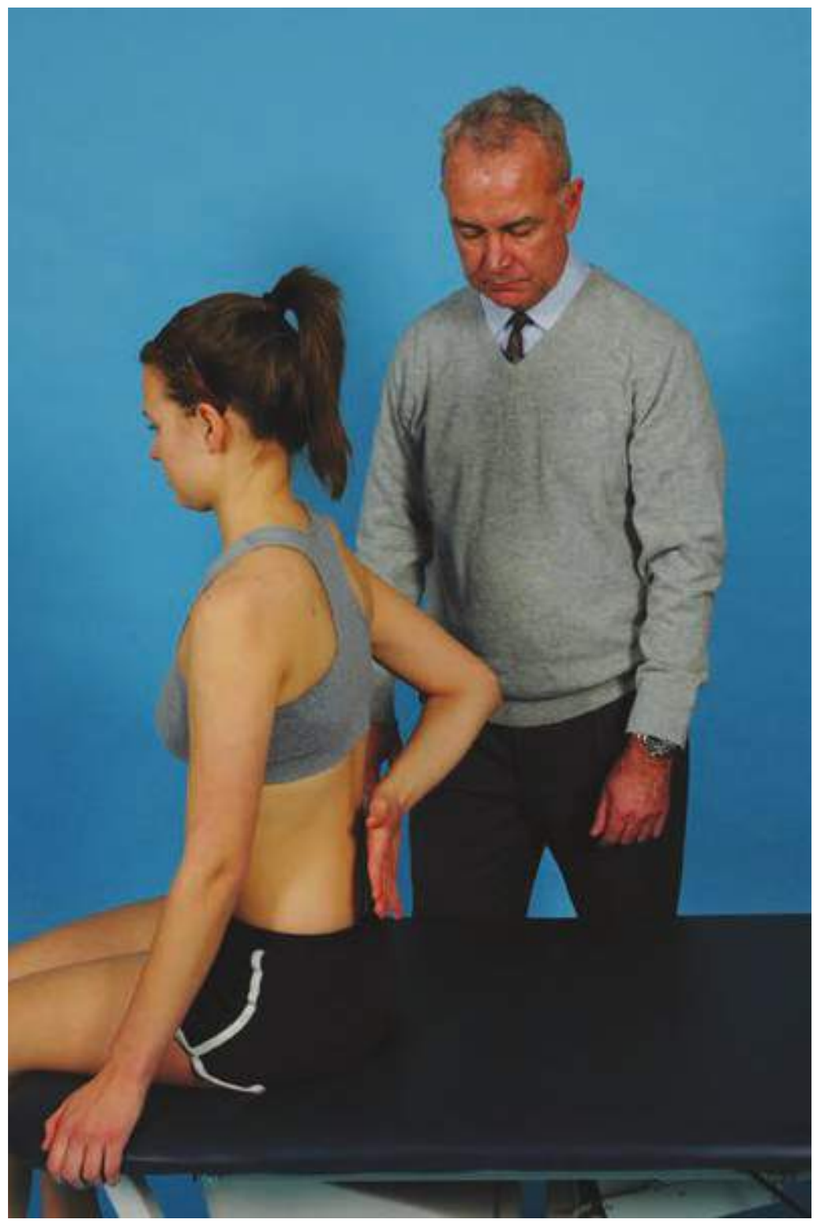

FIGURE 16-33 Lift-off test.

To assess for rhomboid dominance, the patient positions their arms by their side with their elbow flexed to approximately 90 degrees. Resisted ER in this position should not result in any scapular adduction, unless there is rhomboid dominance and poor control of G-H ER.[215] There should also be no superior or anterior gliding of the humerus during this test, unless deltoid dominance is occurring.[215]

Conditions to be ruled out if there is a painless weakness of ER include, but are not limited to, the following:

- A complete rupture of the infraspinatus tendon
- A C5 nerve root palsy
- A suprascapular nerve palsy
- Neuralgic amyotrophy

The subscapularis is best assessed using the lift-off test as described by Gerber and Krushell. The lift-off test is performed with the arm internally rotated so that the posterior surface of the hand rests on the lower back. Actively lifting the hand away from the back (Fig. 16-33) against a resisting force suggest integrity of the subscapularis. Failure to do so indicates a subscapularis tear. The test has been found to have a sensitivity of 80% and a specificity of 100% for a tear of the subscapularis.[299] A similar test is the IR lag sign test (see "Special Tests" section).

Resisted adduction is tested with the arm at 0 degrees of abduction so that the subscapularis is not facilitated.[299] Pain with resisted adduction tends to be fairly rare, but could implicate the pectoralis major, latissimus dorsi, teres major, or teres minor.

CLINICAL PEARL

A patient with subacromial–subdeltoid bursitis, in the absence of a rotator cuff tear, will often demonstrate weakness of the rotator cuff secondary to pain if tested with the arm positioned in the arc of impingement. It will, however, show good strength if tested with the arm out of abduction. A patient with a significant cuff tear usually demonstrates profound weakness of the rotator cuff in various arm positions.

Testing of deltoid function is best done with resisted abduction with the arm at 90 degrees of abduction and neutral rotation (Fig. 16-34) VIDEO.[195] A painful arc cannot be produced by a lesion to the deltoid muscle due to its anatomical position.

Differential diagnosis will be needed to rule out several neurological disorders, which may provoke painless weakness on resisted abduction. These include an axillary nerve palsy, a suprascapular nerve palsy, or a fifth cervical root palsy.

FIGURE 16-34 Resisted deltoid.

FIGURE 16-35 Middle trapezius test.

T e three components of the trapezius are assessed as follows:

- Upper trapezius (and levator scapulae). Usually both sides are tested simultaneously. T e patient is asked to shrug the shoulders to the ears. If the patient is unable to perform this action, he or she lies in the supine position to eliminate the effect of gravity and asked to repeat the test. Resistance is applied by the clinician in an attempt to depress the shoulders VIDEO. Unilateral resistance can be applied to the posterior lateral aspect of the head while stabilizing the shoulder.
- Middle trapezius. T e patient lies in the prone position with the shoulder joint abducted to 90 degrees, elbow extended, and the forearm in maximum supination so that the thumb is pointing to the ceiling (Fig. 16-35) VIDEO. T e clinician applies pressure on the humerus by pushing toward the floor.
- Lower trapezius. T e patient lies in the prone position, with the upper limb supported in the elevated position and aligned in the direction of the lower trapezius muscle fibers (Fig. 16-36) VIDEO. Grades 0–2 are determined by the firmness of the muscle contraction. Grades 2+ and 3− are based on how far the limb is lif ed from the table. Grades 3–5 require the application of resistance by the clinician.

As discussed in the biomechanics section, proper scapular movement and stability are imperative for asymptomatic shoulder function.[24] T e serratus anterior can be assessed in a number of ways VIDEO, including using the wall push-up. A more sensitive test involves putting the patient in the supine position with his or her shoulder flexed to 90 degrees and their elbow flexed. T e patient is asked to protract the shoulder by lif ing the straight arm toward the ceiling. Resistance is applied by the clinician at the hand, pushing downward (Fig. 16-37). Given that the serratus anterior functions to control upward rotation of the scapula during arm elevation, this ability should also be assessed.

Finally, resisted elbow flexion and extension, as well as forearm supination (see Chapter 17), are examined to assess the biceps VIDEO, brachialis VIDEO, and triceps function VIDEO. Isometric elbow extension and flexion with the muscles in a stretched position will help exclude the biceps and triceps

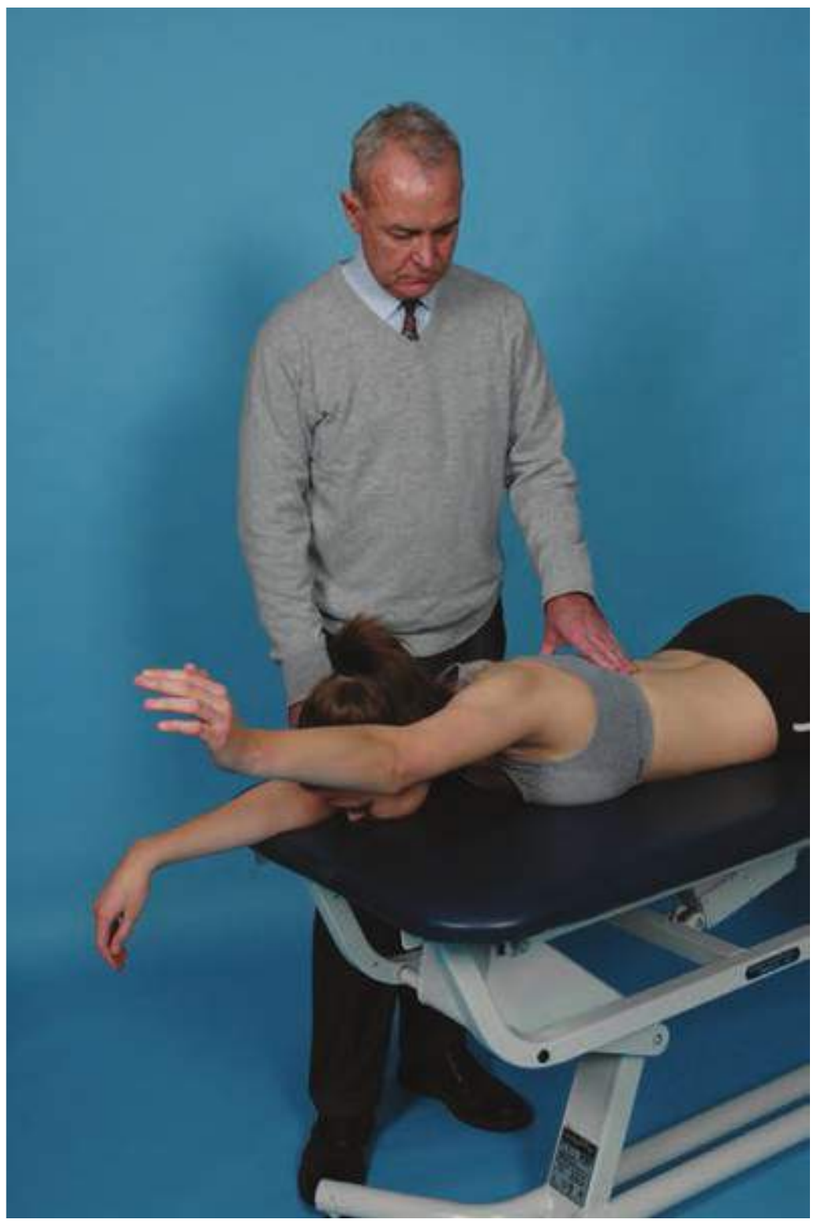

FIGURE 16-36 Lower trapezius test.

muscles. Pain reproduced with resisted elbow flexion could indicate a lesion to one or more of the elbow flexors, such as an intra-articular lesion of the LHB or a lesion in the sulcus of the LHB. T e sulcus lesion can be tested with the patient side-lying, facing away from the clinician, and their arm hanging behind them. T e clinician stabilizes the scapula and applies

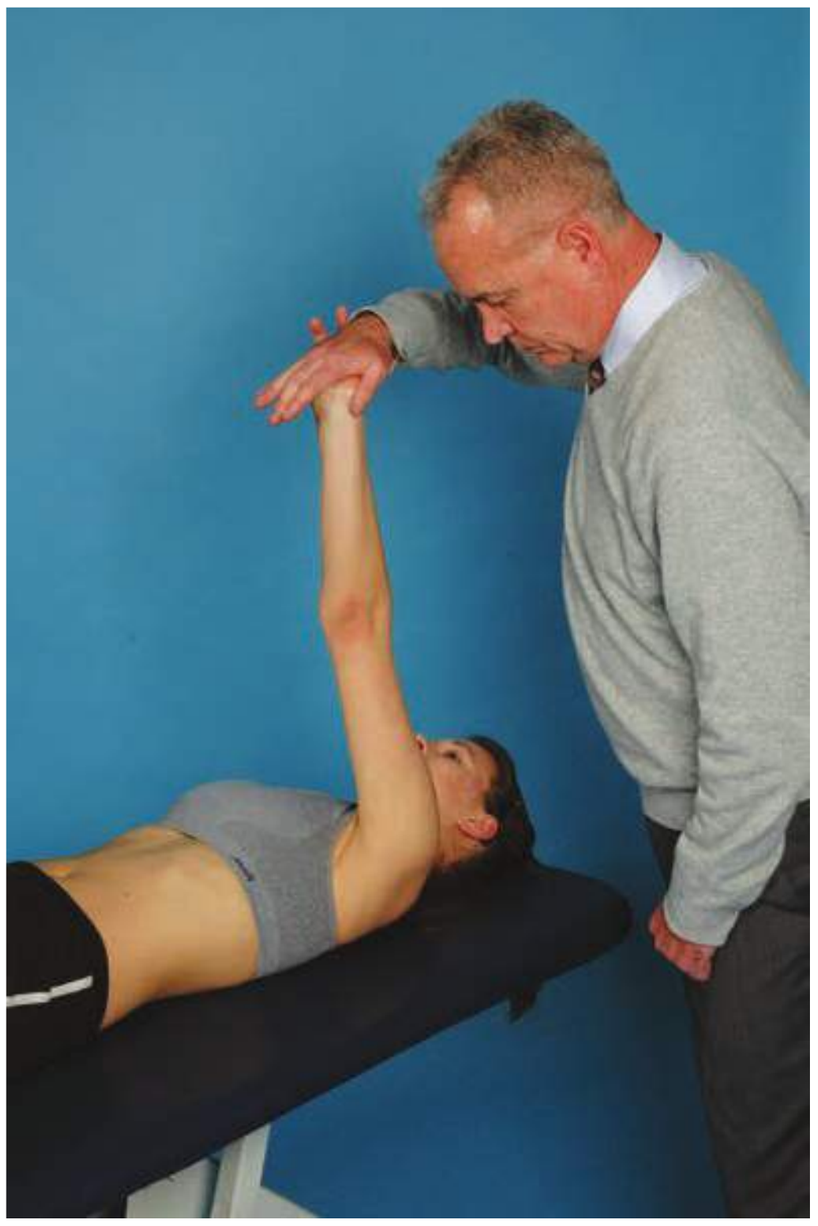

FIGURE 16-37 Serratus anterior test.

a longitudinal force along the humerus in a superior direction to drive the humerus superiorly. A positive sign is pain reproduced with this maneuver.

A painless weakness of elbow flexion can result from a fifth cervical root palsy, or a sixth cervical root palsy (a complete rupture of all of the elbow flexors is an extremely unlikely event.)

The wrist and hand are also evaluated for motor function as appropriate (see Chapter 18).

Examination of Movement Patterns

These tests are concerned with the coordination, timing, or sequence of activation of the muscles during movement.[215]

Serratus Anterior

The patient lies in the prone position and is asked to perform a push-up and then return to the start position extremely slowly. The clinician checks for the quality of scapula stabilization. If the stabilizers are weak, the scapula on the side of impairment will shift outward and upward with a resultant winging of the scapula.

Shoulder Abduction

The patient sits with his or her elbow flexed to control the humeral rotation. The patient is asked to slowly abduct the arm. Three components are evaluated:

- Abduction at the G-H joint
- Rotation of the scapula
- Elevation of the whole shoulder girdle—the abduction movement is stopped at the point at which the shoulder begins to elevate; this typically occurs at approximately 60 degrees of G-H abduction

Functional Testing

The assessment of shoulder function is an integral part of the examination of the shoulder complex. Functional testing of the shoulder complex can include tests designed to detect a biomechanical dysfunction or tests designed to assess the patient's ability to perform the basic functions of ADL. Given the number of different shoulder conditions that exist, it is important to remember that each of the following functional tests may have specific limited applications.

Biomechanical Function

There are only two functional motions within the shoulder girdle: arm elevation using a combination of flexion and abduction, and arm extension with adduction. All other motions of the shoulder are parts or composites of these two basic functional sets.

Basic Function Testing

By referring to Table 16-16, the clinician can determine the functional status of the shoulder for basic functions simply by measuring the amount of available ROM. For example, humeral motions necessary for eating and drinking have been reported at 5–45 degrees of flexion, 5–35 degrees of abduction, and 5–25 degrees of IR relative to the trunk.[300] Combing hair has been found to require 112 degrees of arm elevation.[190]

TABLE 16-16 Range of Motion Necessary at the Shoulder for Functional Activities

Activity	Necessary Range of Motion
Eating	70–100-degree horizontal adduction 45–60-degree abduction
Combing hair	30–70-degree horizontal adduction 105–120-degree abduction 90-degree external rotation
Reach perineum	75–90-degree horizontal abduction 30–45-degree abduction 90-degree or greater internal rotation
Tuck in shirt	50–60-degree horizontal abduction 55–65-degree abduction 90-degree internal rotation
Position hand behind head	10–15-degree horizontal adduction 110–125-degree forward flexion 90-degree external rotation
Put an item on a shelf	70–80-degree horizontal adduction 70–80-degree forward flexion 45-degree external rotation
Wash opposite shoulder	60–90-degree forward flexion 60–120-degree horizontal adduction

Data from Matsen FH III, Lippitt SB, Sidles JA, et al. Practical Evaluation of Management of the Shoulder. Philadelphia, PA: WB Saunders; 1994:19–150; Magee DJ. Shoulder, Orthopaedic Physical Assessment. Philadelphia, PA: WB Saunders; 1992:90–142.

Mannerkorpi[301] used three functional tests (hand-to-neck, hand-to-scapula, and hand-to-opposite scapula) to assess shoulder dysfunction in patients with fibromyalgia (Table 16-17). Yang and Lin[302] assessed the intertester and intratester reliability of these functional tests and found them to be reliable for documenting reduced function of the shoulder.

The assessment tool outlined in Table 16-18 can also be used as a functional test of the shoulder. Lower higher indicate less pain and greater function.

One-Arm Hop Test

The one-arm hop test is a functional performance test for athletes, which can be used in preseason screens or to assist in return-to-play decisions. The test requires the patient to be in a one-arm push-up position on the floor (Fig. 16-38). The patient uses his arm to hop onto a 10.2-cm (4-in) step and back to the floor. The time required to perform five repetitions of this movement as quickly as possible is recorded and compared with the uninvolved arm. With sufficient training, a time of under 10 seconds is considered normal.[303]

The one-arm hop test requires concentric and eccentric muscle strength and coordination while the distal portion of the upper extremity has a significant load placed upon it.[303]

TABLE 16-17 Function-Related Tests

Hand to back of neck (shoulder flexion and external rotation)[a]	0	The fingers reach the posterior median line of the neck with the shoulder in full abduction and external rotation without wrist extension
	1	The fingers reach the median line of the neck but do not have full abduction and/or external rotation
	2	The fingers reach the median line of the neck, but with compensation by adduction in the horizontal plane or by shoulder elevation
	3	The fingers touch the neck
	4	The fingers do not reach the neck
Hand to scapula (shoulder extension and internal rotation)[b]	0	The hand reaches behind the trunk to the opposite scapula or 5 cm beneath it in full internal rotation. The wrist is not laterally deviated
	1	The hand almost reaches the opposite scapula, 6–15 cm beneath it
	2	The hand reaches the opposite iliac crest
	3	The hand reaches the buttock
	4	Subject cannot move the hand behind the trunk
Hand to opposite scapula (shoulder horizontal adduction)[c]	0	The hand reaches to the spine of opposite scapula in full adduction without wrist flexion
	1	The hand reaches to the spine of the opposite scapula in full adduction
	2	The hand passes the midline of the trunk
	3	The hand cannot pass the midline of the trunk

[a]This test measures an action essential for daily activities, such as using the arm to reach, pull, or hang an object overhead or using the arm to pick up and drink a cup of water.
[b]This test measures an action essential for daily activities, such as using the arm to pull an object out of a back pocket or tasks related to personal care.
[c]This test measures an action important for daily activities, such as using the arm to reach across the body to get a car's seat belt or using the arm to turn a steering wheel.
Data from Mannerkorpi K, Svantesson U, Carlsson J, et al. Tests of functional limitations in fibromyalgia syndrome: A reliability study. Arthritis Care Res. 1999;12:193–199.

TABLE 16-18 Functional Testing of the Shoulder

Starting Position	Action	Functional Test
Sitting, cuff weight attached to wrist	Forward flex arm to 90 degrees, elbow extended	Raise 1–3-lb weight: functionally fair Raise arm without weight: functionally poor Cannot raise arm: nonfunctional
Sitting, cuff weight attached to wrist	Extend shoulder, elbow extended	Raise 4–5-lb weight: functional Raise 3–4-lb weight: functional fair Raise arm without weight: functionally poor Cannot extend arm: nonfunctional
Sitting with hand behind low back	Shoulder internal rotation	Raise 5-lb weight: functional Raise 1–3-lb weight: functional fair Raise arm without weight: functionally poor Cannot raise arm: nonfunctional
Sidelying, cuff weight attached to wrist	Shoulder external rotation	Raise 5-lb weight: functional Raise 3–4-lb weight: functional fair Raise arm without weight: functionally poor Cannot raise arm: nonfunctional
Sitting, cuff weight attached to wrist	Shoulder abduction to 90 degrees	Raise 5-lb weight: functional Raise 3–4-lb weight: functional fair Raise arm without weight: functionally poor Cannot raise arm: nonfunctional
Sitting, arm abducted to 145 degrees	Shoulder adduction	Pull 5-lb weight: functional Pull 3–4-lb weight: functional fair Pull 1–2-lb weight: functionally poor Cannot pull 1 lb: nonfunctional

(Continued)

TABLE 16-18 Functional Testing of the Shoulder (Continued)

Starting Position	Action	Functional Test
Sitting	Shoulder elevation (shoulder shrug)	Five repetitions: functional Three to four repetitions: functional fair One to two repetitions: functionally poor Zero repetitions: nonfunctional
Sitting	Scapular depression	Five repetitions: functional Three to four repetitions: functional fair One to two repetitions: functionally poor Zero repetitions: nonfunctional

Shoulder Outcome Scales

Several generic and region-specific outcome tools have been developed and used to document outcomes of patients with shoulder pathologies. A number of shoulder outcome scales have been developed. Five of the most commonly used shoulder outcome scales are the University of California–Los Angeles (UCLA) shoulder scale, the simple shoulder test (SST), the Shoulder Pain and Disability Index (SPADI), the Disabilities of the Arm, Shoulder, and Hand (DASH), and the Penn Shoulder Score (PSS).

University of California–Los Angeles (UCLA) Shoulder Scale. The self-report section of the UCLA Shoulder Scale consists of two single-item subscales, one for pain and the other for functional level (Table 16-19). The items are Likert-type (a psychometric scale) and scored from 1 to 10, with higher scores indicating less pain and greater function.[304]

The Simple Shoulder Test. Lippitt et al.[305] advocate the use of the SST (Table 16-20). The SST is a standardized self-assessment of shoulder function consisting of 12 yes/no questions. The SST has high test and retest reproducibility and is sensitive to a wide variety of shoulder disorders.[305] In addition, the SST has been shown to be a practical tool for documenting the efficacy of treatment for shoulder conditions. Patients without rotator cuff disease or other shoulder disorders are unable to do all 12 functions of the SST.[205,306–308]

TABLE 16-20 The Simple Shoulder Test

1. Is your shoulder comfortable with your arm at rest by your side?
2. Does your shoulder allow you to sleep comfortably?
3. Can you reach the small of your back to tuck in your shirt with your hand?
4. Can you place your hand behind your head with the elbow straight out to the side?
5. Can you place a coin on a shelf at the level of your shoulder without bending your elbow?
6. Can you lift 1 lb (a full-pint container) to the level of your shoulder without bending your elbow?
7. Can you lift 8 lb (a full gallon container) to the level of the top of your head without bending your elbow?
8. Can you carry 20 lb at your side with the affected extremity?
9. Do you think you can toss a softball underhand 10 yards with the affected extremity?
10. Do you think you can throw a softball overhand 20 yards with the affected extremity?
11. Can you wash the back of your opposite shoulder with the affected extremity?
12. Would your shoulder allow you to work full time at your usual job?

Data from Matsen FA, Lippitt SB, Sidles JA, et al. Evaluating the shoulder. In: Matsen FA, Lippitt SB, Sidles JA, et al., eds. Practical Evaluation and Management of the Shoulder. Philadelphia, PA: WB Saunders; 1994:1–17.

When compared with other available shoulder self-assessment questionnaires, the SST has the highest test/retest reliability, takes the shortest amount of time for a patient to complete, is the easiest to score, and has satisfactory responsiveness.[309,310] The questions can be asked at the initial visit and then at subsequent visits to track progress.

Shoulder Pain and Disability Index.[311] The SPADI consists of two self-report subscales of pain and disability. The items of both the subscales are visual analog scales (VASs). The five-item pain subscale asks people about their pain during ADL, and each item is anchored by the descriptors "no pain" (left anchor) and "worst pain imaginable" (right anchor). The eight disability items ask people about their difficulty performing ADL. These items are anchored with the descriptors "no difficulty" (left anchor) and "so difficult it required help" (right anchor). Each item is scored by measuring the distance from the left anchor to the mark made by the person. Subscales are scored in a three-part process. First, item scores within the subscale are summed. Second, this sum is divided by the summed distance possible across all items of the subscale to which the person responded. Third, this ratio is multiplied by 100 to obtain a percentage. Higher scores on the subscale indicate greater pain and greater disability. To obtain the SPADI total score, the pain and disability subscales scores are averaged.[311]

Disabilities of the Arm, Shoulder, and Hand. The acronym DASH was chosen to describe an outcome measure that reflects the impact on function of a variety of musculoskeletal diseases and injuries in the upper extremity.[312] Items covered by the DASH questionnaire are symptoms and functional status. The components included under the concept of symptoms are pain, weakness, stiffness, and tingling/numbness.[312] There are three dimensions under functional status: physical, social, and psychological status. Two versions of the DASH are available: a 30-item questionnaire that has optional three-question modules for sport/music and heavy work activities (Table 16-21), and a 15–20-item questionnaire suitable for office use.

Penn Shoulder Score. PSS is a condition-specific self-report measure that uses a 100-point scale consisting of three subscales, including pain, satisfaction, and function. The pain subscale consists of three pain items that address pain at rest, with no activities, and with strenuous activities (Table 16-22).[313] All are based on a 10-point numeric rating scale with end points of "no pain" and "worst possible pain." Points are awarded for each item by subtracting the number circled from the maximum of 10. Therefore a patient is awarded 30 points for complete absence of pain. If a patient is not able to use the arm for normal or strenuous activities, zero points are awarded for that item. Patient satisfaction with shoulder function is also assessed with a 10-point numeric rating scale (Table 16-23). The end points are "not satisfied" and "very satisfied." A maximum of 10 points for this section indicates that the patient is "very satisfied" with the current level of function of his or her shoulder. The total PSS maximum score of 100 indicates high function low pain and high satisfaction with the function of the shoulder. The PSS has been found to be a reliable and valid measure for reporting outcome of patients with various shoulder disorders.[313]

Patient-Specific Functional Scale. Although not specific to the shoulder, the PSFS, in which patients are asked to choose activities that are difficult to perform and, subsequently, to rate the level of disability for each activity on a rating scale (see Chapter 4), Koehorst et al.[314] reported that the PSFS is a reliable, valid, and responsive instrument that can be used as an evaluated instrument in patients with a primary shoulder complaint.

muscle Length Tests

Pectoralis major

The patient lies in the supine position with the trunk stabilized. The clinician passively abducts the patient's arm and differentiates between the different bands of the pectoralis major.

Clavicular Portion. The patient's arm hangs loosely down over the edge of the table. The clinician moves the patient's shoulder down toward the floor. A slight barrier to the motion is normal, whereas a hard barrier is abnormal.

Sternal Portion. With the patient supine on a mat table, they actively abduct their arm fully. Their arm should maintain contact with the table throughout the range.

Pectoralis minor

The patient lies in the supine position with the trunk stabilized. Adaptive shortening of the pectoralis minor is demonstrated if the lateral border of the spine of the scapula is more than 1 in off the table.[215]

TABLE 16-21 The DASH Questionnaire

Please rate your ability to do the following activities in the last week by circling the number below the appropriate response

	No Difficulty	Mild Difficulty	Moderate Difficulty	Severe Difficulty	Unable
1. Open a tight or new jar	1	2	3	4	5
2. Write	1	2	3	4	5
3. Turn a key	1	2	3	4	5
4. Prepare a meal	1	2	3	4	5
5. Push open a heavy door	1	2	3	4	5
6. Place an object on a shelf above your head	1	2	3	4	5
7. Do heavy household chores (e.g., wash walls, wash floors)	1	2	3	4	5
8. Garden or do yard work	1	2	3	4	5
9. Make a bed	1	2	3	4	5
10. Carry a shopping bag or briefcase	1	2	3	4	5
11. Carry a heavy object (over 10 lb)	1	2	3	4	5
12. Change a light bulb overhead	1	2	3	4	5
13. Wash or blow dry your hair	1	2	3	4	5
14. Wash your back	1	2	3	4	5
15. Put on a pullover sweater	1	2	3	4	5
16. Use a knife to cut food	1	2	3	4	5
17. Recreational activities which require little effort (e.g., cardplaying, knitting, etc.)	1	2	3	4	5
18. Recreational activities in which you take some force or impact through your arm, shoulder, or hand (e.g., golf, hammering, tennis, etc.)	1	2	3	4	5
19. Recreational activities in which you move your arm freely (e.g., playing frisbee, badminton, etc.)	1	2	3	4	5
20. Manage transportation needs (getting from one place to another)	1	2	3	4	5
21. Sexual activities	1	2	3	4	5

Disabilities of the arm, shoulder, and hand

	Not at all	Slightly	Moderately	Quite a Bit	Extremely
22. During the past week, to what extent has your arm, shoulder, or hand problem interfered with your normal social activities with family, friends, neighbors, or groups? (circle number)	1	2	3	4	5

	Not Limited at All	Slightly Limited	Moderately Limited	Very Limited	Unable
23. During the past week, were you limited in your work or other regular daily activities as a result of your arm, shoulder, or hand problem? (circle number)	1	2	3	4	5

Please rate the severity of the following symptoms in the last week (circle number)

	None	Mild	Moderate	Severe	Extreme
24. Arm, shoulder, or hand pain	1	2	3	4	5
25. Arm, shoulder, or hand pain when you performed any specific activity	1	2	3	4	5
26. Tingling (pins and needles) in your arm, shoulder, or hand	1	2	3	4	5
27. Weakness in your arm, shoulder, or hand	1	2	3	4	5
28. Stiffness in your arm, shoulder, or hand	1	2	3	4	5
29. During the past week, how much difficulty have you had sleeping because of the pain in your arm, shoulder or hand? (circle number)	1	2	3	4	5

TABLE 16-21 The DASH Questionnaire (Continued)

	Strongly Disagree	Disagree	Neither Agree nor Disagree	Agree	Strongly Agree
30. I feel less capable, less confident, or less useful because of my arm, shoulder, or hand problem (circle number)	1	2	3	4	5

Scoring DASH function/symptoms: Add up circled responses (items 1–30); subtract 30; divide by 1.20 = DASH score.

Sports/performing arts module (optional)

The following questions relate to the impact of your arm, shoulder, or hand problem on playing your musical instrument or sport. If you play more than one sport or instrument (or play both), please answer with respect to that activity which is most important.

Please indicate the sport or instrument which is most important to you: _____

I do not play a sport or an instrument. (You may skip this section.)

Please circle the number that best describes your physical ability in the past week. Did you have any difficulty

	No Dif culty	Mild Dif culty	Moderate Dif culty	Severe Dif culty	Unable
1. Using your usual technique for playing your instrument or sport?	1	2	3	4	5
2. Playing your musical instrument or sport because of arm, shoulder, or hand pain?	1	2	3	4	5
3. Playing your musical instrument or sport as well as you would like?	1	2	3	4	5
4. Spending your usual amount of time practicing or playing your instrument or sport?	1	2	3	4	5

Work module (optional)

The following questions ask about the impact of your arm, shoulder, or hand problem on your ability to work (including homemakers if that is your main work role).

I do not work. (You may skip this section.)

Please circle the number that best describes your physical ability in the past week. Did you have any difficulty

	No Dif culty	Mild Dif culty	Moderate Dif culty	Severe Dif culty	Unable
1. Using your usual technique for your work?	1	2	3	4	5
2. Doing your usual work because of arm, shoulder, or hand pain?	1	2	3	4	5
3. Doing your work as well as you would like?	1	2	3	4	5
4. Spending your usual amount of time doing your work?	1	2	3	4	5

TABLE 16-22 The Penn Shoulder Score, Part 1: Pain and Satisfaction Subscales

Please Circle the Number Closest to Your Level of Pain or Satisfaction	Of ce Use Only
Pain at rest with your arm by your side: 0 1 2 3 4 5 6 7 8 9 10 No pain Worst pain possible	(10 —# circled)
Pain with normal activities (eating, dressing, bathing): 0 1 2 3 4 5 6 7 8 9 10 No pain Worst pain possible	(10 —# circled) (Score 0 if not applicable)
Pain with strenuous activities (reaching, lifting, pushing, pulling, throwing): 0 1 2 3 4 5 6 7 8 9 10 No pain Worst pain possible	(10 —# circled) (Score 0 if not applicable)
Pain score: = 30	
How satisfied are you with the current level of function of your shoulder? 0 1 2 3 4 5 6 7 8 9 10 No pain Worst pain possible	/10 (# circled)

TABLE 16-23 The Penn Shoulder Score: Function Subscale

Please Circle the Number that Best Describes the Level of Difficulty You Might Have Performing Each Activity	No Difficulty	Some Difficulty	Much Difficulty	Can't Do At All	Did Not Do Before Injury
1. Reach the small of your back to tuck in your shirt with your hand	3	2	1	0	X
2. Wash the middle of your back/hook bra	3	2	1	0	X
3. Perform necessary toileting activities	3	2	1	0	X
4. Wash the back of opposite shoulder	3	2	1	0	X
5. Comb hair	3	2	1	0	X
6. Place hand behind head with elbow held straight out to the side	3	2	1	0	X
7. Dress self (including put on coat and pull shirt off overhead)	3	2	1	0	X
8. Sleep on affected side	3	2	1	0	X
9. Open a door with affected arm	3	2	1	0	X
10. Carry a bag of groceries with affected arm	3	2	1	0	X
11. Carry a briefcase/small suitcase with affected arm	3	2	1	0	X
12. Place a soup can (1–2 lb) on a shelf at shoulder level without bending elbow	3	2	1	0	X
13. Place a one gallon container (8–10 lb) on a shelf at shoulder level without bending elbow	3	2	1	0	X
14. Reach a shelf above your head without bending your elbow	3	2	1	0	X
15. Place a soup can (1–2 lb) on a shelf overhead without bending your elbow	3	2	1	0	X
16. Place a one gallon container (8–10 lb) on a shelf overhead without bending your elbow	3	2	1	0	X
17. Perform usual sport/hobby	3	2	1	0	X
18. Perform household chores (cleaning, laundry, cooking)	3	2	1	0	X
19. Throw overhand/swim/overhead racquet sports (circle all that apply to you)	3	2	1	0	X
20. Work full time at your regular job	3	2	1	0	X

SCORING
Total of columns = ___(a)
Number of Xs × 3 = ___(b), 60–__(b) = ___(c) (if no Xs are circled, function score = total of columns)
Function score = __ (a) ± __(c) = __ × 60__/60

Latissimus Dorsi

The patient lies in the supine position with the trunk stabilized. The patient is asked to perform bilateral shoulder flexion. Under normal circumstances, the patient should be able to perform complete shoulder flexion without any increase in lumbar lordosis occurring.[215] Shoulder flexion that requires an increase in lumbar lordosis to complete is indicative of an adaptively shortened latissimus dorsi.

external rotators

The patient lies in the supine position with the trunk stabilized. The shoulder is positioned at 90 degrees of abduction with the elbow flexed to approximately 90 degrees. The patient is then asked to allow the shoulder to passively internally rotate. IR accompanied by an anterior tilt of the scapula, rather than the range of IR increasing, is indicative of adaptive shortness of the external rotators.[215] This is confirmed by having the patient perform the maneuver again while the clinician prevents the anterior tilt of the scapula from occurring. With the second test, there should be a decrease in the amount of passive IR available.

Passive Accessory motion Tests

The passive accessory motion tests are performed at the end of the patient's available range to determine if the joint itself is responsible for the loss of motion. For all of these tests, the joint is initially positioned in the resting or open-packed position, the patient lies in the supine position with their head supported on a pillow if required, while the clinician stands facing the patient.

Distraction of the G-h Joint

The clinician palpates and stabilizes the shoulder girdle and the anterior thorax. With one hand, the clinician gently grasps the proximal third of the humerus. The clinician distracts the G-H joint perpendicular to the plane of the glenoid fossa in a lateral, anterior, and inferior direction (30 degrees off the sagittal plane) (Fig. 16-39). The quantity of motion is noted and compared with the other side. Alternatively, if the arm is positioned so that the long axis of the humerus is perpendicular to the flattened concave surface of the glenoid, the technique can be performed by pulling on the upper arm (Fig. 16-40).

FIGURE 16-39 Glenohumeral distraction.

Inferior Glide of the G-H Joint

The clinician palpates and stabilizes the coracoid process of the scapula and the lateral clavicle. With the other hand, the clinician gently grasps proximal to the patient's elbow. The humerus is glided inferiorly at the G-H joint, parallel to the superoinferior plane of the glenoid fossa (Fig. 16-41). The quantity of motion is noted and compared with the other side.

Posterior Glide of the G-H Joint

The clinician palpates and stabilizes the coracoid process and the lateral third of the clavicle. With the thenar eminence of the same hand, the clinician palpates the anterior aspect of the humeral head (Fig. 16-42). With the other hand, the clinician gently grasps the distal end of the humerus. From this position, the clinician glides the humerus posteriorly at the G-H joint, parallel to the A-P plane of the glenoid fossa. The quantity of motion is noted and compared with the other side.

Anterior Glide of the G-H Joint

There are two common variations for this technique, one with the patient in the supine position, and the other where the patient lies in the prone position:

- Patient supine. The clinician palpates the posterior aspect of the humeral head with one hand (Fig. 16-43). With the other hand, the clinician gently grasps the distal end of the humerus. From this position, the clinician glides the humerus anteriorly at the G-H joint, parallel to the A-P plane of the glenoid fossa. The quantity of motion is noted and compared with the other side.

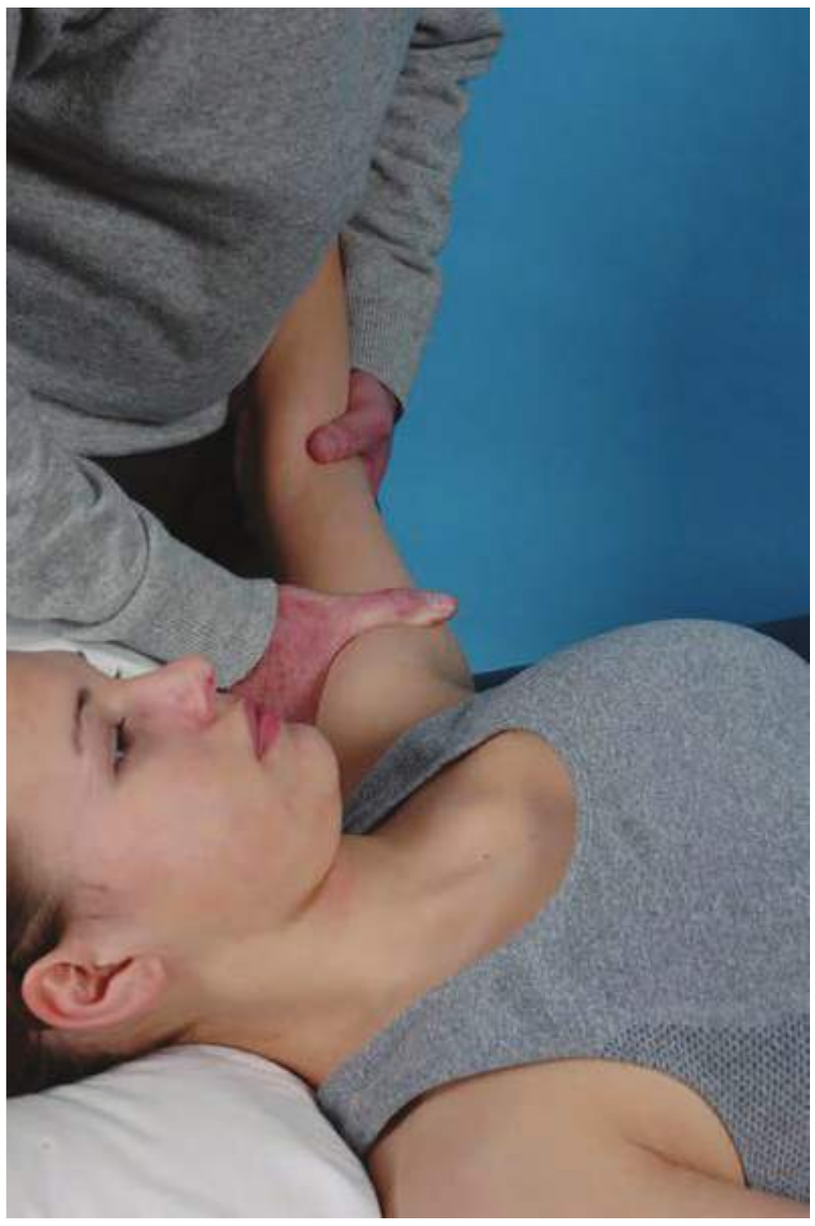

FIGURE 16-41 Inferior glide.

FIGURE 16-42 Posterior glide.

FIGURE 16-40 Glenohumeral distraction using arm pull.

FIGURE 16-43 Anterior glide with patient supine.

- Patient prone. The clinician palpates the posterior aspect of the humeral head with one hand (Fig. 16-44). With the other hand, the clinician gently grasps the distal end of the humerus. From this position, the clinician glides the humerus toward the floor in an anterior direction, parallel to the A-P plane of the glenoid fossa. The quantity of motion is noted and compared with the other side.

The intervention for joint glide restrictions uses similar techniques and positioning as for the assessment except for the following:

- Grade I and II oscillations are used for pain and graded depending on the stage of healing.
- Grade III–V techniques are used to increase range.

Passive Accessory motion Testing of the scapulothoracic Joint

Distraction

The patient lies in the sidelying position. The patient's uppermost arm is placed in IR so that the posterior surface of the hand is positioned on the sacrum, if shoulder ROM allows. The clinician stands in front of the patient. The clinician places one hand over the acromion and the mobilizing hand is positioned adjacent to the inferior angle of the scapula. The clinician moves the scapula medially and inferiorly and then lifts the scapula away from the ribs (Fig. 16-45). The quantity and quality of motion is noted.

superior Glide

The patient is positioned as for the scapulothoracic joint distraction technique, except the uppermost arm is positioned in neutral. Using the mobilizing hand, the clinician glides the scapula in a superior direction (Fig. 16-46).

inferior Glide

The patient is positioned as for the scapulothoracic joint superior glide. Using the mobilizing hand, the clinician glides the scapula in an inferior direction (Fig. 16-47).

medial Glide

The patient is positioned as for the superior glide of the scapulothoracic joint. The clinician positions both hands over the lateral surface of the scapula, with one hand over the axillary border and the other hand over the acromion. Using both hands the clinician glides the scapula in a medial direction (Fig. 16-48).

FIGURE 16-44 Anterior glide with patient prone.

FIGURE 16-45 Distraction of scapulothoracic joint.

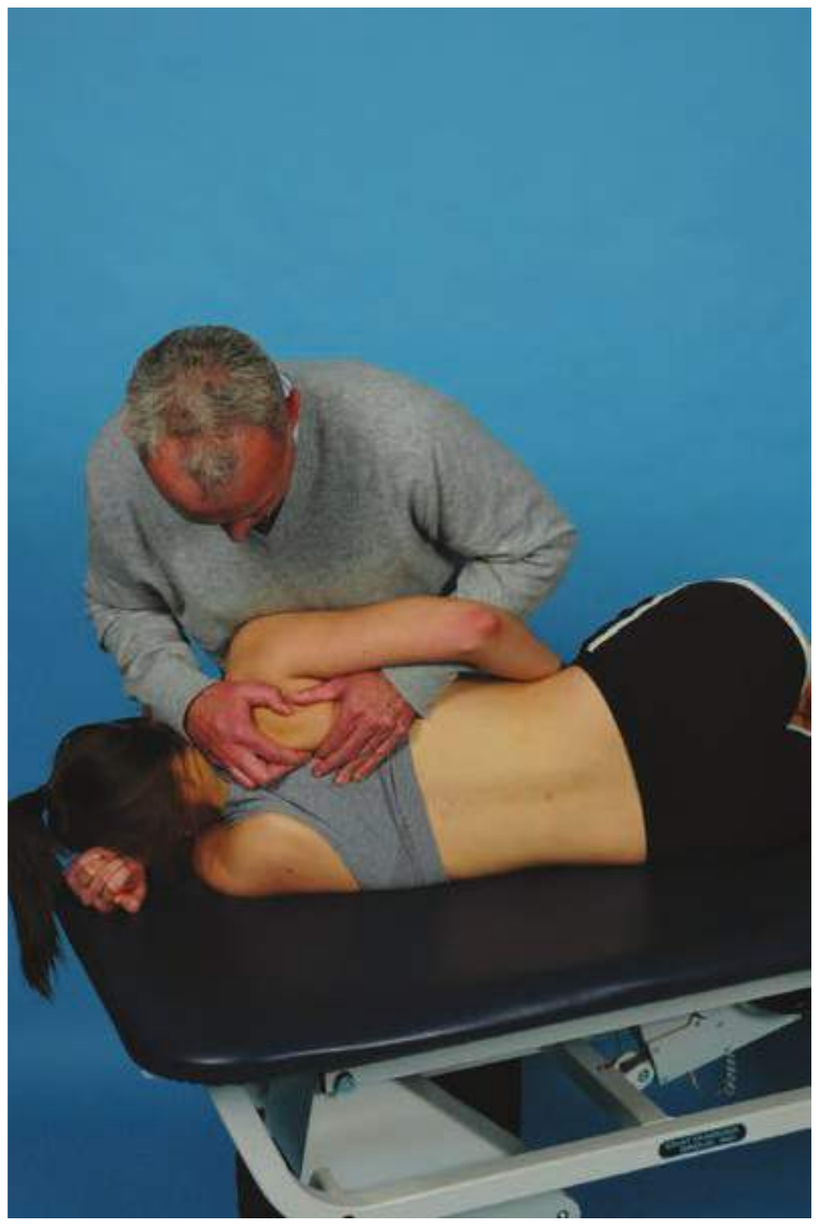

FIGURE 16-46 Superior glide of scapulothoracic joint.

Lateral Glide

The patient is positioned as for the medial glide of the scapulothoracic joint. The clinician places both hands and the fingertips over the vertebral border of the scapula and the scapula is glided in a lateral direction (Fig. 16-49).

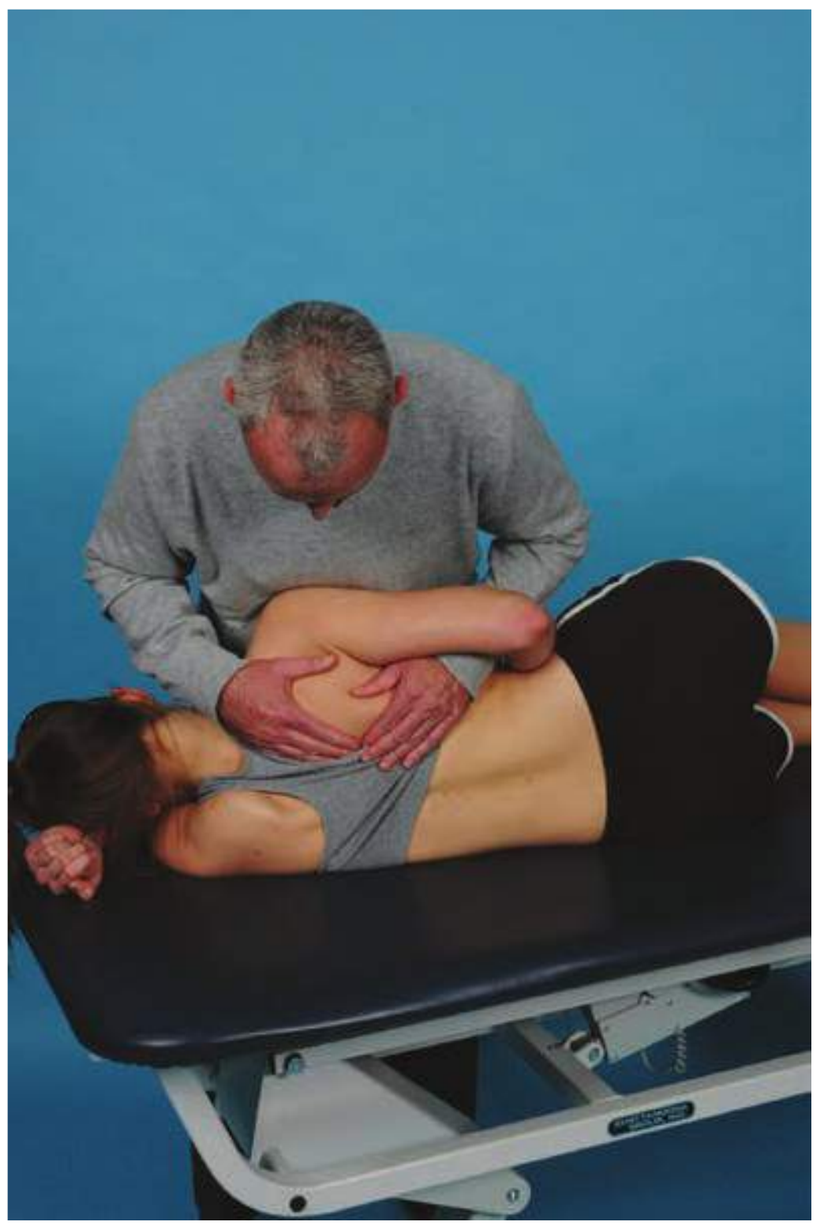

FIGURE 16-47 Inferior glide of scapulothoracic joint.

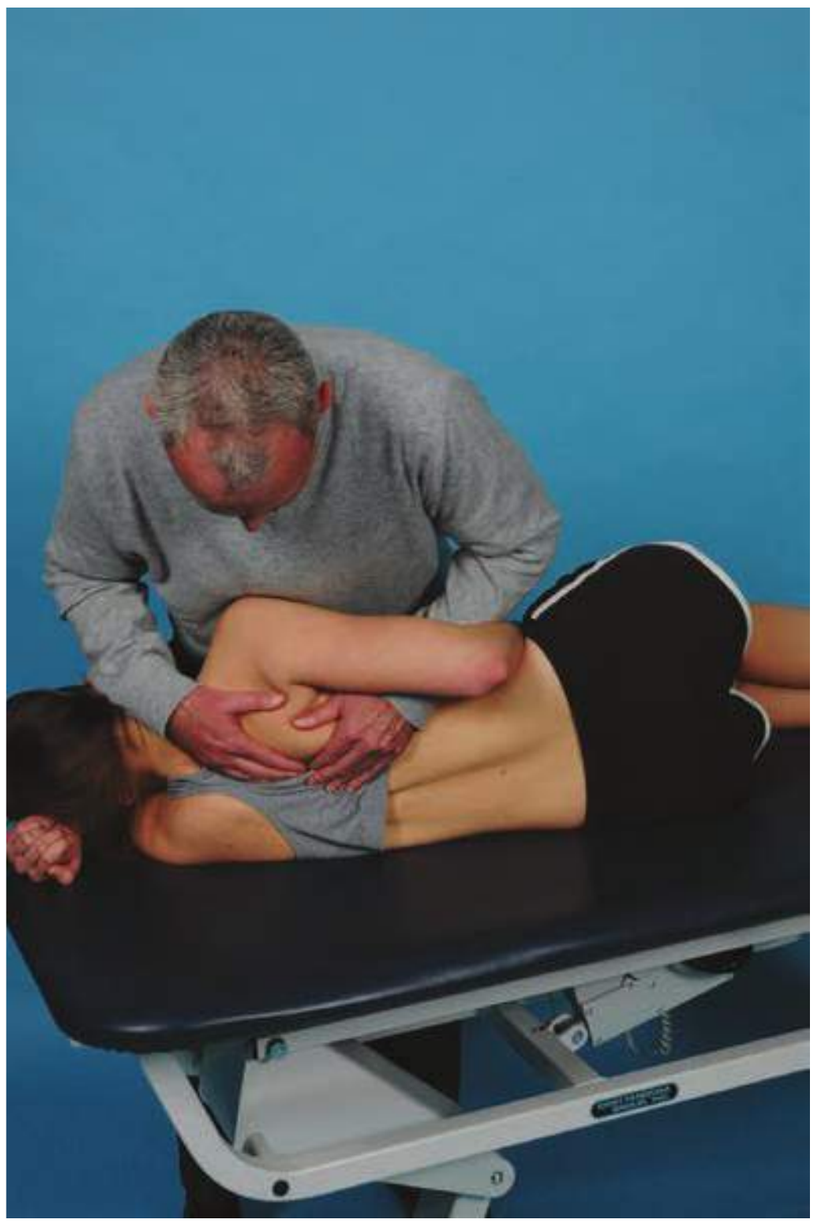

FIGURE 16-48 Medial glide of scapulothoracic joint.

Passive Accessory motion Testing of the Acromioclavicular Joint

Anterior and Posterior rotation of the Clavicle

During G-H abduction, or shoulder elevation, the lateral end of the clavicle moves superiorly, the medial end slides

FIGURE 16-49 Lateral glide of scapulothoracic joint.

TABLE 16-24	Clavicle Motions in Relation to Other Motions	
Moving Bone	**Motion**	**Rotation**
Ribs	Inspiration	Posterior
	Expiration	Anterior
Scapula	Protraction	Anterior
	Retraction	Posterior
	Elevation	Anterior
	Depression	Posterior
Head/neck	Ipsilateral rotation	Posterior
	Contralateral rotation	Anterior
	Ipsilateral flexion	Posterior
	Contralateral flexion	Anterior
	Flexion	Anterior
	Extension	Posterior

and rolls inferiorly, and the clavicle rotates anteriorly. During G-H adduction, or shoulder depression, the lateral end of the clavicle moves inferiorly, while the medial end rolls and slides superiorly. During this motion, the clavicle rotates posteriorly (see Table 16-24).

The patient lies in the sidelying or supine position. The clinician stabilizes the humerus with one hand and grasps the anterior and posterior aspects of the clavicle with the other hand, using the thumb, index, and middle fingers so that the fingers are hooked around the lateral aspect of the clavicle (Fig. 16-50). The clinician passively pulls the clavicle into the limit of anterior rotation and assesses the end-feel (see Fig. 16-50). The clinician then passively pushes the clavicle into the limit of posterior rotation and assesses the end-feel (see Fig. 16-50).

Passive Accessory motion Testing of the sternoclavicular Joint

The patient lies in the supine position. It is assumed that the techniques are performed on the patient's right side.

inferior Glide

Using one thumb, the clinician palpates the superior aspect of the medial end of the clavicle and the S-C joint and applies an inferior glide to the S-C joint (Fig. 16-51). The quantity and quality of motion is noted.

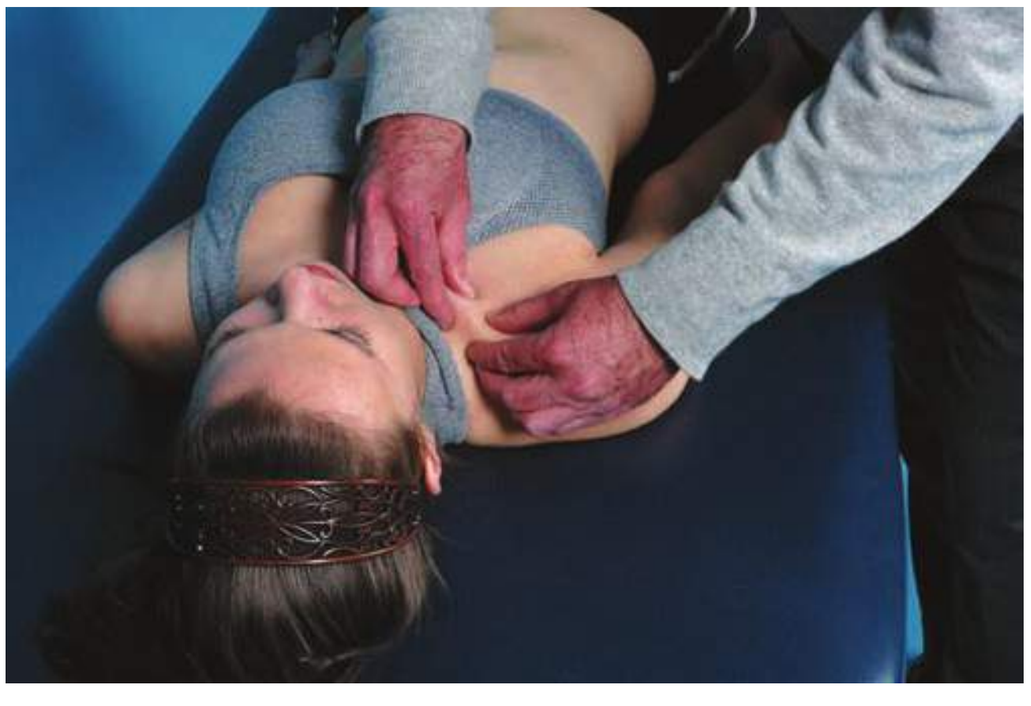

FIGURE 16-50 Anterior and Posterior Rotation of the Clavicle.

FIGURE 16-51 Inferior glide of S-C joint.

superior Glide

Using the thumb and fingers of one hand, the clinician palpates the inferior aspect of the medial end of the clavicle and the S-C joint and applies a posterosuperior glide to the S-C joint (Fig. 16-52). The quantity and quality of motion is noted.

Although some texts advocate assessing the anterior and posterior glides of this joint, both of these techniques can be uncomfortable for the patient, and provide little information for the clinician.

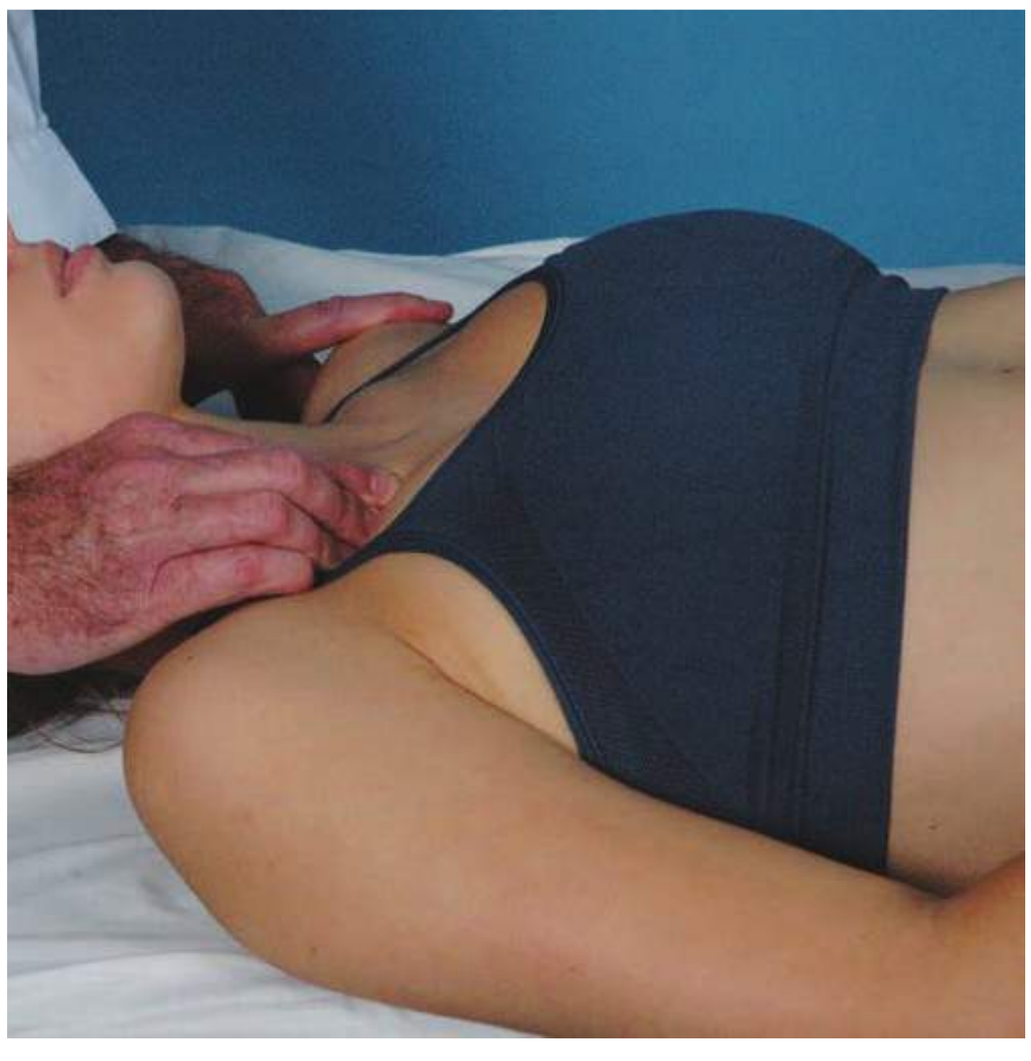

FIGURE 16-52 Superior glide of S-C joint.

special Tests

T e special tests for the shoulder are divided into diagnostic categories. Selection for their use is at the discretion of the clinician and is based on a complete patient history and the findings from the physical examination. It is important to remember that rarely is a diagnostic test sensitive and specific enough to be used as the sole determinant, although multiple tests may provide more diagnostic confidence.

r otator Cuff integrity and subacromial impingement Tests

T e following tests have been described in the literature to assess rotator cuff integrity and the presence of SIS (Tables 16-25 and 16-26). Patients with SIS usually perceive pain when a compressing force is applied on the greater tuberosity and rotator cuff region.[315] Pain may also be elicited with shoulder abduction in IR or ER.[315] It is important to remember that

"impingement" is a broad diagnosis that encompasses a broad range of pathologies, making its diagnostic value questionable.

Neer Impingement Test. While scapular rotation is prevented by one hand of the clinician, the arm of the patient is passively forced into elevation at an angle between flexion and abduction by the clinician's other hand. Overpressure is applied with the G-H joint in neutral, IR, and then ER (Fig. 16-53). A positive Neer impingement test result is thought to represent impingement of the rotator cuff on the anterosuperior glenoid rim or coracoacromial ligament.[316] Post and Cohen[317] found the Neer test to have a sensitivity of 93% in the confirmation of subacromial impingement.

Hawkins–Kennedy Impingement Test.[318] The arm of the patient is passively flexed up to 90 degrees in the plane of the scapula. The arm is stabilized and the forearm is forced into IR (Fig. 16-54). In a cadaver study, Pink and Jobe[316] found that rotator cuff tendons were impinged under the acromion with the Hawkins–Kennedy test.

Ure et al.[319] found that the sensitivity of the Hawkins–Kennedy test was 62% and the sensitivity of the Neer test was 46% in 45 patients with stage II SIS, as determined using arthroscopy.

McDonald et al.[320] assessed the diagnostic accuracy of the Neer and Hawkins impingement signs for the diagnosis of

FIGURE 16-53 Neer impingement test.

subacromial bursitis or rotator cuff pathology in 85 consecutive patients undergoing shoulder arthroscopy by a single surgeon. The Neer sign was found to have a sensitivity of 75% for the appearance suggestive of subacromial bursitis; this compared with 92% for the Hawkins sign.[320] For rotator cuff tearing, the sensitivity of the Neer sign was 85% and that of the Hawkins sign was 88%. Specificity and positive predictive values for the two tests were low, being not much higher than pretest probability. The two tests had a high negative predictive value (96% for bursitis, 90% for rotator cuff tearing) when they were combined.[320]

Another study[321] found that the Hawkins–Kennedy test was more accurate than the Neer test in a series of 44 shoulders, with the former having a sensitivity of 78% and the latter a 0%.

Supine Impingement Test. The patient lies in the supine position with the clinician standing to the side of the patient's involved shoulder. The clinician grasps the patient's wrist and distal humerus and elevates the patient's arm to end range (170 degrees or greater). The clinician then moves the patient's arm into ER and then adducts the arm toward the patient's ear (Fig. 16-55). The clinician now internally rotates the patient's arm (Fig. 16-56). The test is considered positive if the patient reports a significant increase in shoulder pain. This test does not appear to be diagnostic but may have value as a screening test since a negative finding may rule out a rotator cuff tear (Table 16-25).

Internal Rotation Lag Sign (subscapularis tear). The patient sits or stands with the involved arm behind the back and the palm facing outward. The clinician grasps the patient's shoulder with one hand and the wrist with the other and then lifts the patient's arm off the back (Fig. 16-57). The clinician then asks the patient to maintain this position as the wrist is released (Fig. 16-58). A positive test, which is manifested with an inability of the patient to maintain his or her arm off of the back, indicates a subscapularis tear. A study by Hertel et al.[322] reported high sensitivity (97%) and specificity (96%) with this test (Table 16-25), but the study had a potential for bias.

FIGURE 16-57 IR lag sign (subscapularis tear)—First position.

FIGURE 16-58 IR lag sign (subscapularis tear)—Second position demonstrating a positive finding.

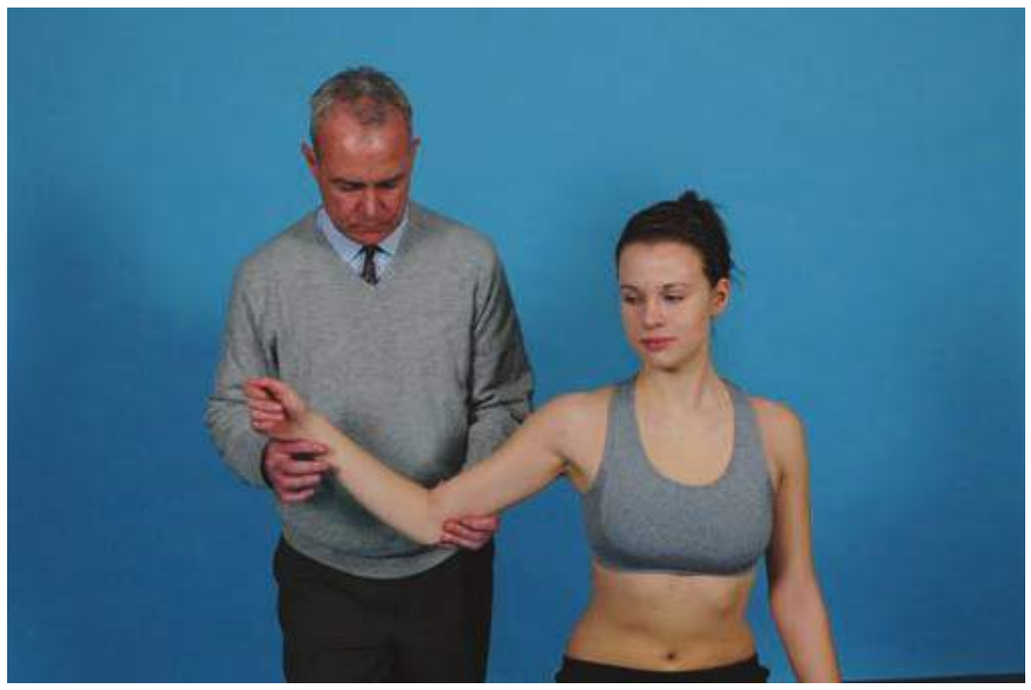

FIGURE 16-59 External rotation lag sign (subscapularis tear)—First position.

External Rotation Lag Sign (subscapularis tear). The patient sits with the clinician standing behind. The clinician grasps the patient's wrist and then places the elbow at 90 degrees of flexion and the shoulder at 20 degrees of elevation in the scapular plane. The clinician passively externally rotates the shoulder and, at the end range, asks the patient to maintain this position (Fig. 16-59) as the patient's wrist is released. A positive test, which is indicated by lag that occurs with the inability of the patient to maintain his or her arm near full ER (Fig. 16-60), indicates a supraspinatus/infraspinatus tear. A study by Hertel et al.[322] reported 70% sensitivity and 100% specificity with this test (Table 16-25), but the study had a potential for bias.

Belly Press Test.[299] The patient sits or stands with the elbow flexed to 90 degrees. The patient is asked to internally rotate the shoulder, causing the palm of the hand to be pressed into the stomach (Fig. 16-61). A positive test, which results in the elbow dropping behind the body into extension, indicates a subscapularis tear. The diagnostic value of this test, which was originally described as an alternative to the lift-off test in those patients without adequate IR of the shoulder is as yet unknown.

The Posterior Impingement Sign. The patient lies in the supine position with the shoulder placed at 90–110 degrees

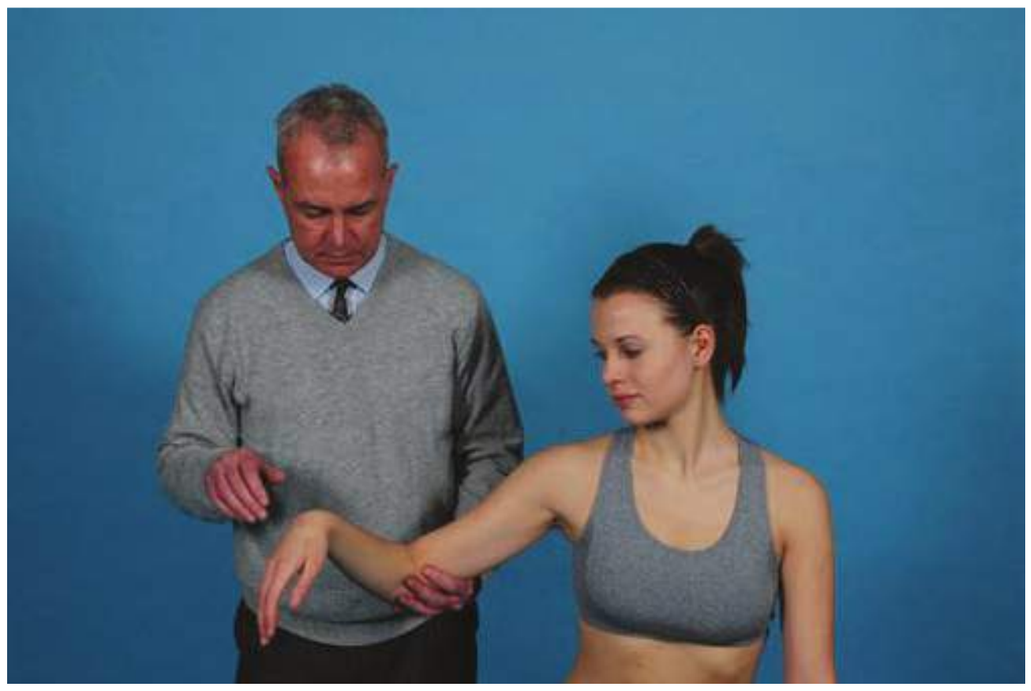

FIGURE 16-60 External rotation lag sign (subscapularis tear)—Second position demonstrating a positive finding.

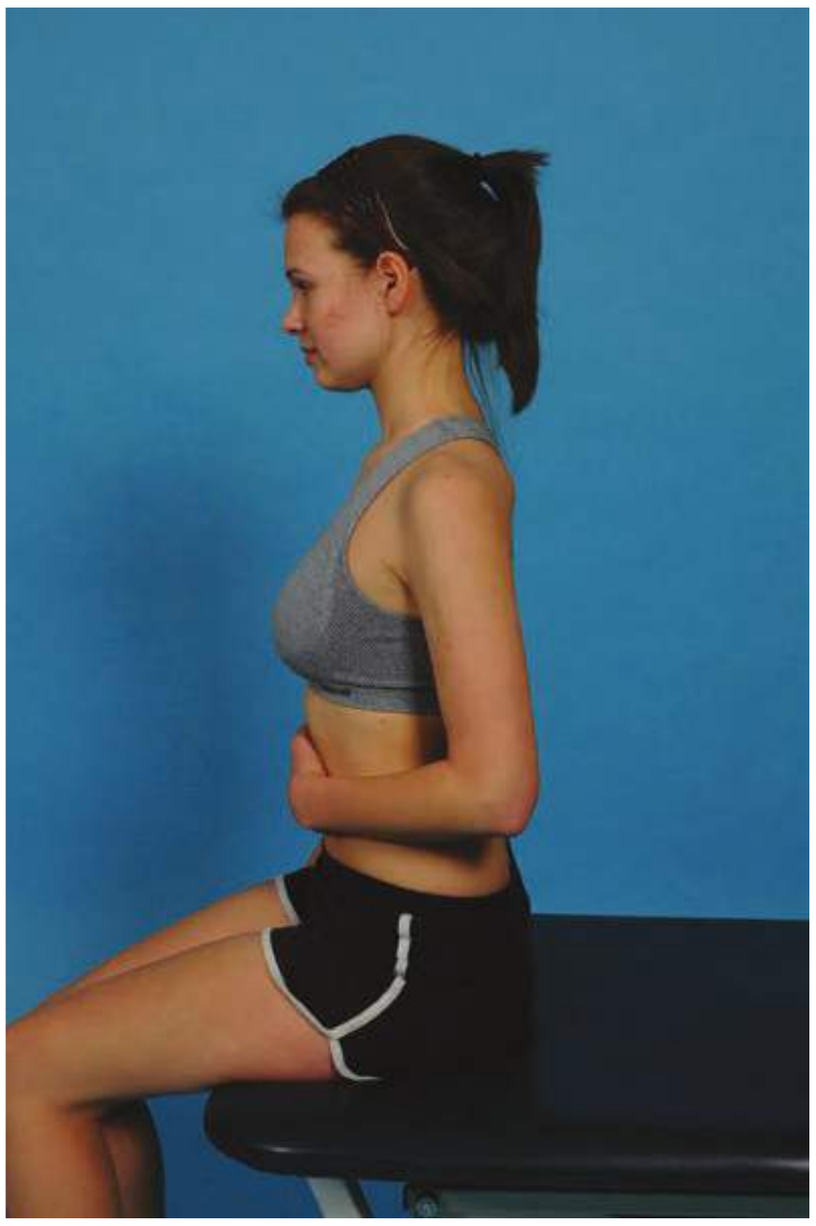

FIGURE 16-61 Belly press test.

of abduction and maximum ER (Fig. 16-62). A positive test is indicated by complaints of pain in the deep posterior shoulder and is indicative of a rotator cuff tear and/or a posterior labral tear (Table 16-25).

Internal Rotation Resisted Strength Test.[323] The patient lies in the supine position with the clinician standing behind the patient. The clinician places the patient's shoulder at 90 degrees of abduction and 80 degrees of ER, with the elbow at 90 degrees of flexion. The clinician first applies a manual resistance to the wrist to assess isometric ER, and then applies manual resistance to the wrist to assess isometric IR. A comparison is made of the two results. The IR-resisted strength test can be used to differentiate between outlet impingement (Fig. 16-63) and nonoutlet or internal impingement based on the apparent weakness of IR versus ER of the arm: if the IR strength is weaker than the ER, the test is considered positive

FIGURE 16-62 The posterior impingement sign.

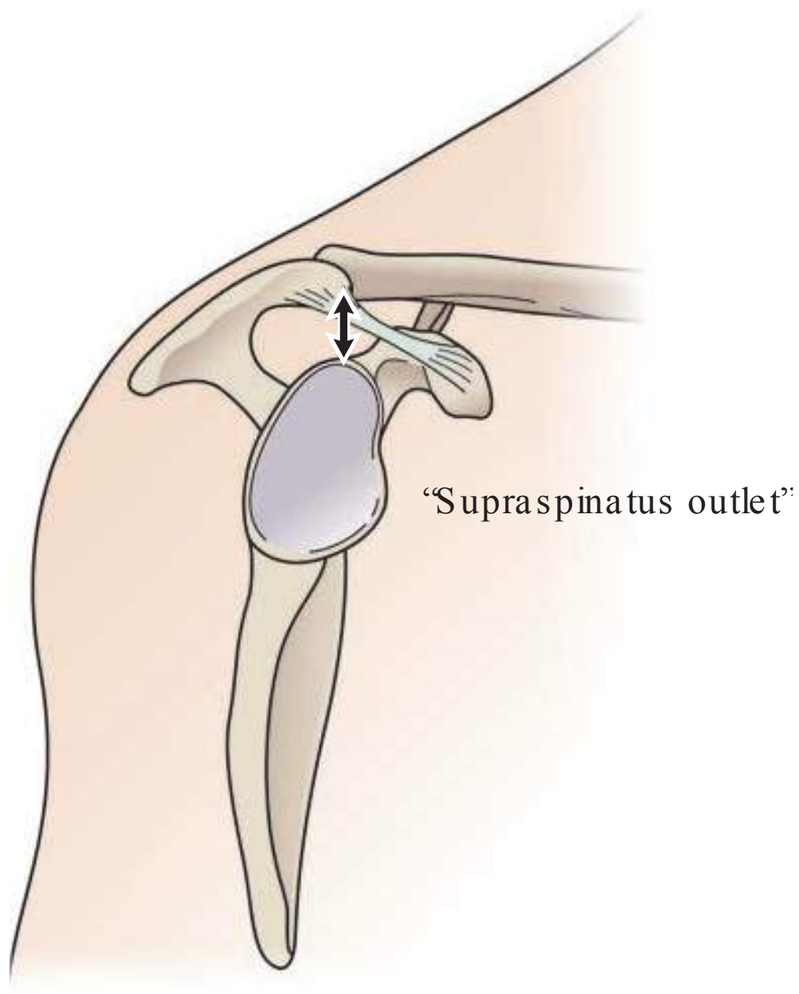

FIGURE 16-63 Supraspinatus outlet.

and the patient has internal impingement, whereas a negative test (more weakness in ER) would suggest classic outlet impingement. A study by Zaslav[323] reported 88% sensitivity and 96% specificity with this test (Table 16-26), but the study had a potential for bias. (Table 16-26).[323]

Infraspinatus Test. The patient sits with the elbow at 90 degrees of flexion, neutral forearm rotation, the elbow adducted against the body, and the shoulder at end-range ER. The clinician stands to the side of the patient and provides an IR force against the patient's isometric resistance. A study by Park et al.[324] reported that a positive test, which indicates subacromial impingement (all stages), occurs if the patient gives way due to either pain or weakness, or if there is a positive ER lag sign. However, even when combining the results of two tests, the study demonstrated only a small effect on posttest probability (Table 16-25).

Cross-body Adduction Test.[325] The patient sits and the clinician stands to the involved side of the patient. The patient is asked to elevate the arm to 90 degrees of shoulder flexion. The clinician then horizontally adducts the patient's arm to end range. A positive test for subacromial impingement or an A-C joint injury is indicated if shoulder pain is present (Table 16-26).

Painful Arc Test.[77] The patient stands and, while being observed by the clinician, is asked to actively abduct the involved shoulder. A positive test for subacromial impingement is indicated if the patient reports shoulder pain in the 60–120-degree range. Pain outside this range is considered a negative test, and pain that increases in severity as the arm reaches 180 degrees is indicative of "a disorder of the A-C joint." Hermann and Rose[326] found that the painful arc test was positive in 48.9% of 50 patients with degenerative impingement. Akgün et al.[327] observed 57.5% positive results with the test in stage II SIS patients. Although this test is good at detecting subacromial impingement, a positive finding is unlikely to aid the clinician in determining a specific diagnosis as there

TABLE 16-26 Diagnostic Test Properties for Subacromial Impingement

are a number of conditions that can be provoked with arm elevation (Table 16-26).

Transdeltoid Palpation (Rent Test).[328] The patient sits or stands with the involved arm relaxed and hanging on the side. The clinician stands behind the patient and holds the patient's distal arm with the patient's elbow flexed to 90 degrees (Fig. 16-64). The clinician then passively moves the patient's G-H joint into full extension, which allows greater palpation of the humeral head and tendons inserting into the greater tuberosity.[328] Palpation is performed at the anterior margin of the acromion. While palpating this area with the shoulder in the fully relaxed and extended position, the clinician moves the patient's arm into internal and external shoulder rotation to allow further palpation of the rotator cuff tendons (Fig. 16-65). In the presence of a complete rotator cuff tear, the eminence of the greater tuberosity appears quite prominent to palpation, and the torn area feels like a "sulcus," "rent," or soft-tissue defect (depression of approximately 1 finger-width) that has avulsed from the tuberosity.[328] Palpating the anterior and posterior margins of the cuff tear may elicit an avulsed edge.[328] It is recommended that this test be used to determine the absence or presence of a rotator cuff tear rather than the size of the tear (Table 16-25).

Yocum Test. The Yocum test is performed by having the patient lift the elbow to shoulder height while resting the hand on the opposite shoulder (Fig. 16-66). A study[292] comparing the Neer, Hawkins–Kennedy, and Yocum tests found all three to demonstrate a high sensitivity for diagnosing subacromial impingement.

Patte Test.[329,330] The Patte test, also known as the "hornblower's sign" (Fig. 16-31), is performed with the patient in the sitting or standing position. The patient's arm is supported at 90 degrees of abduction in the scapular plane, with the elbow flexed to 90 degrees. The patient is then asked to rotate the forearm externally against the resistance of the clinician's

FIGURE 16-64 Transdeltoid palpation (Rent test)—First position.

hand. If the patient is unable to externally rotate the shoulder in this position, the horn-blower's sign is said to be present.

T is test was found to have 100% sensitivity and 93% specificity in the diagnosis of irreparable degeneration of the teres minor muscle when compared with CT arthrography findings in a series of 54 shoulders scheduled for rotator cuff

FIGURE 16-65 Transdeltoid palpation (Rent test)—Second position.

FIGURE 16-66 Yocum test.

repair (Table 16-25).[331] T e loss of integrity of the teres minor was confirmed at the time of surgery.

One study[292] attempted to determine the diagnostic value of three impingement tests (Yocum, Neer, and Hawkins–Kennedy), and four tests were used to determine the location of the specific rotator cuff lesion (Jobe empty can [see Resistive Tests], Gerber lif -off [see resisted tests], Patte test, and Speed's test [see later]) by comparing the clinical findings from the tests with the operative findings in a series of 55 patients with chronic shoulder pain and functional impairment.[332] T e Neer test (89%), the Hawkins–Kennedy test (87%), and the Yocum test (78%), all demonstrated a high sensitivity for diagnosing subacromial impingement. Both the Jobe empty-can test (86%) and the Patte test (92%) demonstrated high sensitivity, but poor specificity (50% and 30%, respectively). Both the Gerber lif -off and the Speed's test demonstrated poor sensitivity (0% and 63%, respectively) and poor specificity (61% and 35%, respectively).[332]

Lock Test.[333,334] T e Lock test is used to help differentiate the cause of symptoms when the patient complains of localized catching shoulder pain, and pain or restricted movement, when attempting to place the hand behind the back. Since the clinician controls the motion, this test can be a very sensitive test to help confirm the presence of an impingement of the supraspinatus tendon. It is assumed that the techniques are performed on the patient's right side.

T e patient lies in the supine position with the right shoulder at the edge of the table, and the elbow positioned 10 degrees posterior to the frontal plane (Fig. 16-67). T e clinician uses his or her right hand to monitor the scapula. T e clinician's lef hand is placed on the patient's forearm.

Af er assessing the resting symptoms, the clinician slowly glides the patient's elbow anteriorly, noting the location of onset of resistance and/or pain in the available range. T e end position for the test is achieved when the patient's right shoulder is in maximal humeral flexion with overpressure, and neither the patient nor the clinician can externally rotate the arm further while at this end range.

In the locking position, the greater tuberosity and its rotator cuff attachments are caught within the subacromial space. Further motion into ER, flexion, or abduction is not possible, unless the arm is allowed to move into less flexion. Positive findings for this test include reproduction of the patient's

FIGURE 16-67 Lock test.

symptoms and a decrease in ROM compared with the uninvolved shoulder.

Dropping Sign.[335] The "dropping sign" is performed with the patient sitting or standing. The clinician places the patient's elbow and shoulder at 90 degrees of flexion. The shoulder is then externally rotated to near end range and the patient is then asked to maintain this position as the wrist is released. A positive test for an infraspinatus tear is indicated by a lag that occurs with an inability to maintain the position, and the arm drops to a neutral position of shoulder rotation. This is called the dropping sign. This test was found to have a 100% sensitivity and a 100% specificity for irreparable degeneration of the infraspinatus muscle (confirmed at the time of surgery), although the test was performed with the arm at the patient's side, which is not the original description (Table 16-25).[331]

Rotator Cuff Rupture Tests

Drop-arm (Codman's) Test. The clinician passively raises the patient's arm to 90 degrees of abduction. The patient is asked to lower their arm with their palm down (Fig. 16-68). If at any point in the descent, the patient's arm drops, it is indicative of a rotator cuff injury (Table 16-27).

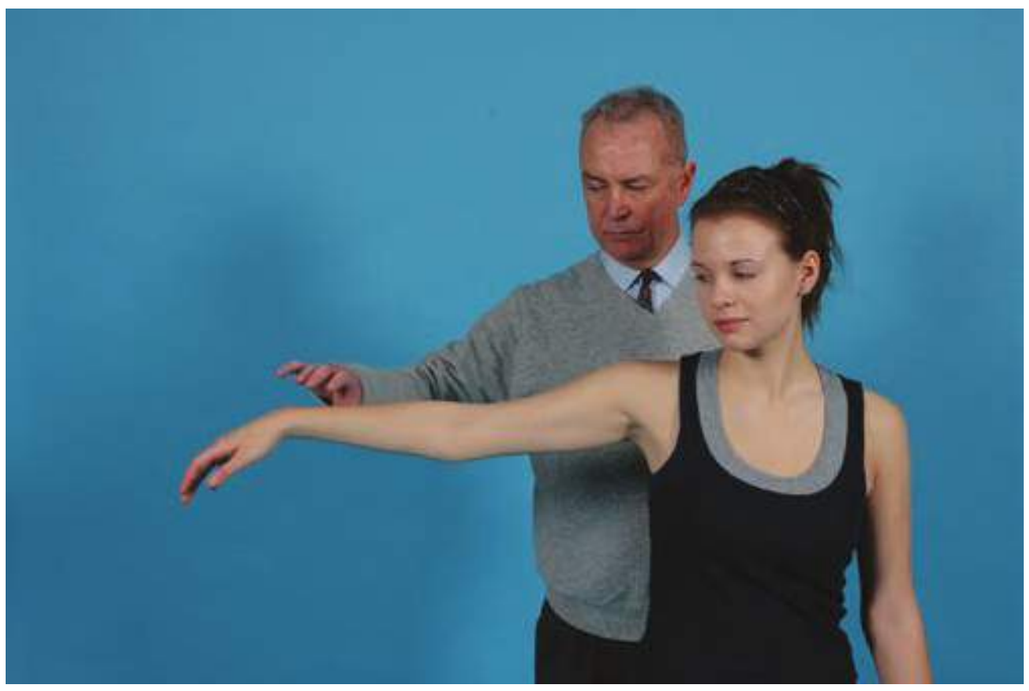

FIGURE 16-68 Drop arm (Codman) test.

Supraspinatus Tests

Two techniques described in the literature can be used to test the supraspinatus muscle. In a 1982 report, Jobe and Moynes[336] suggested that the best position for isolating the supraspinatus was the empty-can position—the elbow extended, the shoulder in full IR, and the arm in the scapular plane (thumbs-down position) (Fig. 16-29) (Table 16-25). In a 1990 article, Blackburn et al[118] recommended testing in the prone position, in the full-can position—the elbow extended and the shoulder abducted to 100 degrees and externally rotated while the patient lifts the arm into abduction (thumbs-up position) (Fig. 16-30) (Table 16-25). Malanga et al.[337] noted that although both techniques significantly activate the supraspinatus muscle, neither truly isolates this muscle for testing because other muscles are active in both positions. However, dropping of the arm in either position usually indicates a significant supraspinatus muscle tear. More subtle weakness may represent early degeneration of the rotator cuff.

Biceps and Superior Labral Tears

The biceps tendon and superior labrum can be involved in various pathological processes including bicipital tendinopathy, biceps rupture, biceps tendon subluxation or dislocation, and tears of the superior labrum (Table 16-28).[195]

Clunk Test. The Clunk test is the traditional test for diagnosing labral tears. The patient lies in the supine position. One

hand of the clinician is placed on the posterior aspect of the shoulder over the humeral head while the other hand grasps the humerus above the elbow (Fig. 16-69). The clinician fully abducts the arm over the patient's head. By placing the hand posterior to the humeral head, the clinician pushes anteriorly while the other hand externally rotates the humerus. A clunk-like sensation may be felt if a free labral fragment is caught in the joint.[195] Clinical studies have found that a click on manipulation of the G-H joint was a common finding in patients with labral tears, even in the absence of joint instability.[338,339]

The sensitivity of this test was found to be low (15%) in one study[340] when it was used to detect labral tears in a series of 96 arthroscopic surgery patients.

Crank Test. The crank test[341] is performed with the patient in the supine position. Their arm is elevated to 160 degrees in the scapular plane of the body and is positioned in maximal internal or ER. The clinician then applies an axial load along the humerus (Fig. 16-70). A positive test is indicated by the reproduction of a painful click in the shoulder during the maneuver. This test was found to have a high sensitivity (91%) and specificity (93%) for diagnosing labral tears in a series of 62 patients who presented with shoulder pain that was refractory to 3 months of conservative management.[341]

The crank test has been found to have a higher sensitivity (90%) than MRI (59%) and equal specificity (85%) to MRI in diagnosing labral tears (Table 16-28).[339]

Jerk Test. This test is used to detect a posteroinferior labral lesion.[342] The patient sits, with the clinician standing to the side and slightly behind the patient. The clinician grasps the patient's elbow with one hand and the scapula with the

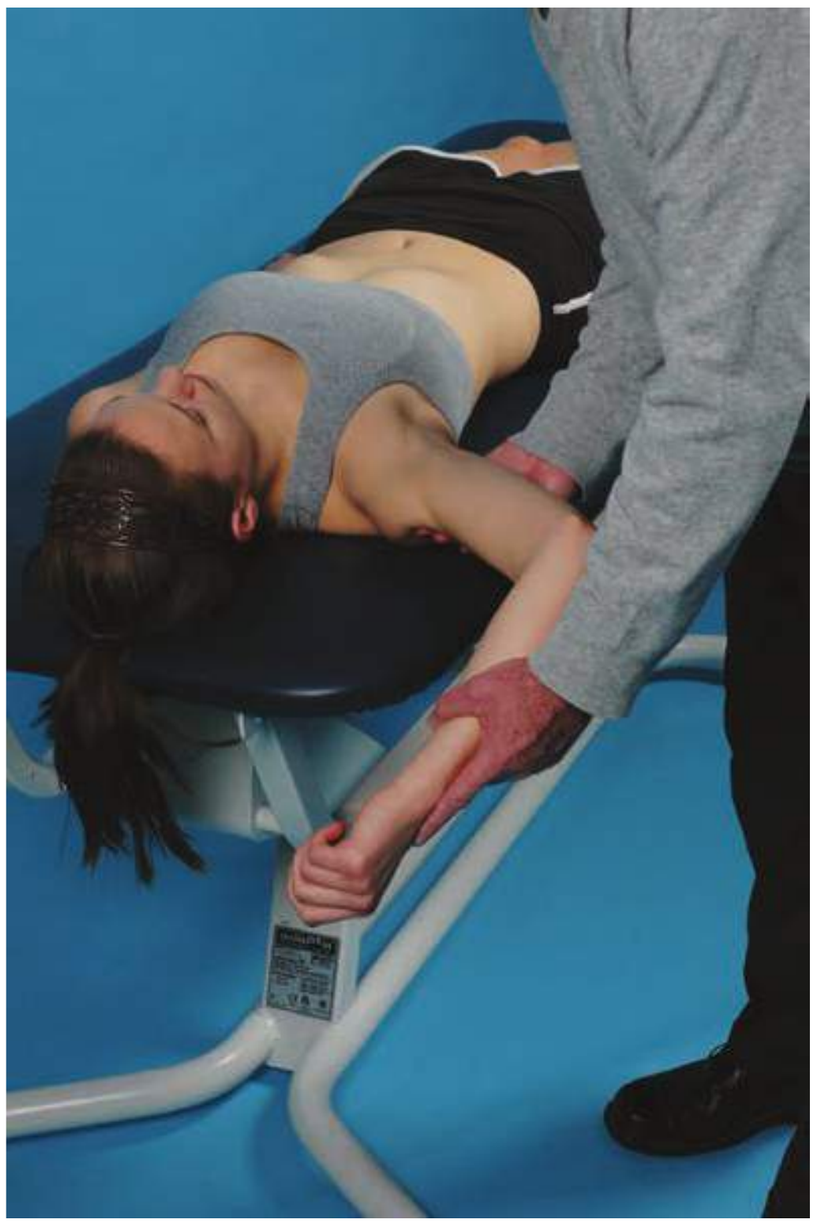

FIGURE 16-69 Clunk test.

other, and then positions the patient's arm at 85–90 degrees of abduction and IR (Fig. 16-71). The clinician then provides an axial compression-based load to the humerus through the elbow while maintaining the horizontally abducted arm. The axial compression is maintained as the patient's arm is moved into horizontal adduction. A positive test is indicated by sharp shoulder pain with or without a clunk or click (Table 16-28).

FIGURE 16-70 Crank Test.

FIGURE 16-71 Jerk test.

Kim Test. This test is used to detect a posteroinferior labral lesion. The patient sits, with the clinician standing on the involved side. The clinician grasps the elbow with one hand and the midhumeral region with the other hand, then elevates the patient's arm to 85–90 degrees of abduction (Fig. 16-72). Simultaneously, the clinician provides an axial load to the humerus and a 45-degree diagonal elevation to the distal humerus concurrent with a posteroinferior glide to the proximal humerus (Fig. 16-73). A positive test is indicated by a sudden onset of posterior shoulder pain. A study by Kim et al.[342] found this test to have a sensitivity of 80% and a specificity of 94%, but more strict methodology needs to be followed to corroborate these statistics (Table 16-28).

Speed's Test. The patient's arm is positioned in shoulder flexion, full ER, full elbow extension, and full forearm supination (Fig. 16-74). Manual resistance is applied by the clinician. The test is positive if localized pain at the bicipital groove is reproduced. Wilk et al.[10] have introduced a dynamic version of the Speed's test. During this maneuver, the examiner provides resistance against both shoulder elevation and elbow flexion simultaneously as the patient elevates the arm overhead.

A positive Speed's test suggests a superior labral tear when resisted forward flexion of the shoulder causes bicipital groove pain or deep pain within the shoulder.[1,343] Speed's test is also used to detect bicipital tendinopathy (Table 16-28) (see "Yergason's Test").[326,344]

FIGURE 16-72 Kim test—First position.

FIGURE 16-73 Kim test—Second position.

FIGURE 16-75 Yergason's test.

Yergason's Test.[345] The patient sits or stands, and the upper arm is positioned with the elbow at 90 degrees of flexion and the forearm pronated. The patient is asked to supinate his or her forearm against the manual resistance of the clinician (Fig. 16-75).

Speed's and Yergason's tests probably discriminate bicipital tendon disorders.[300] However, irritation and edema may also occur in the long head of biceps in any stage of SIS. Biceps tendons may be thickened by fibrinoid degeneration in the SIS.[327,346] This may lead to an inappropriate diagnosis of primary bicipital tendinopathy and subsequent tenodesis.[315] In a number of studies, the sensitivity of the Speed's test in biceps tendon disorders was found to be higher than that of the Yergason's test.[315,344,347]

O'Brien (Active Compression) Test. The O'Brien test (see also "Acromioclavicular Tests" section) is a two-part test. The patient stands with his or her involved shoulder at 90 degrees of flexion, 10 degrees of horizontal adduction, and maximum IR with the elbow in extension. In this position, the patient then resists a downward force applied by the clinician to the distal arm (Fig. 16-76). The patient is asked to report any pain as either "on top of the shoulder" (A-C joint) or "inside the shoulder" (superior labrum anterior and posterior [SLAP] lesion). The test is then repeated in the same manner except that the arm is positioned in maximum ER. The test is positive for a glenoid labral tear if the patient reports pain for clicking or pain "inside the shoulder" with resisted forward flexion in IR of the shoulder that is relieved by ER of the shoulder (Table 16-28).[1] O'Brien et al.[348] reported a sensitivity of 100% and a specificity of 98.5% for detecting a labral abnormality for this test although the test demonstrated poor study design. For example, the authors provided no data on the amount of force used for the test.

Anterior Slide Test. The "anterior slide test"[349] is another clinical test designed to stress the superior labrum.[195] The patient stands or sits with one hand on the hip such that the thumb is positioned posteriorly. One of the clinicians' hands is placed over the patient's shoulder and the other hand behind the elbow (Fig. 16-77). A force is then applied anteriorly and superiorly at the patient's elbow, and the patient is asked to push back against the force. The test is considered positive if pain is localized to the anterosuperior aspect of the shoulder, if there is a pop or a click in the anterosuperior region, or if the maneuver reproduces the symptoms.[195]

The anterior slide test has demonstrated good sensitivity (78%) and high specificity (92%) when used to detect glenoid labrum tears.[349] However, other tests[350–352] found the test to have very low sensitivity, indicating that there is little use for this test in the clinic to detect SLAP lesions.

Compression–Rotation Test. This test is performed with the patient in the supine position and the clinician standing on the involved side of the patient. The clinician passively

FIGURE 16-74 Speed's test.

FIGURE 16-76 O'Brien (active compression) test.

FIGURE 16-77 Anterior slide test.

positions the patient's shoulder at 90 degrees of abduction and the elbow at 90 degrees of flexion. The clinician first applies a compression force to the humerus and rotates the humerus back and forth from IR to ER in an attempt to trap the labrum within the joint (Fig. 16-78). When performing this maneuver, it is recommended that a variety of small and large circles are used, while providing joint compression, in an attempt to grind the labrum between the glenoid and the humeral head. A positive test is indicated by the production of a catching or snapping in the shoulder and McFarland et al.[350] found the test to have a sensitivity of 24% and specificity of 76%. However, another study by Snyder et al.[353] concluded that SLAP lesions can only be diagnosed arthroscopically.

Biceps Load Test. The biceps load test was originally described by Kim et al.[354] During this test, the shoulder is placed at 90 degrees of abduction and maximally externally

FIGURE 16-78 Compression–rotation Test.

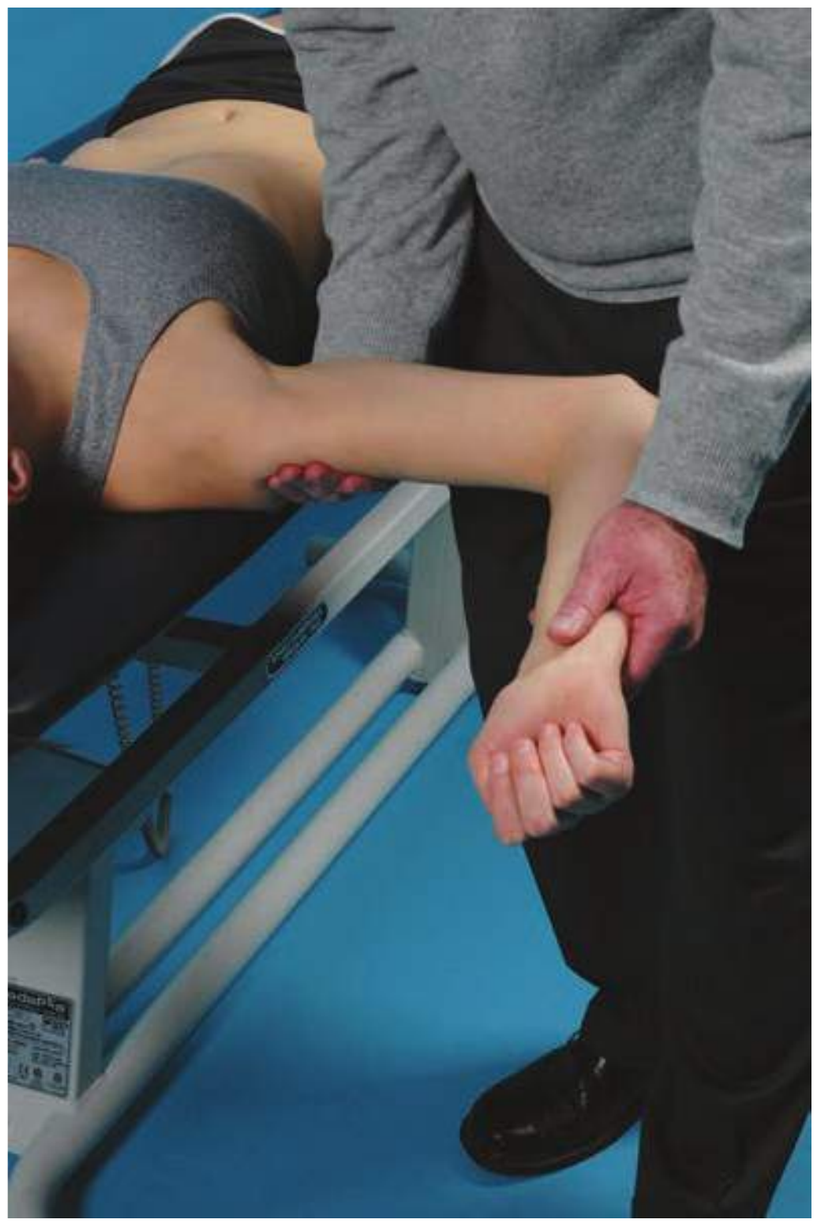

FIGURE 16-79 Biceps load test.

rotated (Fig. 16-79). At maximal ER and with the forearm in a supinated position, the patient is instructed to perform a biceps contraction against resistance.[10] Deep pain within the shoulder during his contraction may indicate a SLAP lesion. Due to many design faults in the original study, this test has since been refined (biceps load II) with the shoulder being placed in the position of 120 degrees of abduction rather than the originally described 90 degrees, as this position was found to add greater sensitivity to the test (Table 16-28).[355]

Pronated Load Test. The pronated load test[10] is performed with the patient in a supine or seated position with the shoulder abducted to 90 degrees and externally rotated, and the forearm in a fully pronated position (to increase tension on the biceps and subsequently the labral attachment).[10] When maximal ER is achieved, the patient is instructed to perform a resisted isometric contraction of the bicep against the clinician's resistance (Fig. 16-80). This test combines the active bicipital contraction of the biceps load test with the passive ER in the pronated position similar to the pain provocation test (see next).

Pain Provocation Test.[356] The patient is seated and the clinician stands behind the involved shoulder. The clinician places the patient's shoulder at 90 degrees of abduction and toward end-range ER, the elbow at 90 degrees of flexion and the forearm in maximum supination (Fig. 16-81). The patient is asked to rate his or her pain in this position. The clinician then fully pronates the patient's forearm and asks the patient to again rate his or her pain. A positive test for a SLAP lesion is indicated if pain is produced with shoulder ER with the forearm in the pronated position or if the severity of the symptoms is greater in the pronated position. A study by Mimori et al.[356] found this test to have high sensitivity (100%) and high specificity (90%), although the study had many design faults.

FIGURE 16-80 Pronated load test.

Resisted Supination External Rotation Test.[357] During this test, the patient lies in the supine position with the clinician standing on the side of the involved shoulder. Supporting the patient's elbow with one hand, the clinician places the patient's shoulder at 90 degrees of shoulder abduction, 80–90 degrees of elbow flexion, and the forearm in neutral pronation/supination (Fig. 16-82). The patient is asked to attempt to supinate his or her arm. The clinician resists against a maximal supination effort while gradually passively externally rotating the shoulder. A positive test for a torn labrum/instability is indicated by the production of pain in the anterior or deep shoulder, clicking or catching in the shoulder, or by reproduction of the patient's symptoms. A preliminary study of 40 patients revealed that this test had better sensitivity (82.8%), specificity (81.8%), positive predictive value (92.3%), negative predictive value (64.3%), and diagnostic accuracy (82.5%), compared with the crank test and O'Brien test.[357]

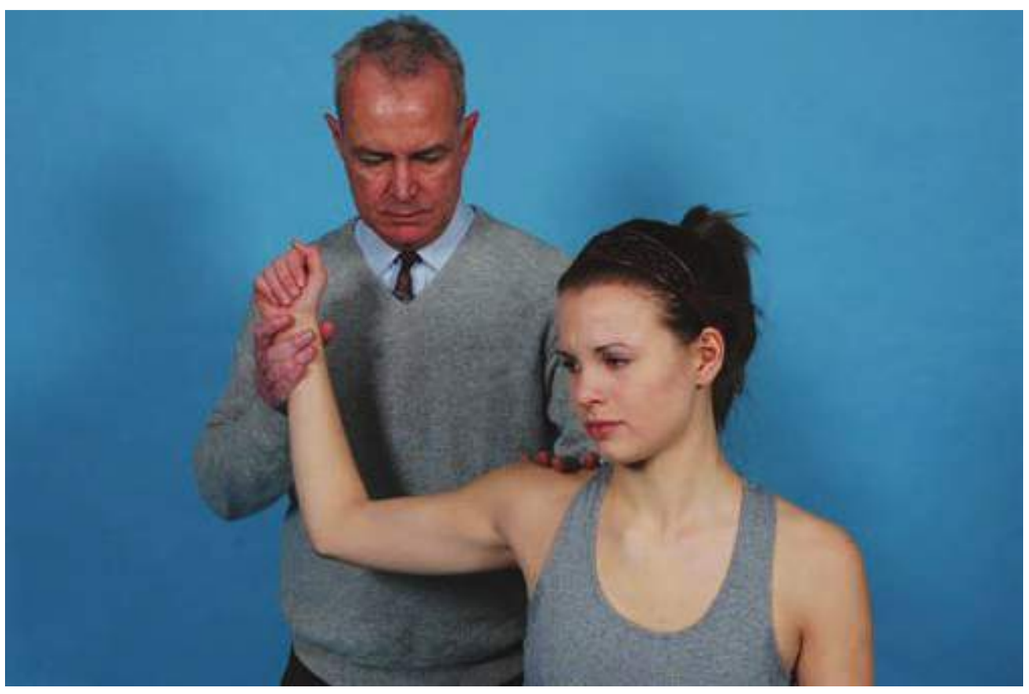

FIGURE 16-81 Pain provocation test.

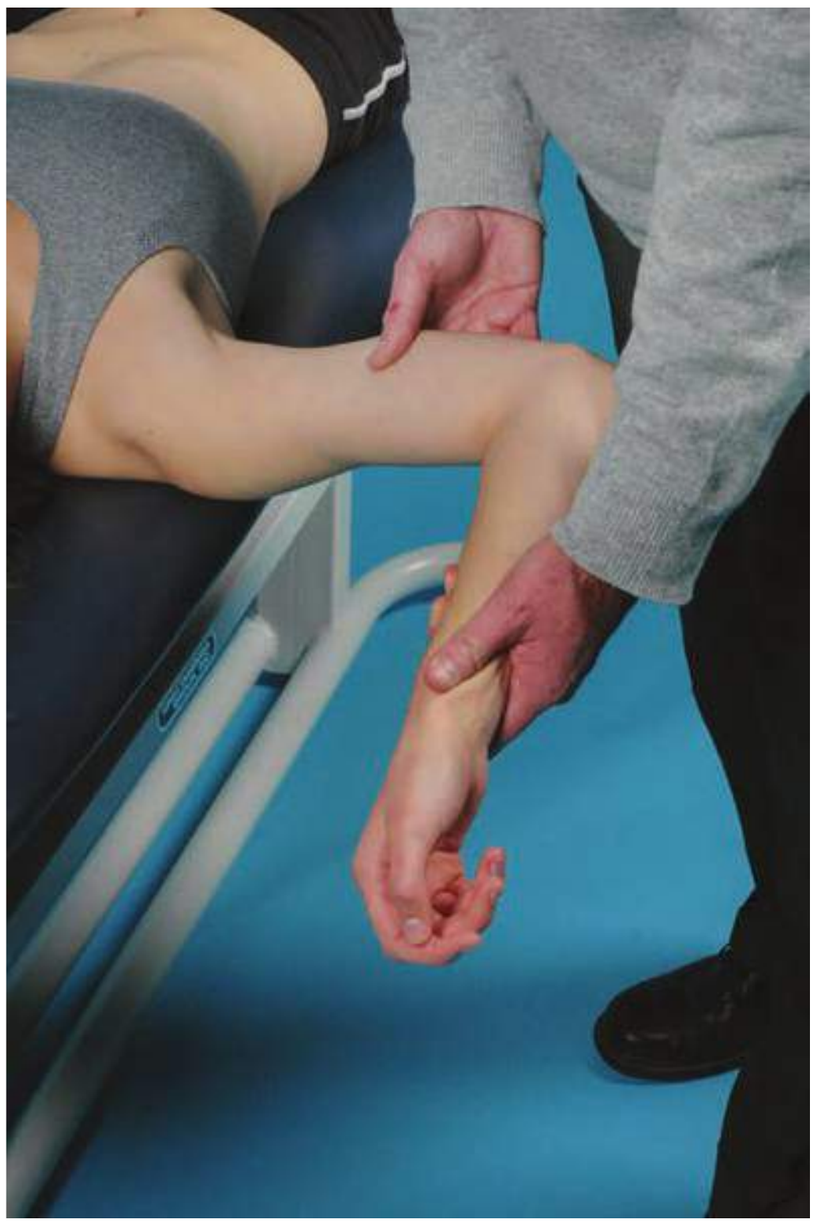

FIGURE 16-82 Resisted supination external rotation test.

Forced Shoulder Abduction and Elbow Flexion Test. The patient sits, with the clinician standing behind and to the side of the involved shoulder. The clinician positions the patient's shoulder in maximum abduction with full elbow extension and notes any reports of pain in the posterior superior aspect of the shoulder (Fig. 16-83). The clinician then flexes

Data from Wilk KE, Reinold MM, Dugas JR, et al. Current concepts in the recognition and treatment of superior labral (SLAP) lesions. J Orthop Sports Phys Ther. 2005;35:273–291.

the patient's elbow. A positive test for a superior labral tear is indicated by the production of pain in the posterior superior aspect of the shoulder during shoulder abduction with elbow extension that is diminished or relieved by the elbow flexion. In a study by Nakagawa et al.,[352] this test was found to have a sensitivity of 67% and a specificity of 67%. However, there were some design flaws with this study. For example, all of the subjects were young throwing athletes, and only two of the 54 subjects were female, leading to spectrum bias.

Wilk et al.[10] recommend that the selection of specific SLAP tests to perform should be based on the symptomatic complaints as well as the mechanism of injury described by the patient (Table 16-29).

Acromioclavicular Tests

O'Brien Test. This is the same test described in the section "Biceps and Superior Labral Tears." The test has been found to be both highly sensitive and specific for diagnosing A-C joint abnormalities.[348] The test is considered positive for A-C joint dysfunction if the pain is localized to the A-C joint on the first position and relieved or eliminated on the second position.[348,358]

Acromioclavicular Resisted Extension Test. This test is performed with the patient's shoulder positioned at 90 degrees of elevation combined with IR and 90 degrees of elbow flexion. The patient is then asked to horizontally abduct the arm against resistance (Fig. 16-84). This test is considered positive if it causes pain at the A-C joint. Chronopoulos et al.[359] reported sensitivity of 72% and specificity of 85% with this test, but this study had some design flaws such as lack of blinding and not reporting patient inclusion/exclusion criteria.

Crossover Impingement/Horizontal Adduction Test. The patient's arm is positioned at 90 degrees of G-H flexion. The clinician passively moves the patient's arm into horizontal adduction and applies overpressure (Fig. 16-85). Although the crossover impingement/horizontal adduction test provokes compressive forces on the rotator cuff tendons that are localized under

FIGURE 16-84 Acromioclavicular resisted extension test.

the A-C joint, it is a test more likely to be used to investigate A-C joint dysfunction.[327,346] Chronopoulos et al.[359] evaluated the crossover impingement test, the active compression test, and the A-C resisted extension test for the isolated and combined diagnostic utility with regard to chronic isolated A-C joint lesions. The study was a retrospective case-control study that used 35 patients diagnosed with chronic isolated A-C joint lesions and 580 control subjects who had undergone surgical procedures for other shoulder conditions. The authors concluded that the three tests studied had isolated clinical utility. They also analyzed the diagnostic utility of multitest regimens based on these three tests (Table 16-30) and suggested that the clinician should use a criterion of one positive test when high sensitivity is required, whereas a criterion of three positive tests is appropriate when high specificity is necessary.[358,359]

Examination of the Passive Restraint System

If following the ROM, strength, and functional movement tests, the clinician is unable to determine a working hypothesis from which to treat the patient, further examination is required. This is more detailed examination involves the assessment of the mobility and stability of the passive restraint systems of the shoulder girdle (Table 16-31).

Stability Testing. It is important to remember that there is no correlation between the amount of joint laxity/mobility and joint instability at the shoulder.[360] Joint stability is more

likely a function of connective tissue support and an intact neuromuscular system.[242]

Many provocative maneuvers for the shoulder complex, including the anterior and posterior apprehension tests, the sulcus test,[361–363] and the load and shif test, have been described previously. T e reproduction of symptoms is important because laxity alone does not indicate instability. Side-to-side translational asymmetry of en has been taken as being representative of disease, but healthy shoulders may also have asymmetry up to grade II laxity.[364,365]

Pain and muscle spasm can make the examination challenging. Rarely is examination with the patient under anesthesia useful for anything other than fine-tuning the amount of capsular shif required at surgery.[366]

Glenohumeral: Load and Shift Test. T e patient lies in the supine position. T e clinician is beside the patient with the inside of the hand over the patient's shoulder and forearm, stabilizing the scapula to the thorax. T e clinician places his or her hand across the G-H joint line and humeral head so that clinician's little finger is positioned across the anterior G-H joint line and humeral head (Fig. 16-86). T e clinician then applies a "load and shif " of the humeral head across the stabilized scapula in an anteromedial direction to assess anterior stability, and in a posterolateral direction, to assess posterior instability. T e normal motion anteriorly is half of the distance of the humeral head. Although attempts have been made to grade or quantify the degree of instability more specifically, the literature supports no consistency in the grading to date.[151,367–370] T is test has been reported to be 100% sensitive for the detection of instability in patients with recurrent dislocation, but not in cases of recurrent subluxation.[368]

Apprehension Test. T e patient lies in the supine position with the arm at 90 degrees of abduction and full ER. T e clinician holds the patient's wrist with one hand while the other hand stabilizes the patient's elbow (Fig. 16-87). T e clinician applies overpressure into ER. Patient's apprehension from this maneuver, rather than his/her pain, is considered a positive test for anterior instability. Pain with this maneuver, but without apprehension, may indicate pathology other than instability, such as posterior impingement of the rotator cuff.[76] In a study by Mok et al.,[371] this test demonstrated a specificity of 61% and a sensitivity of 63%.

Sulcus Sign for Inferior Instability. T e sulcus sign was described by Neer and Foster[362] and is used to detect inferior instability due to a laxity of the superior G-H and coracohumeral ligaments. T e patient's arm is positioned at 20–50 degrees of abduction and neutral rotation.[150,372] A positive test results in the presence of a sulcus sign (a depression greater than a fingerbreadth between the lateral acromion and the head of the humerus) (Fig. 16-88) when longitudinal traction is applied to the dependent arm in more than one position.[373]

T e sulcus sign can be graded by measuring the distance from the inferior margin of the acromion to the humeral head. A distance of less than 1 cm is graded as 1+ sulcus, 1–2 cm as a 2+ sulcus, and greater than 2 cm as a grade 3+ sulcus.[362] A study by Levy et al.[374] evaluated the inter- and intraobserver reproducibility of the clinical examination of G-H laxity in the unanesthetized shoulder. Forty-three asymptomatic division I collegiate athletes underwent bilateral shoulder laxity examination initially and again af er 3 months. Overall intraobserver reproducibility of examination was 46%. When grades 0 and 1 were equalized, overall intraobserver reproducibility improved to 74%. For both the equalized and nonequalized reproducibility values reported by all examiners, the k values for intraobserver correlation were less than 0.5, which suggests that correlations were not better than those achieved by chance alone. Overall interobserver reproducibility was 47%. When grades 0 and 1 were equalized, interobserver reproducibility improved to 78%.

Jobe Subluxation/Relocation Test. T is test is similar to the load and shif test, except that manual pressure is applied anteriorly by the clinician in an attempt to provoke a subluxation, before using manual pressure in the opposite direction to relocate the subluxation. T e patient lies in the supine position with their arm at 90 degrees of abduction and full ER. T e clinician grasps the patient's elbow with one hand to maintain the testing position and grasps the humeral head with the other hand (Fig. 16-89). T e clinician gently applies an anterior pull on the humerus. Pain and apprehension from the patient indicate a positive test for a superior labral tear or anterior instability.[1] Af er pulling the humeral head anteriorly and

TABLE 16-31 Diagnostic Test Properties for Shoulder Laxity[a]

Diagnostic Test or Maneuver	Study Population	Sensitivity	Specificity	Positive Likelihood Ratio	Negative Likelihood Ratio

demonstrating pain and apprehension, the clinician should then push the humeral head posteriorly while maintaining the shoulder in the same position (the relocation part of the test). Reduction of pain and apprehension further substantiates the clinical finding of anterior instability. The sensitivity and specificity of the relocation test is reported to be low when assessing pain response only, but very high when assessing the apprehension response only.[375]

The performance of the relocation part of the test (based on operative findings and manual examination under anesthesia) was compared between two groups of patients: those with anterior instability and with rotator cuff disease.[375] The study found that it is not possible to discriminate between anterior instability and rotator cuff disease by using the relocation test for assessing pain response only.

Modified Jobe Relocation Test. The patient lies in the supine position, and the clinician stands on the involved side of the patient. The clinician prepositions the shoulder at 120 degrees of abduction and then grasps the patient's forearm and maximally externally rotates the humerus. The clinician then applies a posterior to anterior force to the posterior aspect of the humeral head. If the patient reports pain with this maneuver, an anterior-to-posterior force is then applied to the proximal humerus. A positive test for labral pathology is indicated by a report of pain with the anterior-directed

FIGURE 16-86 Load and shift test.

force and release of pain with the posterior directed force. In a small study of 14 overhead throwing athletes, aged 21–31 years, Hamner et al.[376] found the test to have high sensitivity (92%) and high specificity (100%). However, there were a number of design faults in the study that led to potential bias, and further research is required.

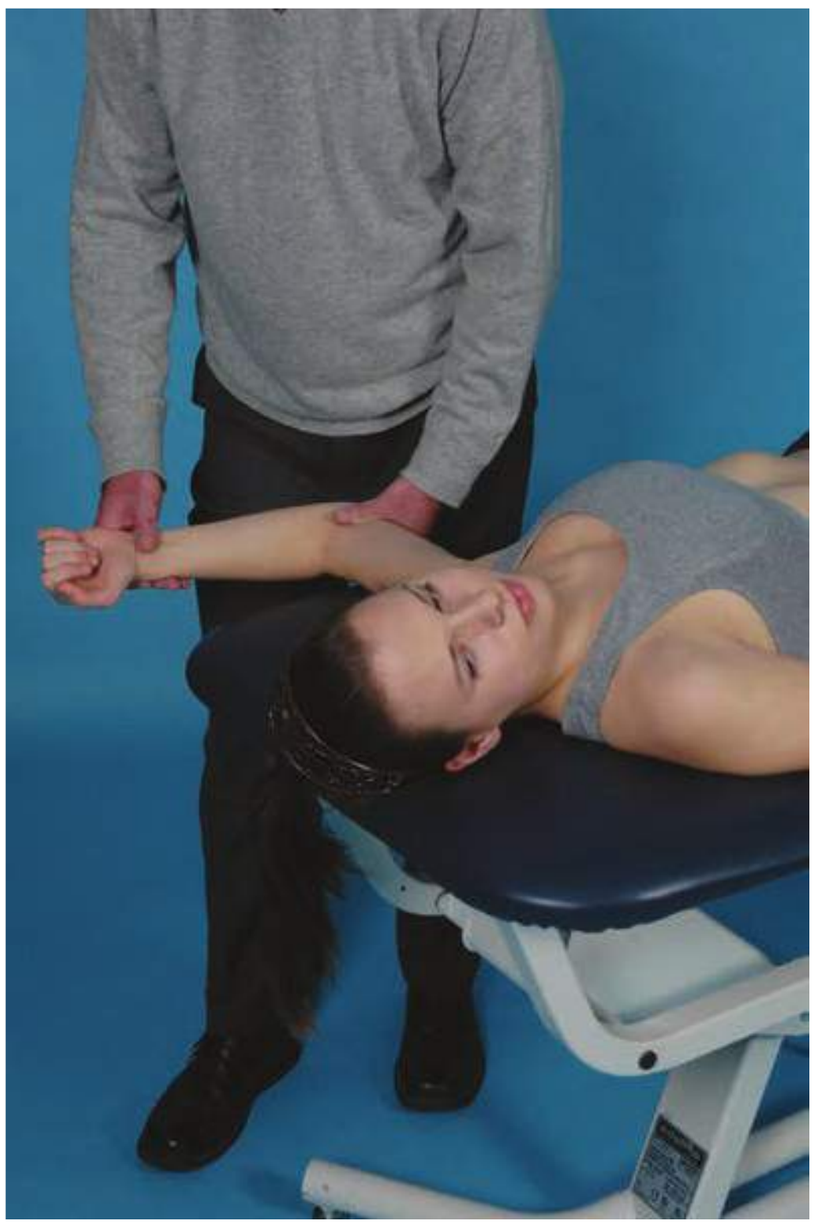

FIGURE 16-87 Apprehension test.

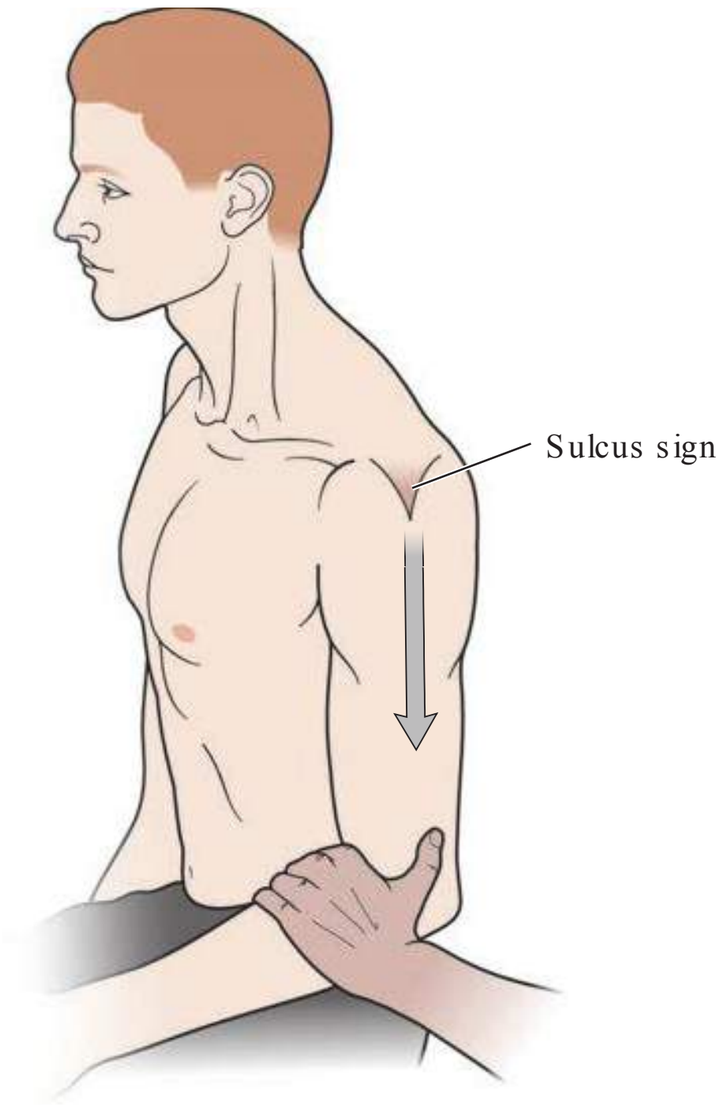

FIGURE 16-88 Sulcus sign.

Rockwood Test for Anterior Instability. The patient is seated with the clinician standing.[377] With the arm by the patient's side, the clinician passively externally rotates the shoulder. The patient then abducts the arm to approximately 45 degrees, and the test is repeated. The same maneuver is again repeated with the arm abducted to 90 degrees, and then 120 degrees (Fig. 16-90) to assess the different stabilizing structures. A positive test is indicated when apprehension is noted in the latter three positions (45, 90, and 120 degrees).

Anterior Release Test/Surprise Test. The patient lies in the supine position with the shoulder at 90 degrees of abduction and the elbow flexed to 90 degrees.[378] The clinician passively moves the patient's shoulder into ER while applying a posteriorly directed force to the head of the humerus. At

FIGURE 16-89 Subluxation/relocation test.

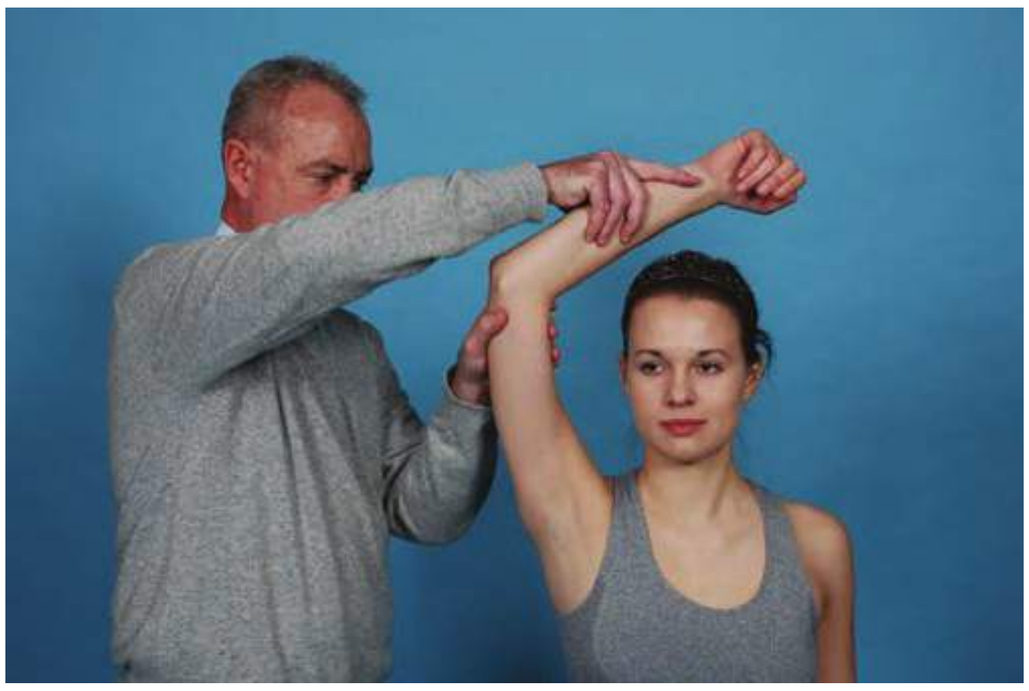

FIGURE 16-90 Rockwood test for anterior instability.

the point of end-range ER, the clinician quickly releases the posterior force (Fig. 16-91) and notes whether the patient displays any sign of apprehension. In a study by Lo et al.,[379] which assessed the validity of the apprehension, relocation, and surprise tests as predictors of anterior shoulder instability, for those subjects who had a feeling of apprehension on all three tests, the mean positive and negative predictive values were 93.6% and 71.9%, respectively. The surprise test was the single most accurate test (sensitivity 63.89%; specificity 98.91%). An improvement in the feeling of apprehension or pain with the relocation test added little to the value of the tests. The results of this study would suggest that a positive instability examination on all three tests is highly specific and predictive of traumatic anterior G-H instability.[379]

Anterior Fulcrum Test. The patient lies in the supine position with the shoulder positioned at approximately 90 degrees of abduction and ER.[380] The clinician moves the arm into horizontal abduction while applying an anterior force to the G-H joint in a fulcrum maneuver (Fig. 16-92). The clinician notes the amount of translation and end feel in comparison with the opposite extremity. The test can be repeated at 45 degrees of abduction (to test the middle G-H ligament) and in adduction (to assess the superior G-H ligament).

FIGURE 16-92 Anterior fulcrum test.

Lachman Test of the Shoulder. The patient lies in the supine position and the shoulder is abducted overhead to approximately 120–135 degrees of abduction and full ER (Fig. 16-93).[381] The clinician then translates the G-H joint anteriorly and notes the amount of humeral translation as well as the endpoint of translation, in comparison with the uninvolved shoulder. Theoretically in this position, the

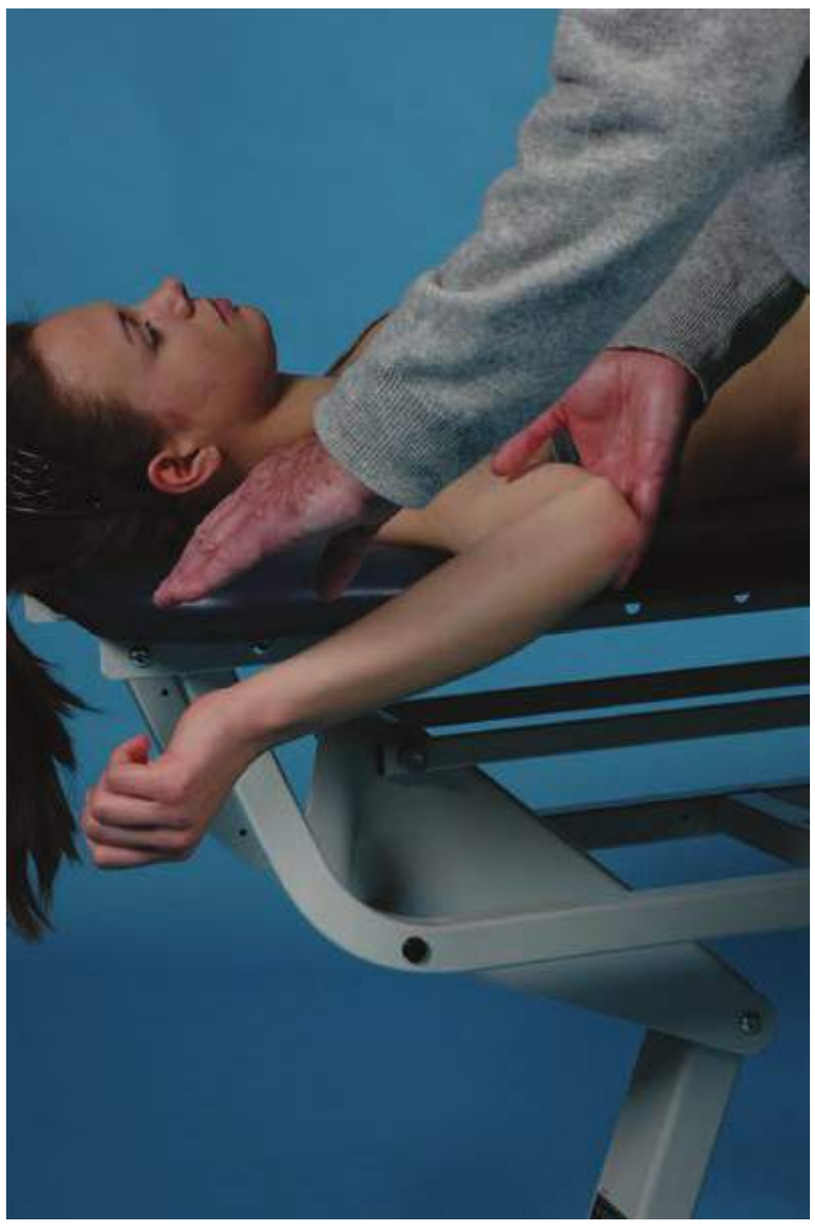

FIGURE 16-91 Anterior release test.

FIGURE 16-93 Lachman test of the shoulder.

integrity of the inferior G-H ligament and the anterior–inferior capsule is tested.

Thoracic Outlet syndrome Tests

T ese tests are described in "Special Tests" section in Chapter 25.

Diagnostic studies

T e conclusions on the radiology reports concerning single-plane views, which include an A-P view with the humerus in IR, and a second A-P view with the humerus in ER (see Chapter 7), should be treated with caution as they have been well documented to result in misdiagnosis.[382]

If A-C separation is suspected, a weighted view is performed with a weight suspended from the wrist on the involved side. Alternative or specialized views are sometimes used in an attempt to better define specific structures. For example, with a suspected shoulder dislocation, the West Point or Lawrence view (inferior–superior axial projection) is used to help display the inferior glenoid fossa and its relationship to the humeral head, in addition to the lateral perspective of the proximal humerus.

Arthrography aids in the diagnosis of full-thickness rotator cuff tears.[383] Bone scans are rarely used in the diagnosis of shoulder pain, but a CT scan report can be useful in confirming the clinical findings in some cases.[1] T e MRI is very reliable in detecting lesions of the capsule and labrum, as well as associated rotator cuff tears. It can generally indicate the approximate size of a rotator cuff tear and may also indicate whether the critically important subscapularis tendon is torn.[1,384,385]

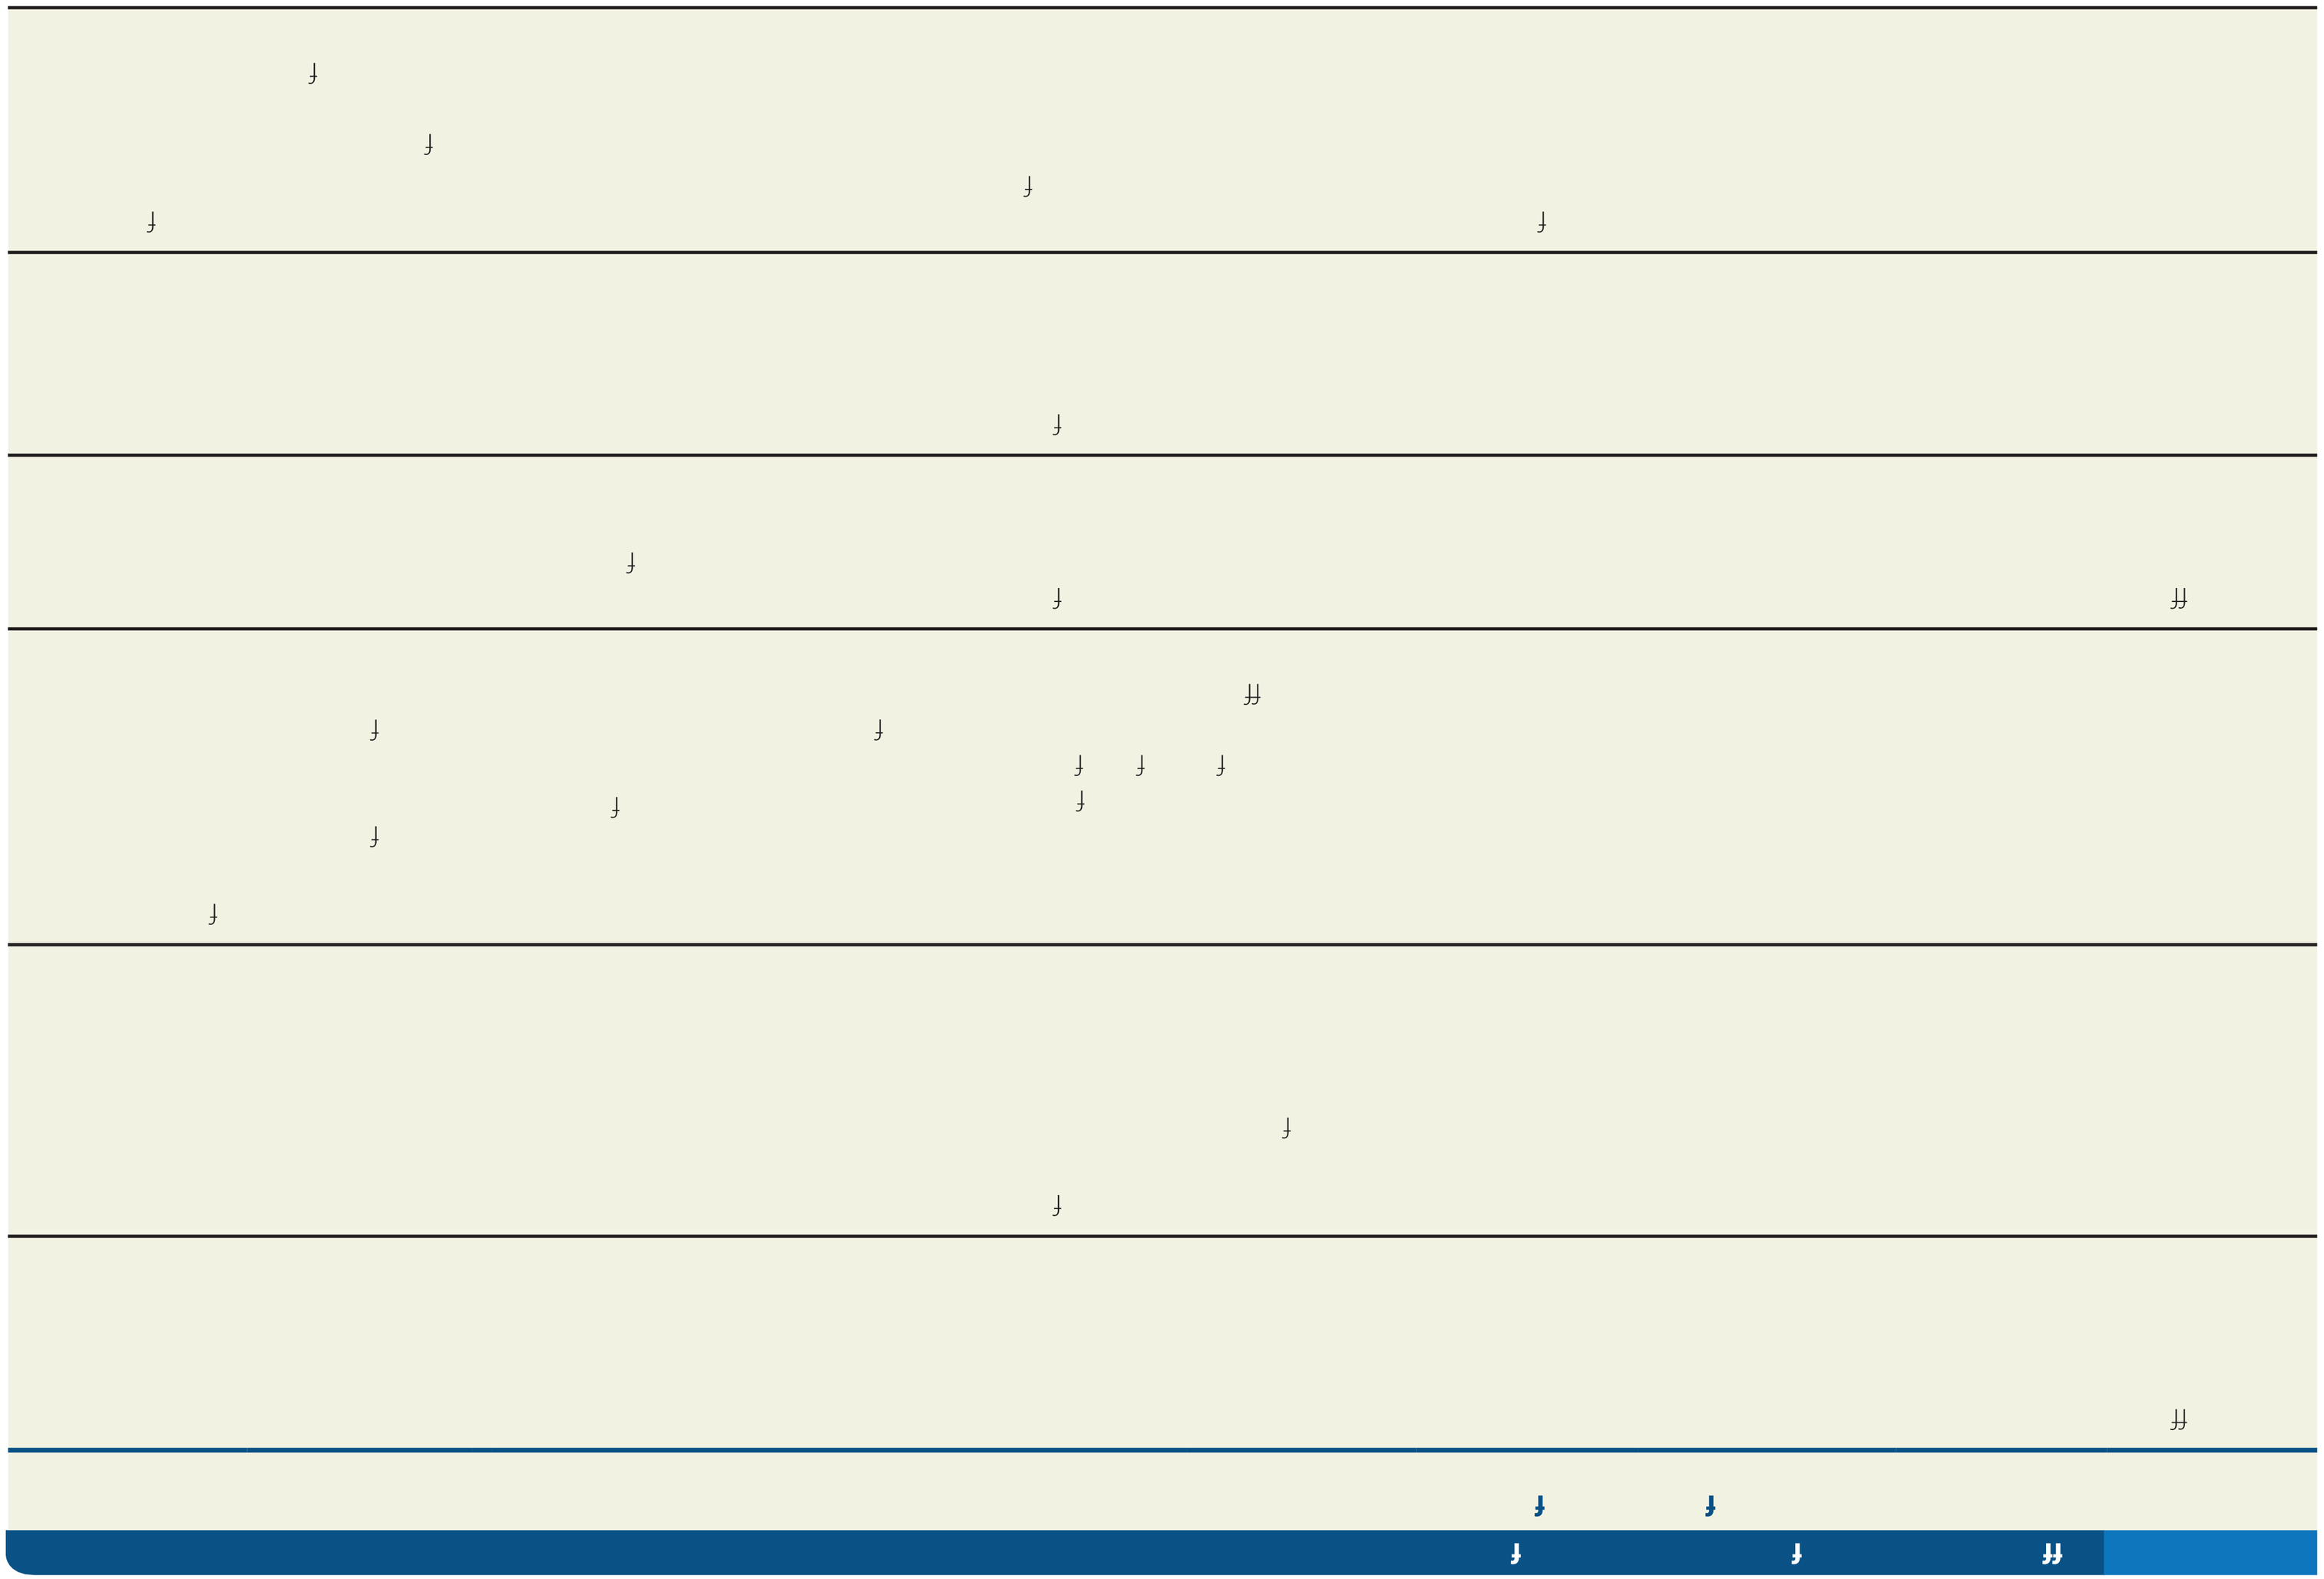
In a limited number of studies, a comparison has been made as to the accuracy of physical diagnostic tests versus arthroscopic examination. One such study found that the physical therapists were unable to differentiate between a partial and complete tear of the rotator cuff tendons.[386] However, a later study showed that physical therapists were able to discern subacromial disorders and passive restraint disorders with an agreement of 85% and 67%, respectively.[387]

evaluation

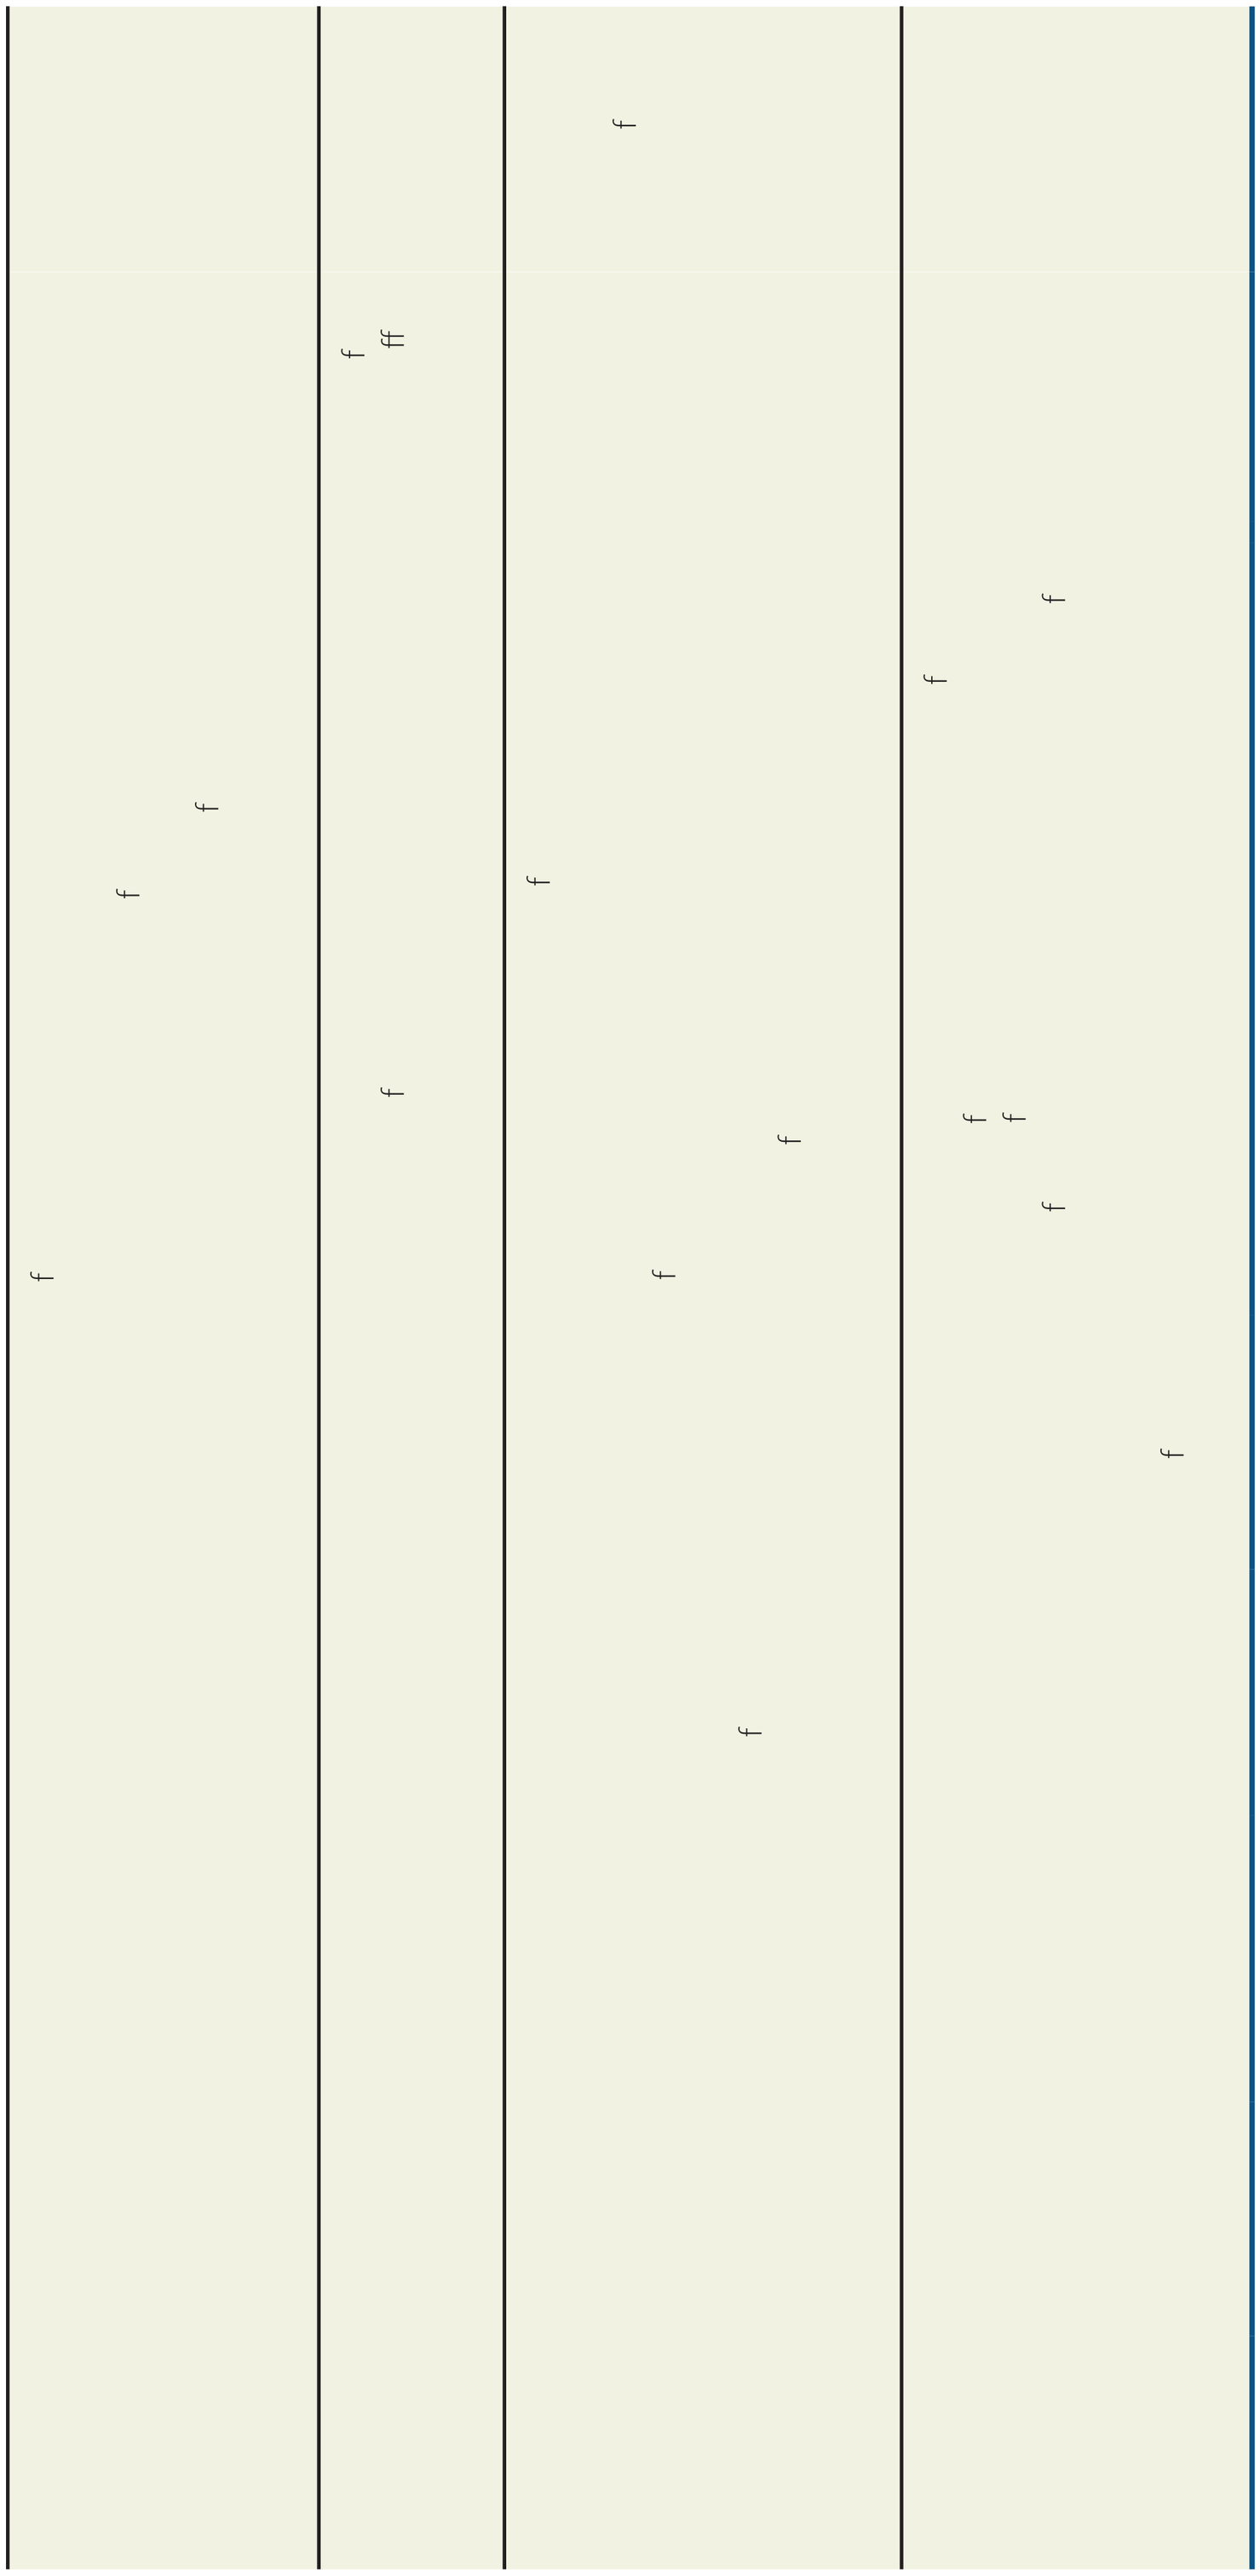
Following the examination, and once the clinical findings have been recorded, the clinician must attempt to determine a specific diagnosis or a working hypothesis, based on a summary of all of the findings. T is diagnosis can be structure related (medical diagnosis) (Table 16-32), or a diagnosis based on the preferred practice patterns as described in the Guide to Physical T erapist Practice. Further details on the specific conditions listed in Table 16-30 is provided in the following sections.

iNTer VeNTiON s Tr ATeGies

With the possible exceptions of acute traumatic shoulder dislocation and acute traumatic inability to raise the arm (acute massive rotator cuff tear), a minimum 6-week period of conservative empiric intervention is typically indicated for shoulder injuries. A number of guiding principles can be used in the conservative rehabilitation of the shoulder:[388]



- T e shoulder must be rehabilitated according to the stage of healing and degree of irritability. T e degree of irritability can be determined by inquiring about the vigor, duration, and intensity of the symptoms. Greater irritability is associated with very acutely inflamed conditions. T e characteristic sign for an acute inflammation of the shoulder is pain at rest, which is diffuse in its distribution and of en referred from the site of the primary condition.[333] Pain above the elbow indicates less severity than pain below the elbow. Chronic conditions usually have a low irritability, but can have an associated loss of AROM and PROM. T e degree of movement and the speed of progression are both guided by the signs and symptoms.
- Rehabilitate the shoulder using scapular planes rather than the straight planes of flexion, extension, and abduction as the scapular planes are more functional.
- Short lever arms should initially be used with exercises as they decrease the torque at the shoulder. Short levers can be achieved by flexing the elbow or by exercising with the arm closer to the body.
- Obtain a stable scapular platform as early as possible.
- Achieve the closed-pack position of the G-H joint at the earliest opportunity. All ROM exercises for the shoulder have traditionally been initiated in the early ranges of flexion with the goal of achieving full elevation. Given the protection afforded the joint by the passive restraint system, thought should be given to providing ROM exercises initiated at the end ranges of elevation according to patient tolerance. Exceptions to this would be the patient whose condition precluded such exercises, that is, following shoulder surgery, adhesive capsulitis, or instability.
- Reproduce the forces and loading rates that will mimic the patient's functional demands as the rehabilitation progresses.



T e manual techniques to increase joint mobility and the techniques to increase sof -tissue extensibility are described in "T erapeutic Techniques" section.

ACUTe Ph As e

T e goals of the acute phase include the following:

- Protection of the healing site.
- Restoration of pain-free ROM throughout the remainder of the kinetic chain.
- Enhance patient comfort by decreasing pain and inflammation.
- Retard muscle atrophy.
- Minimize the detrimental effects of immobilization and activity restriction.[252,253,389–392]

- Maintain general cardiovascular fitness using lower extremity aerobic exercises such as walking.
- Independence with a home exercise program.

The principles of PRICEMEM (protection, rest, ice, compression, elevation, manual therapy, early motion, and medication) are applied as appropriate during the early stages of the acute phase. Icing for 20–30 minutes three to four times a day, concurrent with nonsteroidal anti-inflammatory drugs (NSAIDs) or aspirin, can assist in reducing pain and swelling.

Early active-assisted and passive exercises are performed to nourish the articular cartilage and assist in collagen tissue synthesis and organization.[393–397] These exercises are initiated in pain-free arcs, below 90 degrees of abduction/flexion. Recommended ROM exercises for the acute phase include the following:

- Codman's or other pendulum exercises (Fig. 16-94) VIDEO. Codman's pendulum exercise is commonly prescribed after shoulder surgery or injury to provide grade I and grade II distraction and oscillations resulting in decreased pain and early joint mobilization.[398] A study[398] which measured EMG activity of the shoulder muscles found that the pendulum exercise did not have a significant effect on shoulder EMG activity. Generally, the supraspinatus/upper trapezius muscle activity was significantly higher than the deltoid and infraspinatus activity—especially in patients with shoulder pathology. Many shoulder protocols suggest holding a weight while performing the pendulum exercises as rehabilitation progresses. Ellsworth et al.[398] found that performing the pendulum exercise with added weight did not result in significant increased shoulder EMG activity for the deltoid and infraspinatus muscles in subjects with or without shoulder pathology. However, patients with shoulder pathology had more difficulty relaxing their supraspinatus/upper trapezius muscles than did the healthy subjects.[398] Other PROM exercises can also be introduced. These include passive shoulder flexion (Fig. 16-95) VIDEO, abduction VIDEO, ER (Fig. 16-96) VIDEO, and IR (Fig. 16-97) and elbow flexion and extension VIDEO.
- Active-assisted ROM (AAROM) exercises. AAROM may include wand or cane exercises that move the arm into functional planes while incorporating combinations of forward flexion (Fig. 16-98) VIDEO, extension, abduction (Fig. 16-99), IR, and ER (Fig. 16-100). Over-the-door pulley exercises are performed later in the acute phase as tolerated. However, care must be taken with these exercises in the presence of impingement or

FIGURE 16-94 Codman's pendulum.

FIGURE 16-100 Active-assisted shoulder external rotation.

FIGURE 16-101 Resisted shoulder external rotation.

adhesive capsulitis as these exercises can reinforce poor scapulohumeral motion.

- Active exercises. These can be performed in a variety of positions including standing, sitting, or lying (Figs. 16-17 and 16-20).

Strengthening exercises for the shoulder are introduced as early as tolerated, initially using isometric exercises, with the arm positioned below 90 degrees of abduction and 90 degrees of flexion before advancing to progressive-resistive exercises (PREs) (Figs. 16-101 to 16-105). Elbow flexion (Fig. 16-106) and extension PREs are also introduced as appropriate VIDEO. Specific scapular rehabilitation PREs are typically initiated with the isometric exercises, such as the scapular setting exercise VIDEO. Patterns of scapular retraction and protraction are initiated in single planes and then progressed to elevation and depression of the entire scapula. To improve backward reaching, the patient must first learn correct retraction procedures.

Jobe and Pink[98] believe that the order of strengthening in the rehabilitation process should follow a progression based on muscle function. They advocate strengthening the G-H protectors (rotator cuff muscles) and scapular pivoters (levator scapulae, serratus anterior, middle trapezius, and rhomboids VIDEO) initially because of the role they play in providing stability. In contrast, exercises for the humeral "positioners" (deltoid) and the humeral "propellers" (latissimus dorsi and pectoralis major) are introduced in the

FIGURE 16-102 Resisted shoulder horizontal abduction.

FIGURE 16-103 Resisted shoulder flexion.

FIGURE 16-105 Resisted eccentric shoulder external rotation.

"Functional Phase" section. Exercises for the G-H protectors include the AAROM wand exercises, progressing to AROM in the pain-free ranges throughout the functional planes. In addition, the incorporation of scapular retraction and scapular elevation exercises with G-H movements help stimulate a cocontraction of the G-H protectors and allow for a more normal physiologic sequence to redevelop. Scapular pivoter exercises include the scapular pinch, which is an isometric activity involving scapula retraction toward the midline (Fig. 16-28), and the YTWL exercise (the letters describe the shape the arms adopt) VIDEO.[139,143] Other resisted exercises for the scapula can be introduced at this stage to promote proximal stability. Examples include wall push-ups and isometric chair push-ups at varying degrees of elbow flexion (Fig. 16-107).

Once the arm can be safely elevated and held in the position of 90-degree abduction while standing or sitting, the patient lies in the supine position and the arm is actively raised as high as the pain-free range will allow (from 90 to 180 degrees, depending on tolerance), first without resistance and then with resistance VIDEO. From this position, the patient performs a serratus punch with a "plus." If applicable, the patient is progressed from modified push-ups (Fig. 16-108) to full push-ups (Fig. 16-109) VIDEO. At the end of each push-up as the arm is fully straightened, an extra push is applied. This extra push with the push-up is termed as push-up plus (Fig. 16-110). This exercise strengthens the pectoralis minor, and the lower and middle serratus anterior.[13,118]

The application of joint compression with contraction through the application of closed-chain exercises is important, as closed-chain activities help to balance compression and shear forces at the shoulder. These activities also encourage the correct sequencing of muscle contraction around the shoulder girdle and emphasize the cocontraction of force couples at the scapulothoracic and G-H joints.[85] This results in a correct scapular position and stabilization.[139] Closed-chain exercises may be done early in the rehabilitation phase as they do not put shear on the joint. They also allow the rotator cuff muscles to be activated without being inhibited by pain or deltoid overactivity. The closed-chain exercises can be initiated in the lower ranges using a table (Fig. 16-111), and then progressed to having the hands stabilized in the quadruped

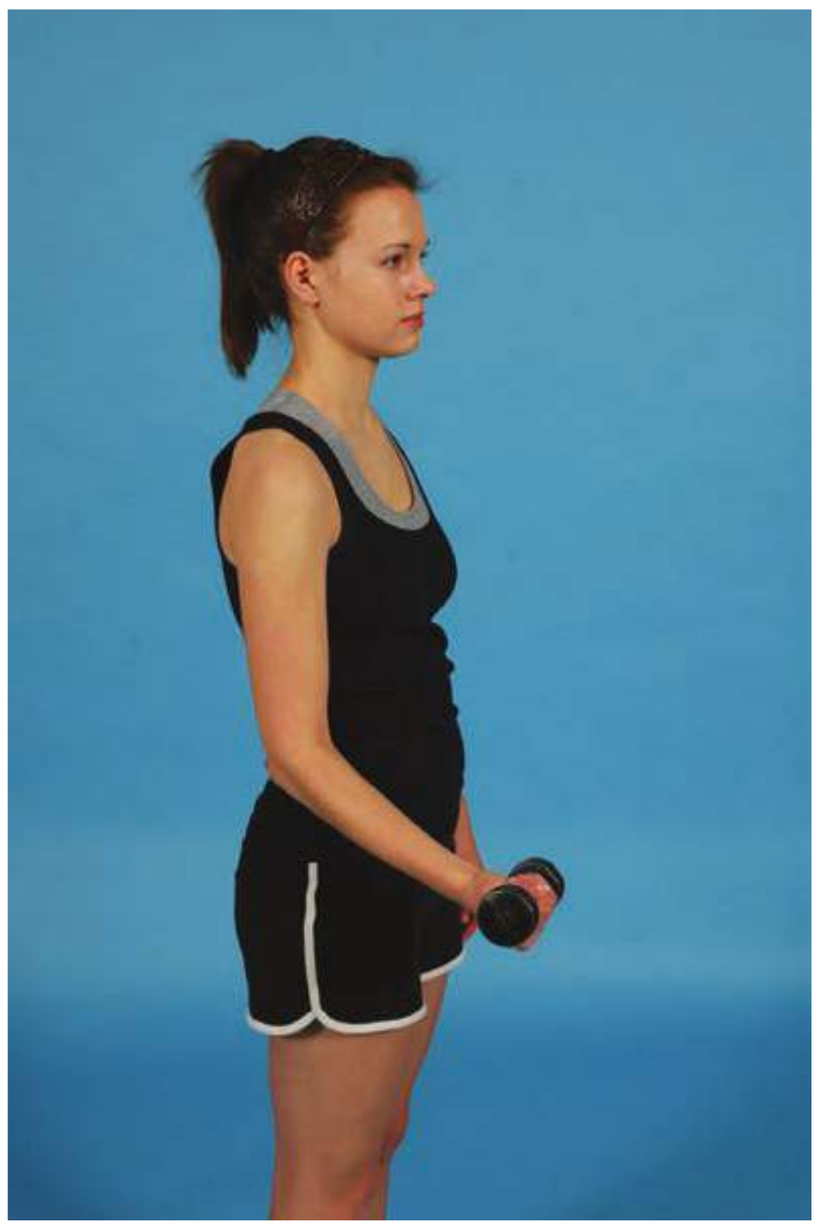

FIGURE 16-104 Resisted eccentric shoulder IR.

FIGURE 16-106 Elbow flexion PRE.

FIGURE 16-107 Isometric chair push-ups.

FIGURE 16-108 Modified push-up.

FIGURE 16-109 Full push-up.

FIGURE 16-110 Push-up plus.

position, using a ball (Fig. 16-112). T ese exercises are started at elevations of 60 degrees or less and are moved up to 90 degrees of flexion, and then abduction, as tolerated to allow for healing of the tissues.[24,139,143,146]

Other closed-chain exercises can be performed by placing both hands on a table and flexing the shoulder to less than 60 degrees and abducting to 45 degrees. Progression is made to weight bearing on a tilt board or a circular board (Fig. 16-113) within tolerance. Other exercises that provide joint compression include the following:

- Sidelying to sitting transfers (Fig. 16-114).
- Elbow rest. T e patient supine in a semireclined position, leaning on the elbows, with the humerus in a neutral or

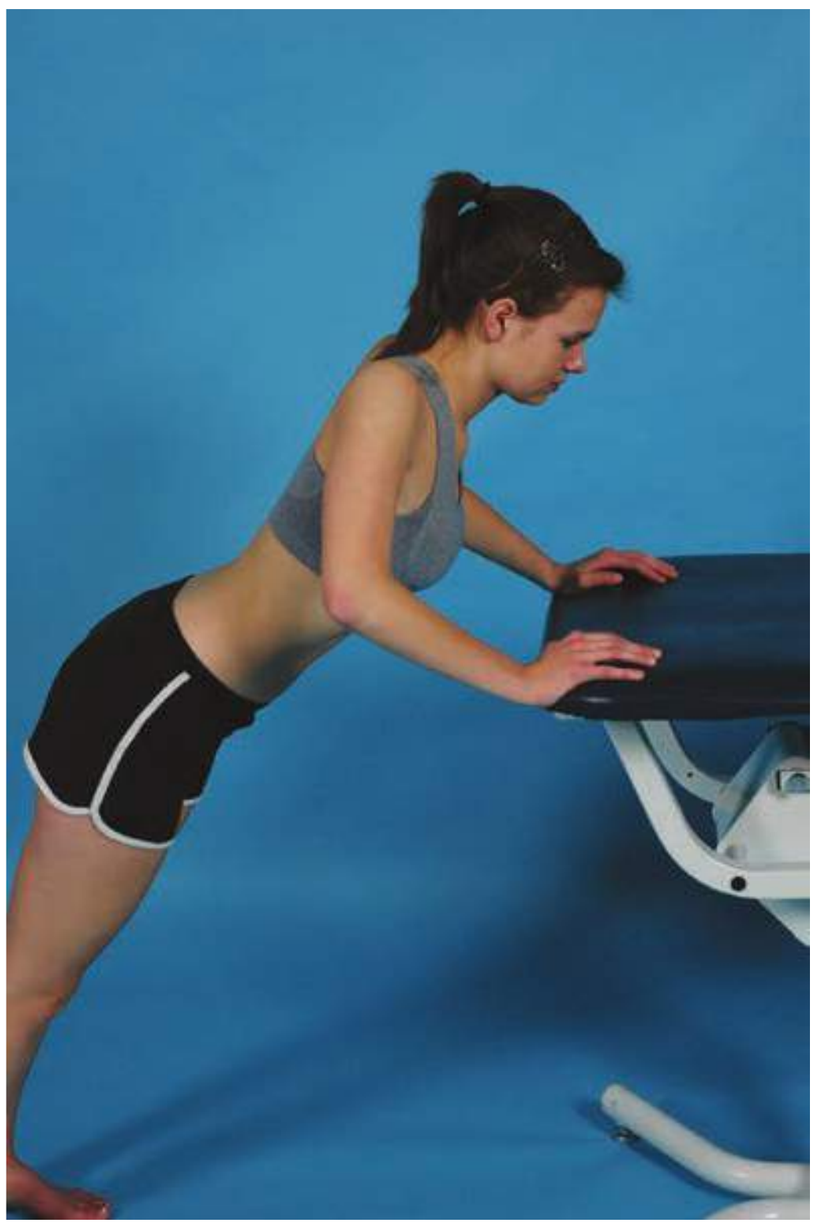

FIGURE 16-111 Closed-chain exercise using upper extremity compression.

FIGURE 16-112 Joint compression in the quadruped position.

extended position (Fig. 16-115). This exercise can also be performed with the patient in prone (Fig. 16-116). Manual resistance can be applied by the clinician to make the exercise more challenging.

- Table press-up. The patient stands facing away from the bed with the hands resting on the bed. While supporting the body though the hands and arms, the patient moves their feet further away from the bed. The patient then raises and lowers their body by straightening the elbows (Fig. 16-117). The exercise can be made more challenging by moving the feet further away from the bed. This exercise works the triceps muscles, the pectoralis major and minor, and the latissimus dorsi muscles.[13] This exercise can be progressed to include pushing and pulling exercises and quadruped and tripod balancing (Fig. 16-118).

FIGURE 16-113 Weight bearing on an unstable surface.

FIGURE 16-114 Sidelying to sit transfer.

FIGURE 16-115 Elbow recline.

FIGURE 16-116 Prone on elbows with shoulder compression.

FIGURE 16-117 Table push-up.

Flexibility exercises to stretch both the joint capsule and the shoulder girdle muscles are a vital component of the rehabilitation process. These include the sleeper stretch (Fig. 16-119) performed in sidelying on the throwing side to stabilize the scapula against the bed, and both the shoulder and elbow flexed to 90 degrees VIDEO and then with the arm abducted to 90 degrees

FIGURE 16-118 Quadriceps balancing.

FIGURE 16-119 Sleeper stretch.

VIDEO The rollover sleeper stretch exercise is similar except that the shoulder is only flexed 50–60 degrees and the patient is rolled forward 30–40 degrees from vertical. Both exercises can be modified by rolling the trunk posteriorly 20–30 degrees to stabilize the scapula and by using a towel placed under the elbow to increase the stretch at the posterior shoulder.[399] Gentle grade I or II oscillations are performed by the clinician as tolerated by the patient. Another stretch that can be performed is the supine horizontal adduction with IR stretch. To perform the stretch, the patient lies in the supine position with the shoulder flexed to 90 degrees. The clinician applies a stabilizing force to the lateral border of the scapula while the arm is horizontally adducted. At this point, the clinician applies a gentle force into IR. Cadaveric studies designed to determine the best position to stretch the posterior shoulder soft-tissue structures have quantified the strain on the posterior cuff and capsule in a number of positions.[400,401] These studies reported increased strain on the posterior capsule with the arm at 60 and 90 degrees of elevation combined with IR.

In the throwing athlete, emphasis should be placed on horizontal adduction of the shoulder stretching exercises to improve flexibility of the posterior shoulder region. The traditional cross body stretch is performed in standing without scapular stabilization and using the opposite hand to horizontally adduct the targeted shoulder (Fig. 16-120). To enhance scapular stabilization and to control excessive external rotation, the technique

FIGURE 16-120 Cross body stretch.

can be performed in sidelying with the trunk rolled posteriorly 20–30 degrees. If the arm performing the stretch is placed superiorly to the one being stretched, the amount of external rotation can be controlled via counterpressure.

CLiNiCAL PeArL

- One study[402] that examined the immediate effects of the sleeper stretch, performed three times for 30 seconds, found an increase in both horizontal adduction and internal rotation ROM following the stretches.
- Another study[403] reported a significantly greater increase in IR using the cross body stretch as compared to the sleeper stretch.

To supplement the stretches applied by the clinician, a number of techniques can be used by the patient to maintain and improve the ROM gains achieved in the clinic (see "Therapeutic Techniques" section).

Kinetic chain preparation can begin in the early stages while the shoulder is recovering from the injury or surgery. The length of the kinetic chain required depends on the needs of the patient and the goals of the rehabilitative process. Longer kinetic chains are associated with the more active patients, and may include the entire lower kinetic chain and the trunk in addition to the upper extremity (see "Biomechanics" section). Kinetic chain preparation will allow for the normal sequencing of velocity and force when the patient returns to their normal activities or athletic pursuits.[139,143]

According to Kibler,[139] progression to the functional phase of the rehabilitative process requires that the following criteria be met:

- Progression of tissue healing (healed or sufficiently stabilized for active motion and tissue loading)
- Pain-free ROM of at least 120-degree elevation
- Manual muscle strength in nonpathologic areas 4+ /5
- Scapular control, with dominant side/nondominant side scapular asymmetry less than 1.5 cm with lateral slide test (LST)

FUNCTiONAL Phase

The functional phase is designed to address any tissue overload problems and/or functional biomechanical deficits. The goals of the functional phase include the following:

- Attain full range of pain-free motion with normal joint kinematics
- Improve muscle strength to within normal limits
- Improve neuromuscular control
- Restore normal muscle force couples

CLiNiCAL PeArL

The number of repetitions the patient is asked to perform should be based on the number the patient can do correctly with control not a predetermined number.

CLiNiCAL PeArL

Generally speaking, exercise machines are not functional, emphasize anterior muscle groups rather than posterior muscle groups (often opposite of the desired effect), and use long lever arms making controlling the motion difficult and increasing the risk of a joint shear.

The exercises during this phase are performed slowly at first and are then progressed to higher functional speeds. Isolated muscle contractions can be achieved by placing the patient in the muscle test position for that muscle. Three sets of the strengthening exercises should be performed daily using weights of 1–10 lb. The number of repetitions is determined by tissue response (pain, fatigue, and compensatory patterns).

Correct activation and functioning of the scapula pivoters is essential. Proper strengthening of the scapular pivoters assures that the scapula follows the humerus, providing dynamic stability and assuring synchrony of the scapulohumeral rhythm. As the scapulothoracic muscles are not required to contract powerfully over short periods, or produce large amounts of force, it could be hypothesized that the scapulothoracic muscles serve a primarily postural function. Thus, in the rehabilitation of the scapulothoracic muscles, their postural function should be addressed and retrained. This can be accomplished in the form of endurance exercises by training the muscles with low weights and high repetitions.[259]

CLiNiCAL PeArL

While the patient is performing exercises for the scapulohumeral rhythm, the clinician should note the following:[404]

- In the first phase of arm abduction (0–30 degrees), no or minimal scapula movement should occur.
- In the second phase (30–90 degrees), the scapula should rotate but show minimal protraction or elevation.
- In the third phase (90–108 degrees), external rotation to the humerus is necessary.

In scaption, the scapulohumeral rhythm is slightly different, with more individual variation in the movement, and more scapular rotation and protraction are common.[404]

Exercises for the scapular pivoters include the following:

- Shoulder shrugs (periscapular—trapezius, levator scapula). Resistance can be added to this exercise by having the patient hold dumbbells in the hands.
- Prone rowing. The patient lies prone on the table with a weight in the hand. With the elbow flexed to approximately 90 degrees, the patient raises the elbow to the ceiling (Fig. 16-121). This exercise strengthens the upper trapezius, levator scapulae, lower trapezius, posterior deltoid, and to a lesser extent, the middle trapezius, rhomboids, and middle deltoid.[13,118,405]
- Modified push-ups (see Fig. 16-108).
- Sidelying abduction exercises VIDEO are performed with the subject lying on his or her side and moving into

FIGURE 16-121 Prone rowing.

45-degree abduction in a neutral rotation position from a neutral or adducted position. Using MRI, sidelying abduction has been shown to produce the greatest signal intensity increase in three muscles of the rotator cuff: supraspinatus, infraspinatus, and subscapularis, as well as the deltoid.[406] A number of other exercises have been reported to demonstrate high subscapularis activity. T ese include IR at 90 degrees of abduction, the push-up plus, the diagonal exercise (Fig. 16-122A and 122B), and the dynamic hug exercise (Fig. 16-123).

T ree exercises that are specific for the middle and lower trapezius include the following:

- Scapular pinches or squeezes.
- T umb tubes. T ese are performed with the elbow extended and the thumb pointing posteriorly while grasping resistive tubing. T e patient then performs a series of shoulder extension and/or horizontal abduction motions at various degrees of elevation.
- Power square patterns. T ese are performed by having the patient elevate the shoulders, pull back (retract) the shoulders while maintaining the elevation, depressing the shoulders while maintaining the retraction, and then moving the shoulders forward (protracting) while maintaining the depression.

FIGURE 16-123 Dynamic hug exercise.

Once scapular control has been achieved, exercises for the humeral positioners (the rotator cuff and deltoid) can be initiated to prevent humeral head migration, and to restore voluntary arthrokinematic control of the humeral head through rotator cuff coactivation and stabilization, as well as activation of the biceps and pectoralis major.[404] For example, by strengthening the infraspinatus, teres minor, and subscapularis muscles (relative to the supraspinatus and the deltoid), it may be possible to reestablish the normal balance and force couple during elevation of the G-H joint.[4,38,407]

Open-chain exercises designed to further strengthen the rotator cuff muscles are emphasized. T ese exercises may include the following:

- Elevation in the plane of the scapula (scaption)—also known as "empty the can," "supraspinatus exercise,"

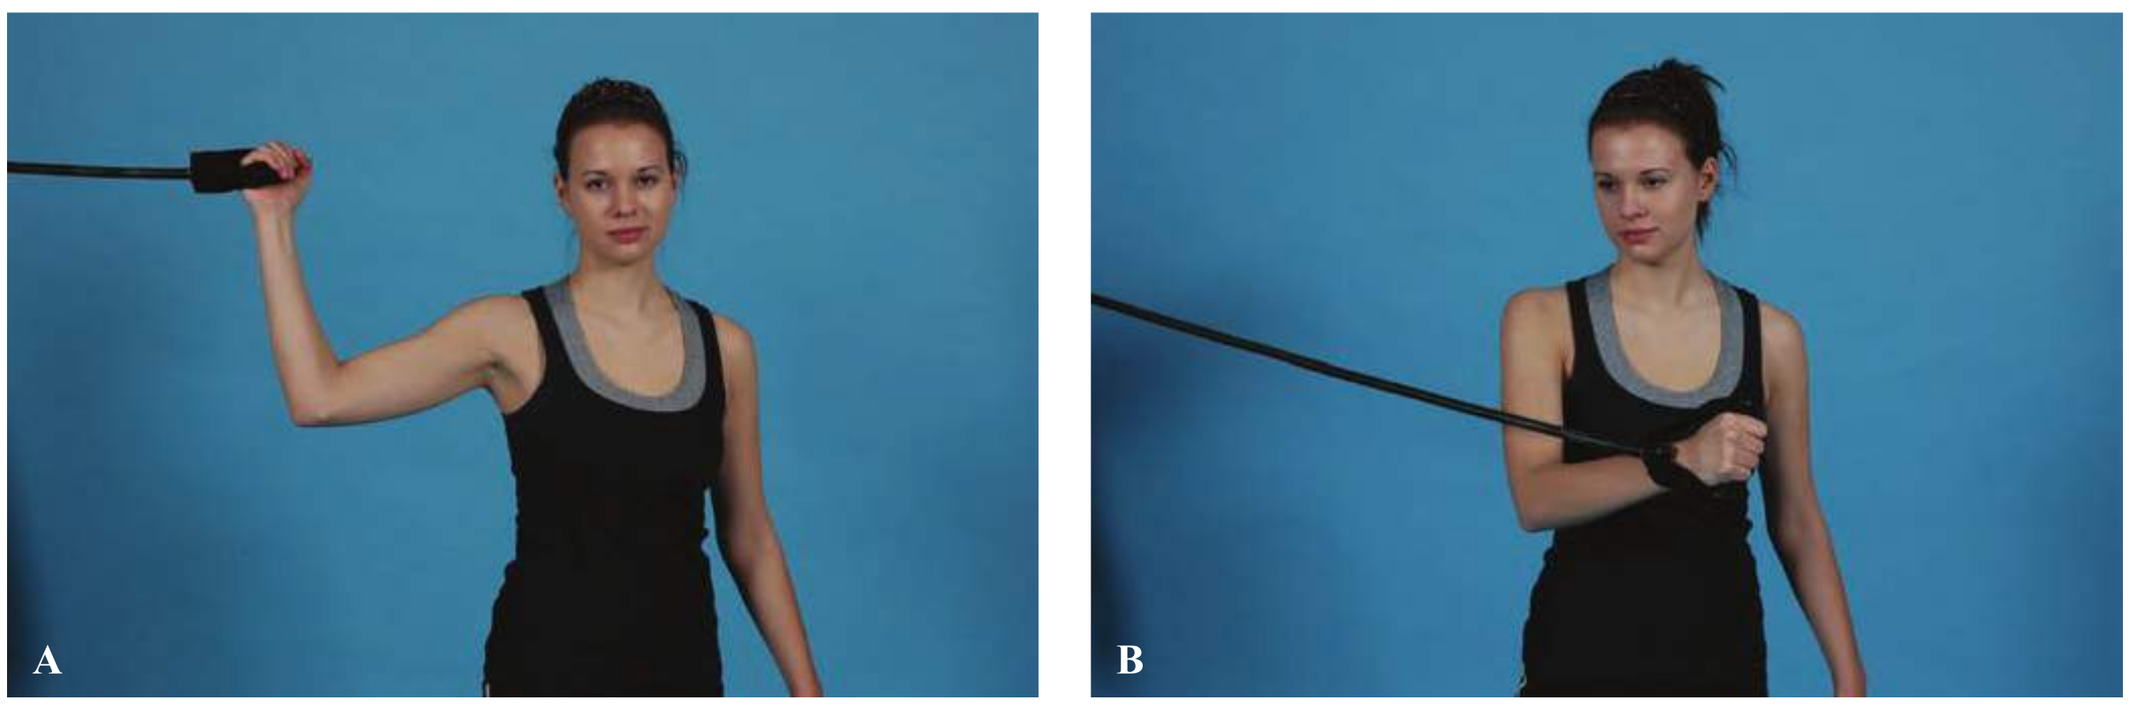

FIGURE 16-122 Diagonal exercise for the upper extremity. A: Start position. B: End position.

FIGURE 16-124 Resisted empty can exercise.

"supraspinatus fly," and "Jobe's exercise"—is defined to be abduction in the plane of the scapula (90 degrees combined with 30 degrees of flexion) and IR (Fig. 16-124).[336] Although useful as a special test, this motion does not help to reestablish scapulohumeral rhythm and can be counterproductive as it is often painful early in the rehabilitation process.

- Elevation in the plane of the scapula (scaption) in ER (full-can position) (Fig. 16-125). This exercise strengthens the scapula pivoters and may be preferable in the presence of impingement.[13,118,405]

CLINICAL PEARL

A controlled laboratory study[408] that observed scapular kinematics during arm elevation against an elastic load found that the changes in scapular motion during the loaded condition were in a direction that could be considered to have a potential to lead to injuries, suggesting caution when using these exercises in individuals with poor scapular control.

- Military press. This exercise, which is performed by raising both the hands from shoulder height straight up toward the ceiling, strengthens the supraspinatus, subscapularis, upper trapezius,[406] anterior deltoid, middle serratus anterior, lower serratus anterior, and middle deltoid.[13,118] As the military press can cause impingement, care must be taken with its use. This exercise is probably better used in a prevention program.

FIGURE 16-125 Resisted full-can exercise.

TABLE 16-33 Scapular and Humeral Control Exercises

Scapular Control	Humeral Control
Bent-over rowing	Prone horizontal abduction
Push-ups with a plus (maximum shoulder protraction)	Scaption in internal rotation (thumbs down)
Press-ups	Scaption with external rotation (thumbs up)
Forward punch-outs	Prone extension
Scapular squeezes	Sidelying internal and external rotation Prone 90 degrees/90 degrees (90-degree abduction, 90-degree elbow flexion) external rotation

- Scapula retraction with horizontal abduction of the externally rotated shoulder, done in prone (Fig. 16-35). Blackburn et al.[118] demonstrated that externally rotating the humerus during prone exercise increased EMG activity to the highest levels. Horizontal abduction (90 or 100 degrees) in ER strengthens the middle trapezius, infraspinatus and to a lesser extent, the teres minor and posterior deltoid (Table 16-33).[13,118,259,405] The patient lies prone on the table with both arms abducted to 90 or 100 degrees and thumbs pointing toward the ceiling. With or without a weight in the hand, the patient then raises his/her thumbs toward the ceiling (Fig. 16-35). If the arm is abducted to 100 degrees in the frontal plane, the lower trapezius is exercised.[118]
- Scapular retraction with horizontal abduction of the internally rotated shoulder, performed in prone (Fig. 16-126); this is similar to the previous exercise, but the patient now has the thumbs pointing down toward the ground. He or she is again prone and his or her arms are abducted to approximately 90 degrees. He or she then raises his or her hypothenar eminence toward the ceiling. This exercise strengthens, in order of effectiveness, the posterior deltoid, middle trapezius, rhomboids, middle deltoid, levator scapulae, infraspinatus, teres minor, upper trapezius, and lower trapezius.[13,118,405] This exercise can also be done in standing by using elastic resistance.
- Scapular dump (as though trying to empty things out of a can) exercises that incorporate arm, scapular, and trunk movements.
- Short-arc (pain-free) exercises into scaption, abduction, and forward flexion to 30 degrees initially and then to 90 degrees. These exercises should be performed in ER to facilitate clearance of the greater tuberosity under the coracoacromial ligament.

FIGURE 16-126 Prone shoulder retraction with glenohumeral joint in IR.

The open-chain exercises should also include resisted shoulder external VIDEO (Fig. 16-127) and internal VIDEO (Fig. 16-128) rotation with the arm in increasing amounts of abduction VIDEO to strengthen the infraspinatus/teres minor and subscapularis muscles, respectively. To avoid concurrent strengthening of the

FIGURE 16-127 Resisted external rotation.

FIGURE 16-128 Resisted IR.

deltoid during the earlier phases of strengthening, the patient is instructed to hold a magazine or towel roll between the extremity and the trunk while strengthening the rotator cuff muscles. This forced adduction relaxes the deltoid and isolates the oblique muscles of the rotator cuff.

Once control in most of the range has been achieved, diagonal proprioceptive neuromuscular facilitation (PNF) exercises can be used to teach control and stabilization throughout the whole range. The shoulder D2 pattern (flexion, abduction, and ER) is especially useful for instability.[404]

Once the muscles can contract in the correct sequence, the humeral propellers (i.e., the latissimus dorsi, teres major, pectoralis minor, and pectoralis major) are trained concentrically, while the humeral positioners and protectors (i.e., infraspinatus, teres minor, supraspinatus, posterior deltoid, and biceps) and scapula pivoters are trained eccentrically.

In addition to addressing the musculature of the shoulder complex, the clinician must address the whole kinetic chain involved in an activity to which the patient is planning to return. This may include rehabilitation of the legs and hips to focus on the generation of appropriate activity-specific force and velocity from the lower extremity.[139,143] Examples include exercises that develop normal agonist–antagonist force couples in the legs such as squats, plyometric depth jumps, lunges, and hip extensions. Most shoulder activities involve rotation and diagonal patterns.[143,146] Thus the exercises must incorporate trunk rotation exercises (using medicine ball or tubing), which integrate leg and trunk stabilization and incorporate diagonal patterns (Fig. 16-129). These exercises are progressed to incorporate combined patterns of hip and trunk rotation in both directions, and hip and shoulder diagonal patterns from the left hip to the right shoulder and from the right hip to the left shoulder.[143,146]

Endurance activities in the legs should also be emphasized. Both aerobic endurance for recovery from exercise bouts and anaerobic endurance for agility and power work are advocated. These can be done using mini-trampoline exercises, agility drills with running and jumping, jumping jacks, and slider or Fitter boards.[139]

The arthrokinematic movements of the joints in the entire kinetic chain must be addressed for hypomobility and hypermobility, as appropriate. These joints include the A-C joint, the S-C joint, the scapulothoracic joint, the cervical and

FIGURE 16-129 Trunk rotation exercises with medicine ball.

upper thoracic spine, and the upper ribs. For example, the clinician should check for GIRD, restriction of the inferior G-H ligament, and any loss of range in the pectoralis major and pectoralis minor.

CLiNiCAL PeArL

The circle concept of instability[35,144] relates to the fact that injury to structures on one side of the joint sufficient to result in instability can, simultaneously, cause injury to structures on the other side or other parts of the joint, particularly in the presence of trauma. For example, a traumatic anterior instability of the shoulder can lead to injury of the posterior structures. Thus, the clinician must always be aware of potential injuries on the opposite side of the joint even if symptoms are predominantly on one side. In addition, if a joint is hypermobile in one direction, it may be hypomobile in the opposite direction. For example, with anterior instability, the posteroinferior capsule tends to be tight and therefore requires mobilization, whereas the anterior capsule is hypermobile and requires protection.[404]

Proprioception exercises can be introduced as soon as the patient has gained scapular control. These exercises can include the aforementioned closed-chain activities for the upper extremity. Open kinetic chain activities may also be used, but they are not as effective, and they do not require the same level of stability.[404]

Activity-specific progressions must be completed before full return to function is allowed. This is done to test all of the working components involved in the activity. Very few deviations from the normal parameters of arm motion, arm position, force generation, smoothness of all of the kinetic chain, and from preinjury form should be allowed as most of these adaptations will be biomechanically inefficient.[139,143,146,409,410] Advanced stabilization exercises are designed to test the ability of the patient to stabilize the scapula statically in positions above 30 degrees, most commonly in an open kinetic chain. The patient is asked to perform isometric hold or eccentric break activities of the internal and external rotators in various positions of G-H abduction, scaption, and forward flexion. Closed-chain exercises include wall falls, table falls, and balancing on different balance devices. Closed-chain exercises in this phase may also include the following:

- Regular push-ups (Fig. 16-109) are progressed as tolerated.
- Medicine ball catch-and-throw (Fig. 16-130 to 16-134) VIDEO

Dynamic weight-shifting exercises are introduced during this phase. With the patient weight bearing on all fours in the quadruped position, and while keeping their hands stationary in the same position, the patient can rock the body forward and backward, and side to side. A similar exercise can be performed on an unsteady surface by using equipment such as the BOSU trainer VIDEO Alternatively, the patient can slide their hands, or one hand, forward, backward, and side to side while maintaining their trunk still. Resistance can be added using a Fitter board (Fig. 16-135).

Finally, dynamic stabilization exercises that involve controlled eccentric movement of the scapula while the arm moves are introduced.[139] Eccentric exercises are particularly important for those patients where tensile overloading is suspected to be the cause, and for the overhead athlete population.[388,411] Exercises such as bent over rows, and lunges with dumbbells are good examples.

FIGURE 16-130 Medicine ball throw and catch.

FIGURE 16-131 Medicine ball throw and catch.

FIGURE 16-133 Medicine ball throw and catch.

T e criteria for return to activity include the following[139]:

- Little or no pain
- Functional ROM with involvement of the whole kinetic chain
- Normal movement patterns and functional ability
- Appropriate levels of fitness
- Near-normal strength
- Ability to perform the necessary skills

Table 16-34 may be referred to for a typical program given for a pitcher returning to full function. T is program can and

T e primary impairment in pattern 4D, when applied to the shoulder, is hypomobility due to capsular restriction. In addition to limited joint movement and decreased ROM associated with pain, the impairments in this pattern include decreased motor control and muscle performance.

T e clinical findings in this pattern include, but are not limited to, pain, limited ROM in a capsular pattern of restriction, an alteration in the scapulohumeral rhythm, crepitus, and a positive impingement sign.

Arthritis

Traumatic Arthritis of the G-h Joint

Traumatic or primary G-H arthritis is an entity that has been well described and documented by Neer et al.,[335,412] who highlighted the presence of significant posterior glenoid erosion causing static posterior subluxation of the humeral head. Traumatic arthritis of the G-H joint rarely occurs in individuals under the age of 45. T e condition is characterized by pain, progressive functional impairment, and reports of instability.[413] Passive horizontal adduction is usually the most limited and painful motion.

Conservative intervention consists of rest, modification of activity, and NSAIDs. Electrotherapeutic modalities and physical agents may be used to control pain and the active inflammation. Joint mobilizations of grade I or grade II may also be used to decrease pain. Once pain and inflammation is under control, the rehabilitation progresses to strengthening of the shoulder protectors and scapular pivoters, as described in the "Intervention Strategies" section.

immobilization

Postsurgical immobilization occurs at any age, although it is more common in the elderly. T e clinical progression is similar to that of traumatic arthritis. T is condition should ideally be treated by prophylaxis.

r heumatoid Arthritis

Rheumatoid arthritis is described in Chapter 5. Conservative intervention for this population includes patient education on how they can influence their disease process by alleviating the impairments, functional limitations, and disability. Electrotherapeutic modalities and cryotherapy can be used to help control pain and inflammation. T ermal modalities may also be used in the nonacute phases. T erapeutic exercise can be beneficial for the patients who are weak and stiff prior to the onset of end-stage arthritis, where the ROM and strength can be regained, or at least maintained.[414] However, caution must be used with those patients with end-stage arthritis who have stiffness secondary to joint incongruity, as they may actually have their symptoms exacerbated with aggressive stretching exercises.[414]

When pain becomes too severe and conservative intervention is unable to relieve this pain and restore function, surgical measures are considered. T ese measures may include synovectomy, G-H arthrodesis, or total joint arthroplasty.

septic Arthritis

See Chapter 5.

Osteonecrosis of the humeral head

Osteonecrosis of the humeral head is described in Chapter 5.

hemorrhagic shoulder (milwaukee shoulder)

L'épaule sénile hémorragique (the hemorrhagic shoulder of the elderly) was first described in 1968. It consisted of recurrent, blood-streaked effusions of the shoulder along with radiographic findings of severe degenerative G-H arthritis and a chronic tear of the rotator cuff.[415] The term Milwaukee shoulder was not introduced until 1981.[416–418]

The condition generally affects a subset of the elderly population who have G-H arthritis in conjunction with a complete rotator cuff tear.

One theory to explain the Milwaukee shoulder describes a hydroxyapatite-mineral phase that develops in the altered capsule, synovial tissue, or degenerative articular cartilage. This releases basic calcium phosphate crystals into the synovial fluid.[416–418] These crystals are phagocytized by synovial cells and form calcium phosphate crystal microspheroids. These induce the release of activated enzymes from these cells, causing destruction of the periarticular tissues and articular surfaces.[419]

Another theory is the cuff tear theory. In 1983, Neer et al.[420] postulated that untreated chronic, massive tears would lead to a degenerated G-H joint. The mechanism of destruction of the articular cartilage was said to include mechanical and nutritional alterations in the shoulder.[420] The mechanical factors include A-P instability of the humeral head resulting from a massive tear of the rotator cuff, and rupture or dislocation of the LHB that leads to proximal migration of the humeral head and acromial impingement.[419] G-H articular wear was thought to occur as a result of repetitive trauma from the altered biomechanics associated with the loss of the primary and secondary stabilizers of the G-H joint.[419] Changes in the composition of the articular cartilage follows because of inadequate diffusion of nutrients and the diminished quantity of synovial fluid.[419] Degenerative arthritis and subchondral collapse eventually develops.[419]

If the resultant rotator cuff tear arthropathy causes relatively mild symptoms, intervention should consist of mild anti-inflammatory medication and gentle stretching exercises to maintain or regain a functional ROM.[419] A strengthening program should follow to improve the active use of the arm for ADL. If conservative management fails, a humeral hemiarthroplasty is the procedure of choice to provide reliable relief of pain and functional improvement.[419]

Frozen shoulder/Adhesive Capsulitis

Since this condition also involves an inflammation of the capsule, a patient with this condition could also be classified under preferred practice pattern 4E.

The frozen shoulder syndrome was first described by Duplay in 1872,[421] who used the term periarthritis scapulohumeral. It was not until 1934 that Codman[60] used the term frozen shoulder to describe this condition. In 1945, Neviaser introduced the term adhesive capsulitis to reflect his findings of a chronic inflammatory process at surgery and autopsy.[422]

Although the etiology of frozen shoulder remains elusive, the understanding of the pathophysiology has recently improved. Factors associated with adhesive capsulitis include female gender,[423] age older than 40 years,[424] trauma,[424] diabetes,[229,251,425–428] prolonged immobilization,[429] thyroid disease,[430–432] stroke or myocardial infarction,[426,433] certain psychiatric conditions,[434,435] and the presence of autoimmune diseases.[436,437]

The prevalence of frozen shoulder in the general population is slightly greater than 2%,[423,438] and 11% of the adult diabetic population.[425] Approximately 70% of patients with adhesive capsulitis are women, and 20–30% of those affected subsequently will have adhesive capsulitis develop in the opposite shoulder.[439] Complicating the diagnosis is the fact that there are many conditions that can cause shoulder stiffness (Tables 16–35 and 16–36).

TABLE 16-35 Intrinsic Causes of Shoulder Stiffness

Cause	Example
Bursitis	Subacromial Calcific tendinitis Snapping scapula
Biceps tendon	Tenosynovitis Partial or complete tears SLAP lesions
Rotator cuff	Impingement syndrome Partial rotator cuff tears Complete rotator cuff tears
Trauma	Fractures Glenoid Proximal humerus Surgery Postoperative shoulder, breast, head, neck, chest Gastrointestinal disorders Esophagitis Ulcer Cholecystitis
Instability—glenohumeral	Recurrent dislocation anterior and posterior Chronic dislocation
Arthritides	Glenohumeral and acromioclavicular Osteoarthritis Rheumatoid Psoriatic Infectious Neuropathic
Miscellaneous	Osteonecrosis Hemarthrosis Osteochondromatosis Suprascapular nerve palsy

TABLE 16-36 Extrinsic Causes of Shoulder Stiffness

Cause	Example
Neurologic	Parkinson's disease Automatic dystrophy (CRPS) Intradural lesions Neural compression Cervical disk disease Neurofibromata Foraminal stenosis Neurologic amyotrophy Hemiplegia Head trauma
Muscular	Poliomyositis
Cardiovascular	Myocardial infarction Thoracic outlet syndrome Cerebral hemorrhage
Infections	Chronic bronchitis Pulmonary tuberculosis
Metabolic	Diabetes mellitus Progressive systemic sclerosis (scleroderma) Paget's disease Thyroid disease
Inflammatory	Rheumatologic disorders Polymyalgia rheumatica
Trauma	Surgery Axillary node dissection, sternotomy, thoracotomy Fractures Cervical spine, ribs, elbow, hand, etc.
Medications	Isoniazid, phenobarbitone
Congenital	Klippel–Feil Sprengel's deformity Glenoid dysplasia Atresia Contractures Pectoralis major Axillary fold
Behavioral	Depression Hysterical paralysis
Referred pain	Diaphragmatic irritation
Neoplastic	Pancoast tumor Lung carcinoma Metastatic disease

Data from Cohen BS, Romeo AA, Bach BR. Shoulder injuries. In: Brotzman SB, Wilk KE, eds. Clinical Orthopaedic Rehabilitation. Philadelphia, PA: Mosby; 2003:125–250.

Nash and Hazelman[440] have described the concept of primary and secondary frozen shoulders, with the former idiopathic in origin, and the latter either traumatic in origin or related to a disease process, neurologic, or cardiac condition.

Primary Adhesive Capsulitis

Primary adhesive capsulitis is characterized by an idiopathic, progressive, and painful loss of active and passive shoulder motion, particularly ER, which causes the individual to gradually limit the use of the arm. Difficulty is reported with putting on a jacket or coat, putting objects into back pockets, or hooking garments in the back.[204,441–443] Inflammation and pain can cause muscle guarding of the shoulder muscles, without true fixed contracture of the joint capsule. Disuse of the arm results in a loss of shoulder mobility, whereas continued use of the arm through pain can result in development of subacromial impingement.[439] Over a period of weeks, compensatory movements of the shoulder girdle develop to minimize pain.[439] With time, there is resolution of pain and the individual is lef with a stiff shoulder and with severe limitation of function.

secondary or idiopathic Adhesive Capsulitis

Zuckerman and Cuomo[444] defined idiopathic adhesive capsulitis as a condition characterized by substantial restriction of both active and passive shoulder motion that occurs in the absence of a known intrinsic shoulder disorder. Two clinical forms are recognized:

1. One form is defined as when the pain is more noticeable than the motion restriction. T is condition is self-limiting, and the patient spontaneously recovers within 6 months to a year. Two studies[445,446] of patients with idiopathic adhesive capsulitis found that the vast majority of patients with this condition were successfully treated with a specific shoulder-stretching exercise program.
2. T e other form is defined as when the pain, which can radiate below the elbow, is as noticeable as the restriction. T e patient complains of pain at rest and is unable to sleep on the involved side. ER of the G-H joint is usually affected more than abduction or flexion.[204] T e initial phase of this condition is characterized by pain and progressive loss of motion lasting 2–6 months. T is form responds well to a series of corticosteroid injections or local anesthetic (distension therapy).

To formulate a logical approach to the intervention of patients with adhesive capsulitis, the clinician needs to determine the degree of inflammation and irritability. To help in this determination, it is necessary to have a better understanding of the underlying cellular and biochemical pathophysiology of this disease.

T ere is disagreement as to whether the underlying pathologic process is an inflammatory condition,[447–449] or a fibrosing condition.[450] Significant evidence exists[436,437,449,451] in support of the hypothesis that the underlying pathologic changes in adhesive capsulitis are synovial inflammation with subsequent reactive capsular fibrosis, making adhesive capsulitis an inflammatory and a fibrosing condition, depending on the stage of the disease. T e initial biologic trigger in this cascade

of inflammation and subsequent fibrosis is unknown, although it is likely to involve multiple factors. In some areas, there seems to be a seasonal variation in patients presenting with adhesive capsulitis, suggesting that a virus is responsible.[439]

stages of Progression

Adhesive capsulitis is suggested by Neviaser[422] to pass through four stages based on pathologic changes in the synovium and the subsynovium, with each stage having an individual intervention strategy, although there is controversy about this idea.[76]

Stage I. In stage I, patients present with mild signs and symptoms of less than 3 months' duration, which are often described as achy at rest and sharp at extremes of ROM. The symptoms often mimic those of an impingement syndrome, where restriction of motion is minimal and pain that appears to be due to a rotator cuff tendinopathy has been present for less than 3 months. However, the patient reports a progressive loss of motion and intervention protocols for rotator cuff tendinopathy fail. A capsular pattern of motion (loss of ER and abduction) is present, and a more subtle loss of IR in adduction. In adhesive capsulitis due to type 1 diabetes mellitus, the capsular pattern is typically equal to the limitation of ER and IR, which is greater than the limitation of abduction.

In this early stage, the majority of motion loss is secondary to the painful synovitis, rather than a true capsular contraction.

Stage II. This stage, often referred to as the Freezing Stage, is characterized by persistent, and more intense pain, even at rest. Patients presenting with stages I and II adhesive capsulitis have pain on palpation of the anterior and posterior capsules and describe pain radiating to the deltoid insertion. Night pain and disturbed sleep occur during acute flares. An intra-articular injection of steroid and local analgesic given by a physician can be extremely useful in the diagnosis and intervention of adhesive capsulitis.[439] After the injection, passive G-H ROM is reevaluated. If the patient has significant improvement in pain and normalization of motion, the diagnosis of stage I adhesive capsulitis is confirmed.[439] If the patient has a significant improvement in pain but no significant improvement in ROM, then by definition he or she has stage II adhesive capsulitis, although it must be emphasized that these stages represent a continuum of the inflammatory and scarring processes.[447]

In stage II, symptoms have been present for 3–9 months with progressive loss of ROM and persistence of the pain pattern described above. The motion loss in stage II adhesive capsulitis reflects a loss of capsular volume and a response to the painful synovitis. The patient demonstrates a loss of motion in all planes, as well as pain in all parts of the range. The patient will typically demonstrate an inability to reach overhead, behind the head, and behind the back resulting in difficulty dressing, self-grooming, bringing eating utensils to the mouth, and reaching the hand into the back pocket of pants. Evaluation of AROM and PROM should be performed because documenting the initial ROM, especially passive motion, is critical in determining the efficacy of the intervention plan. There is normally a decreased joint play associated with limited external rotation and abduction, with some limitation of IR and elevation in flexion. The causes of the restricted PROM need to be assessed and a differentiation must be made between protective muscle guarding, adaptive changes in musculotendinous structures, or capsular adhesions and contracture.

CLiNiCAL PeArL

It is important to note that the restricted ROM seen in patients with adhesive capsulitis occurs both actively and passively, which is in contrast to a number of other shoulder condition in which a loss of AROM of the G-H joint occurs, but reasonably good if full PROM is maintained.[72]

Stage III. In stage III, often referred to as the Frozen Stage, patients present with a history of painful stiffening of the shoulder and a significant loss of ROM. Symptoms have been present for 9–14 months and have been observed to change with time. Patients often report a history of an extremely painful phase that has resolved, resulting in a relatively pain-free but stiff shoulder.

Poor scapulohumeral rhythm is observed during elevation of the arm. There is a dominance of the upper trapezius resulting in hiking of the shoulder girdle. This is attributed to a decreased inferior glide of the G-H joint, which prevents G-H abduction.[452] In addition, there is general muscle weakness secondary to decreased use.

Stage IV. Stage IV, also known as the "Thawing Stage" for adhesive capsulitis, is characterized by the slow, steady recovery of some of the lost ROM resulting from capsular remodeling in response to use of the arm and shoulder. Although many people feel less restricted in this phase, objective measurements show only minor improvement.[453] No arthroscopic or histologic data are available for patients with stage IV adhesive capsulitis because these patients rarely undergo surgery. Patients who present with stages III and IV adhesive capsulitis often report a history of long-standing pain at rest and pain at night that have resolved spontaneously.[454] The objective findings typically include a stiff shoulder, with striking alteration of scapulohumeral mechanics and limited use of the arm during ADL. A capsular pattern of motion is a characteristic finding. Resistance in the form of a capsular end-feel is felt before pain is reached as the G-H joint is taken through PROM.

Other pathologic conditions that can create a painful restriction of G-H motion should be ruled out. Typically, the physician uses a routine radiographic evaluation to rule out other causes for a stiff, painful shoulder including G-H arthritis, calcific tendinopathy, or long-standing rotator cuff disease.[439] Radiographs usually are negative in patients with frozen shoulder, although there may be evidence of disuse osteopenia.[439] MRI has been used for investigative purposes in patients with adhesive capsulitis and has shown an increased blood flow to the synovium in frozen shoulder.[455]

intervention

The conventional management for adhesive capsulitis incorporates patient advice, analgesics, NSAIDs, steroid injection, and a wide array of PT methods.[456] The primary goal of conservative intervention is the restoration of the ROM and focuses on the application of controlled tensile stresses

to produce elongation of the restricting tissues.[251,252,439,457–459] Once this has been established, strengthening of the rotator cuff and the three parts of the deltoid muscle is important. Systematic reviews concerning PT interventions with adhesive capsulitis have traditionally compared the efficacy of one component of PT. For example, comparing the effect of ultrasound alone or mobilization alone. T e outcomes from these studies have been, perhaps not surprisingly, poor. However, when combined PT methods are analyzed, the results have been more encouraging. Pajareya et al.[456] performed a randomized control trial of 122 patients to study the effectiveness of ibuprofen and a combination of PT techniques versus ibuprofen alone. T e PT intervention (three times a week for 3 weeks) included short-wave diathermy, joint mobilizations, and passive G-H stretching exercises up to the patient's tolerance. At 3 weeks it was concluded that the PT group demonstrated more beneficial effects than the group using ibuprofen alone.[456]

T ese results must be taken in the context of earlier studies that have indicated that a gradual return of full mobility occurs within 18 months to 3 years in most patients, even without specific intervention.[460–462] In a prospective study by Diercks et al.,[463] 77 patients with idiopathic frozen shoulder syndrome were included to compare the effect of intensive physical rehabilitation treatment, including passive stretching and manual mobilization (stretching group) versus supportive therapy and exercises within pain limits (supervised neglect group). All patients were followed up within 24 months af er the start of treatment. T e study concluded that supervised neglect yielded better outcomes than intensive PT and passive stretching in patients with frozen shoulder with regard to the functional end result and the speed of recovery.

T ese conflicting findings may be the result of an incorrect treatment approach. As a general guideline, the patient with capsular restriction and low irritability may require aggressive sof tissue and joint mobilization, whereas patients with high irritability may require pain-easing manual therapy techniques.[464] In contrast, the emphasis on intervention for limited ROM due to nonstructural changes is aimed at addressing the cause of the pain.[255,438,444,451,461,465–467] T e trust and confidence of the patient is essential, and it is important to ensure that no harm is caused, or that the clinician does not indicate any frustration. During the acute phase, pendulum exercises and low-grade joint mobilization techniques are recommended to relieve pain and apply a gentle stretch to the capsule. In addition, passive stretching of the upper trapezius and levator scapulae muscles can be performed by the clinician and then taught to the patient as part of a home exercise program. During the subacute phase, more aggressive ROM exercises can be incorporated using PNF techniques, wall climbing, and wall/corner stretches. As ROM returns, strengthening becomes the focus, initiating with isometrics, and then progressive strengthening of the shoulder complex during the chronic phase.

CLiNiCAL Pe Ar L

It is important for the clinician to remember that CRPS type I is a potential complication after shoulder injury or immobility (see Chapters 5 and 18).

A number of questions are of en raised by the patient with regard to corticosteroid injections. Although these questions are best answered by the appropriate physician, there is extensive information regarding the efficacy of intra-articular corticosteroid in the intervention of patients with adhesive capsulitis.[468–472] Hazelman[473] summarized numerous studies on the use of intra-articular corticosteroid and reported that the success of intervention is dependent on the duration of symptoms.

- Patients treated within 1 month of the onset of symptoms recovered in an average of 1.5 months.
- Patients treated within 3 months of the onset of symptoms reported a significant improvement in symptoms.
- Patients treated within 2–5 months of the onset of symptoms recovered within 8.1 months of onset of symptoms.
- Patients treated af er 5 or more months of the onset of symptoms had a more delayed recovery, with the time necessary for full recovery reported to be dependent on the duration of symptoms.
- Patients treated 6–12 months af er the onset of symptoms required an average of 14 months for full recovery.

T ese data, along with others, support the hypothesis that adhesive capsulitis is an inflammatory and fibrotic condition.[447,449,450,468,474] Early intervention with intra-articular corticosteroid may provide a chemical ablation of the synovitis, thus limiting the subsequent development of fibrosis and shortening the natural history of the disease.[447] With resolution of the synovitis and loss of the cytokine stimulus to the capsular fibroblasts, capsular remodeling and recovery of ROM take place.[447]

Surgical intervention is reserved for those patients who do not respond to conservative intervention. Historically, arthroscopy has been of little diagnostic and therapeutic value in patients with adhesive capsulitis of the shoulder,[424] and closed manipulation appears to be the operation of choice if conservative methods fail. However, closed manipulation is contraindicated in patients with significant osteopenia, recent surgical repair of sof tissues about the shoulder, or in the presence of fractures, neurologic injury and instability.[439]

selective hypomobility

A generalized decrease in shoulder ROM may be due to a number of reasons such as arthritis or adhesive capsulitis. Selective hypomobility is usually the result of a restriction of the joint capsule. An asymmetrical restriction of the capsule causes an obligate translation away from the side of the joint where the tightness is located. For example, a posterior capsule restriction causes an increase in anterior translation of the humeral head during cross-arm adduction and with flexion of the G-H joint.[45] T e posterior capsule restriction also results in a superior translation of the humeral head with flexion of the G-H joint.

Passive movement testing may be used to detect the direction of the hypomobility by examining the end-feel, and the amount of translation that occurs. Such tests include the load and shif test, the anterior release test, and the sulcus sign test.

ROM tests are used to determine the amount of internal and ER. There is a close association between the amount of IR at the G-H joint and the posterior shoulder capsule tightness.[475]

The intervention for this impairment includes a warm-up phase using a moist heating pad or upper-body ergometer. The patient is then taught the position to adopt to stretch the restricted portion of the capsule. The maximum stretch position is then maintained for approximately 20 minutes, or as long as the patient can tolerate, whichever occurs first. The patient is instructed to perform the warm-up and stretch at home. The duration of the stretch is gradually increased until the patient is able to tolerate the stretch position for 60 minutes per day.

The patient performs multiple angle isometrics or short-arc exercises in the newly acquired range to improve neuromuscular dynamic control. When full ROM has been restored, the patient performs full range resistive exercises and combinations of arm and trunk exercises, such as PNF.

According to Sahrmann, correction of resting scapular malalignment is always indicated in this patient population, particularly when the PROM is not restricted by more than 20 degrees.[215]

Downwardly rotated scapula

The G-H joint becomes the site of compensation because the scapula does not fully rotate upwardly.[215] The scapula should be constantly supported in its correct position by providing support for the arm. Exercise intervention should include strengthening for the serratus anterior and the trapezius. Stretching exercises are prescribed for those muscles found to be adaptively shortened in the examination. Those muscles usually include the rhomboid and levator scapulae.

Scapular Depression

This syndrome is characterized by weakness and lengthening of the upper trapezius.[215] It is often accompanied by adaptive shortness of the latissimus dorsi, pectoralis major, and pectoralis minor. When the scapula fails to elevate sufficiently during G-H flexion or abduction, the lower trapezius becomes more dominant than its upper counterpart. The intervention should focus on providing support for the shoulder so that it does not become depressed. The patient is instructed to perform shoulder shrugs with the G-H joint in its anatomic position and also with the shoulder flexed above 120 degrees. A mirror can be used to teach the patient to correct the depression of the shoulder girdle during arm elevation. Stretching exercises are prescribed for those muscles found to be shortened in the examination.

Scapular Abduction syndrome

This syndrome is characterized by excessive scapular abduction during G-H flexion or abduction.[215] It is also associated with a lengthening of the trapezius and possible lengthening of the rhomboid muscles and adaptive shortening of the serratus anterior, resulting in poor control of the scapula. Adaptive shortness of the deltoid or supraspinatus muscles can also indirectly hold the scapula in an abducted position. Intervention should focus on stretching the short G-H and thoracohumeral muscles and improving the performance of the adductor components of the lower and middle trapezius muscles.

Scapular Winging syndrome

This syndrome is characterized by an inability to elevate and/or lower the arm without the scapula winging or its inferior angle tilting. This syndrome results from a weakness and adaptive shortness of the serratus anterior, with accompanying shortness of the pectoralis minor and scapulohumeral muscles.

Intervention should focus on stretching the pectoralis minor to correct the tilting and serratus anterior for strengthening and retraining.

Humeral Anterior Glide syndrome

This syndrome is characterized by a humeral head that is positioned more than one-third anteriorly to the acromion, and which moves anteriorly during G-H abduction.[215] Other findings typically include relative tightness of the posterior capsule when compared with the anterior, weak or lengthened subscapularis, adaptive shortness of the scapulohumeral external rotators, and the pectoralis major.

Intervention should shorten and strengthen the subscapularis, and stretch the humeral external rotators and the pectoralis major.

Humeral Superior Glide syndrome

This syndrome is characterized by an excessive movement of the humeral head in a superior direction during G-H flexion, abduction, or elevation.[215] Clinical findings usually include adaptive shortness of the deltoid, weakness of the rotator cuff muscles, and adaptive shortness of the humeral internal and/or external rotators. Intervention focuses on the deltoid; increasing its length if shortened, and diminishing its activity if dominant. The patient should be instructed to avoid performing activities that involve ER in adduction as well as abduction exercises and resisted shoulder flexion with the elbow extended, as these can exacerbate the condition.

Glenohumeral instability

The structures involved in the maintenance of the static and dynamic stability of the shoulder, also provide neurologic feedback that mediates reflex stabilization around the joint.[476,477] Laxity is the physiologic motion and a necessary attribute of the G-H joint that allows normal ROM, which is normally asymptomatic.[366] Laxity is not always synonymous with instability.[478] It is a necessary attribute of the shoulder that permits motion. Instability is the abnormal symptomatic motion of the G-H joint that affects normal joint kinematics and results in pain, subluxation, or dislocation of the shoulder.[145,476,479,480]

In the early years of life, the G-H joint is fairly stable due to the active mechanisms stabilizing the joint. However, if an individual becomes deconditioned, the dynamic mechanisms become unable to provide support and the joint becomes involved in a self-perpetuating cycle of instability, less use, more shoulder dysfunction, and further instability. In addition to redundance of the shoulder capsule, underlying causes of G-H instability can include genetic, collagen, and biomechanical factors.[366]

There is considerable variation in the amount of translation normally elicited in an asymptomatic shoulder.[364,365,369,481] Shoulder laxity tests show that translations in the asymptomatic shoulder as compared with the contralateral symptomatic shoulder can be as large as 11 mm in one direction.[365,482] Although it has been shown that healthy shoulders can have asymmetric translation in at least one direction, no healthy shoulder is asymmetric in all three directions.[365]

Characteristic of G-H instability is the complaint of the shoulder "slipping" or "popping out" during overhead activities. Instability of the shoulder can be classified by frequency (acute or chronic), magnitude, direction, and origin.[76] Acute traumatic instability with dislocation of the shoulder is the most dramatic variety, and often requires manipulative reduction. Shoulder instability may also be classified according to the direction of the subluxation as either unidirectional (anterior, posterior, or inferior), bidirectional, or multidirectional. Posterior instability, which results either from avulsion of the posterior glenoid labrum from the posterior glenoid, or stretching of the posterior capsuloligamentous structures, is often difficult to diagnose with no single test having high sensitivity and specificity. Isolated inferior dislocations, also known as Luxatio erecta, are extremely rare, accounting for only 0.5% of all dislocations.[483131,184,484]

Most patients presenting with hypermobility or instability of the anterior G-H joint are athletic adolescents or young adults with joint laxity.[366,485] Anterior instability occurs when the abducted shoulder is repetitively placed in the anterior apprehension position of ER and horizontal abduction. Such individuals may have pain with overhead movements due to an inability to control the laxity through muscle support. They may develop enough instability directed superiorly that they present with impingement-like symptoms (instability–impingement overlap), especially in positions of abduction and ER.[486] In general, the patients have had normal asymptomatic shoulder function until some event precipitates symptoms. The event usually involves only relatively minor trauma when compared with the traumatic causes of unidirectional instability, or repetitive microtrauma as occurs in patients who participate in swimming and gymnastics.[286] The most common presenting complaint is pain.[487,488]

Unilateral dislocations occurring from acute traumatic events include the Bankart lesion or Hill–Sachs lesion. The Bankart lesion is an avulsion of the anterior inferior labrum from the glenoid rim and requires surgical stabilization (traumatic, unidirectional instability with Bankart lesion requiring surgery or TUBS), using the Bankart procedure, which addresses the lesion without significant loss of ER,[489] or a capsular reconstruction procedure.

CLiNiCAL PeArL

Multidirectional instability (see later) is often described using the abbreviation AMBRII (atraumatic onset of multidirectional instability that is accompanied by bilateral laxity or hypermobility. Rehabilitation is the primary course of intervention to restore G-H stability. However, if an operation is necessary, a procedure such as a capsulorrhaphy is performed to tighten the inferior capsule and the rotator interval).[490]

The Hill–Sachs lesion is a compression fracture of the posterior humeral head at the site where the humeral head impacted the inferior glenoid rim. Dislocation of the G-H joint is not uncommon in older people, although the incidence is less after 50 years of age.[204] Chronic recurrent dislocations of the shoulder can lead to degenerative arthritis. An older person who dislocates a shoulder is likely to have concurrently torn the rotator cuff and should be examined with this idea in mind.[491–493] Lesser traumatic injuries can cause subluxation of the shoulder to such a degree that recurrent subluxation rather than dislocation becomes the source of dysfunction.[145]

The predominant pattern of instability is best determined from the patient's medical history and provocative maneuvers on physical examination.[366] The mechanism for a subluxation or recurrent dislocation usually involves a FOOSH injury, whereby the arm is forced into abduction, extension, and ER. Due to the potential for nerve injury with these dislocations, a thorough neurovascular examination is essential.[76]

Anterior instability

Anterior instability of the G-H joint is the most common direction of instability. Repetitive overhead activities such as throwing can lead to microtrauma at the shoulder, leading to eventual breakdown of both the static and dynamic stabilizers of the joint, or G-H instability. Once the stability of the G-H joint has been compromised, the structures of the rotator cuff can become injured, resulting in a tear of one or more of the muscles. Patients who describe symptoms occurring in the abducted and externally rotated position have chronic anteroinferior instability.

The mechanism for an anterior dislocation is abduction, ER, and extension and is common in throwing and racquet sports, gymnastics, and swimming. Following an acute trauma, the patient typically complains of severe pain and a sense that the shoulder is "out." Radiographs confirm the dislocation, and reduction is often necessary. Frank anterior subluxation and dislocation of the G-H joint is rare in children but common in adolescents.[494] Severe pain causes the patient to immobilize the involved arm, in a slightly abducted and externally rotated position with the other hand. Spasm will typically occur to stabilize the joint. The humeral head will be palpable anteriorly and the posterior shoulder will exhibit a hollow beneath the acromion (see "Special Tests" section). In younger age groups (approximately 25 years and younger), the chance of recurrent anterior dislocation after the initial event is greater than 95%.[495] Recurrences are rare in patients older than 50 years of age.[480]

When anterior instability is suspected, the clinician should assess for tightness of the posterior capsule. Posterior capsule tightness has been shown to accentuate anterior translation and superior migration.[370] Loss of IR in young patients may be an important finding suggestive of posterior capsular contracture that is often associated with subtle instability.[206] The posterior joint glide is also restricted. Symptoms also include varying degrees of instability, transient neurologic symptoms, and easy fatigability.[488] Warner et al.[496] reported a lower IR-to-ER ratio for peak torque and total work in the dominant shoulder of patients with instability as compared with healthy controls. This suggests that an association exists between the relative IR weakness and anterior instability.[366]

SLAP Lesions

Athletes performing overhead movements, particularly baseball pitchers, may develop a "dead arm" syndrome[497] in which they have a painful shoulder with throwing and can no longer throw a baseball with their preinjury velocity. The main problem is usually a tear of the superior labrum, the so-called SLAP lesion.[1] SLAP lesions are described as superior labral lesions that are both anterior and posterior.[353] There are several injury mechanisms that are speculated to be responsible for creating SLAP lesions ranging from single traumatic events to repetitive microtraumatic injuries.[10] During a dislocation, tears to the glenoid labrum occur in isolation or in combination. The superior aspect of the labrum is more mobile and prone to injury due to its close attachment to the LHB tendon.[76] The lesion typically results from a FOOSH injury, sudden deceleration or traction forces such as catching a falling heavy object, or chronic anterior and posterior instability.[353,498]

Traumatic SLAP lesions can also develop in the nonathletic population.[498] This occurs as the result of a fall or motor vehicle accident (e.g., drivers who have their hands on the wheel and sustain a rear-end impact).

SLAP lesions have traditionally been classified into four main types[498] by signs and symptoms:

- *Type I.* This type involves a fraying and degeneration of the edge of the superior labrum. The patient loses the ability to horizontally abduct or externally rotate with the forearm pronated without pain.[499]
- *Type II.* This type involves a pathologic detachment of the labrum and biceps tendon anchor, resulting in a loss of the stabilizing effect of the labrum and the biceps.[500]
- *Type III.* This type involves a vertical tear of the labrum, similar to the bucket-handle tear of the knee meniscus, although the remaining portions of the labrum and biceps are intact.[76]
- *Type IV.* This type involves an extension of the bucket-handle tear into the biceps tendon, with portions of the labral flap and biceps tendon displaceable into the G-H joint.[76]

Maffet et al.[501] have suggested expanding the classification scale to a total of seven categories, adding descriptions for types V through VII.

- *Type V.* This type is characterized by the presence of a Bankart lesion of the anterior capsule that extends into the anterior superior labrum.
- *Type VI.* This type involves a disruption of the biceps tendon anchor with an anterior or posterior superior labral flap tear.
- *Type VII.* This is described as the extension of a SLAP lesion anteriorly to involve the area inferior to the middle G-H ligament.

Diagnosis of a SLAP lesion can often be difficult as the symptoms are very similar to those of instability and rotator cuff disease. No findings on physical examination have been found to be specific for identifying patients with a SLAP lesion. The patient typically complains of pain with overhead activities and symptoms of catching or locking.[502]

Several special tests can be used to help identify the presence of a SLAP lesion (see "Special Tests" section), including the O'Brien (active compression) test, the clunk test,[338,339] the crank test,[341] the Speed's test,[498] the Jobe relocation test, the biceps load test,[354] and the anterior slide test.[349]

Conservative intervention should address the underlying hypermobility or instability of the shoulder using dynamic stabilization exercises of the G-H joint to effectively return function and symptomatic relief to the patient (see "Intervention Strategies" section).

Arthroscopic labral debridement is not an effective long-term solution for labral pathology.[503]

Studies of surgical labral repairs are generally good to excellent in terms of returning patients to their prior level of activity, whether sports or work.[76,502,504,505]

Posterior instability

Posterior instabilities are rare and only comprise approximately 2% of all shoulder dislocations.[187] Posterior dislocations are often associated with seizure, electric shock, diving into a shallow pool, or motor vehicle accidents. Patients who have a posterior instability pattern typically report symptoms with the arm in a forward flexed, adducted position, such as when pushing open heavy doors. Posterior dislocations are classified as subacromial (posterior and inferior to the acromion process—the most common), subglenoid (posterior and inferior to the glenoid rim), and subspinous (medial to the acromion and inferior to the scapular spine).[76]

The most characteristic sign for a posterior dislocation is a loud clunk as the shoulder is moved from a forward flexed position into abduction and external rotation, a positive finding that is often misdiagnosed as an anterior dislocation. The findings for a posterior dislocation are usually severe pain, limited ER, often to less than 0 degree, and limited elevation to less than 90 degrees. There is usually a posterior prominence and rounding of the shoulder as compared to the opposite side, and a flattening of the anterior aspects of the shoulder. Looking down at the patient's shoulders from behind can best assess these asymmetries.

inferior instability

Inferior dislocations are very uncommon and are typically elicited by carrying heavy objects at one's side (i.e., grocery bags or a suitcase), or by hyperabduction forces that cause a levering of the humeral neck against the acromion.[479,503]

The diagnosis for this type of dislocation is relatively straightforward, as the patient's arm is typically locked in abduction.[76] The sulcus sign can be used to assess inferior stability.

multidirectional instability

Multidirectional instability is a symptomatic G-H instability that is present in more than one direction.[479] It is commonly believed that females have more joint laxity than males, a fact propagated by the medical literature and medical training.[366] In describing multidirectional instability of the shoulder, a typical patient is presented, as "an adolescent female who can habitually and reproducibly sublux one or both shoulders."[484] However, with the exception of a few articles, there is inadequate evidence to confirm this view. One of the exceptions was a recent study by Borsa et al.,[506] which demonstrated that healthy women have significantly more anterior joint laxity

and less anterior joint stiffness than do men. Another study by Huston and Wojtys[507] used an instrumented arthrometer to assess knee joint laxity in athletic and nonathletic men and women. Overall, they found women to have significantly more knee joint laxity than men. Interestingly, they found that athletic women had significantly less knee joint laxity than nonathletic women did, and athletic men had significantly less knee joint laxity than nonathletic men. These findings imply that physical training and conditioning may decrease joint laxity.[506]

The patient with a multidirectional instability is difficult to diagnose as there is usually no associated traumatic event or mechanism of injury. Rotator cuff pain is often the first presenting symptom. Patients with multidirectional instability typically have scapulothoracic dyskinesia that contributes to the instability.[290]

Lephart et al.[508] showed that patients with multidirectional instability also have deficits in shoulder proprioception. Therefore the intervention for patients with instability should begin with a rehabilitation program aimed at improving the dynamic stabilizers, neuromuscular coordination, and proprioception of the G-H and scapulothoracic joints.[24,366,509]

Intervention

Intervention goals for G-H instability or hypermobility are similar regardless of the instability classification. The goal is to restore dynamic stability and control to the shoulder using the dynamic stabilizers to contain the humeral head within the glenoid.[19,115,187,486,509]

A brief period of sling immobilization is usually necessary for comfort. Prolonged immobilization should be avoided because of the tendency of the shoulder to stiffen quickly, especially in the elderly population.[204] For patients with an anterior instability, ROM exercises for the G-H joint should emphasize posterior capsule stretching to decrease the accentuation of the anterior translation and superior migration. The positions and exercises to modify or avoid based on the direction of instability are illustrated in Table 16-37.[510]

The general approach for all forms of G-H instability includes the following:

- Scapular stability exercises. These can be started early and include the scapular pinch (see Fig. 16-27) and shoulder shrug exercises.[24] In this early stage, the control of the scapula position can be aided by taping the scapular in a retracted or elevated position, or by the use of a figure-8 collar, both of which help to normalize the scapular muscle firing pattern.[24]
- Closed-chain exercises. These are normally performed with the hand stabilized on a wall or object, simulate normal functional patterns, and reorganize and reestablish normal motor firing patterns.[24,141,146,289] All of the movements of the scapula and shoulder are coupled and are predictable based on arm position.[153,511] Similarly to the lower extremity, closed-chain exercises should involve integration of all the joints in the appropriate kinetic chain with the specific scapular maneuvers of elevation, depression, retraction, and protraction.[24]
- Early exercises to rehabilitate scapular dyskinesis. These include modified push-ups, and progress to facilitation patterns that include hip extension, trunk extension, and scapular retraction.[410] Clock exercises, in which the hand is placed on a wall and the scapula is rotated in elevation/depression and retraction/protraction, also develop coordinated patterns for scapular control.[410]

Open-chain exercises follow the isometric and closed-chain activities as these exercises are more strenuous.[24] Open-chain exercises include PNF patterns, diagonals, upright rows, and ER and scapular retraction activities, as well as machine exercises consisting of lat pull-downs.[24]

Progression of the scapular rehabilitation can be evaluated using the scapular slide measurements, and once the lateral slide asymmetry is less than 1 cm, specific strengthening for the rotator cuff can commence.[24]

Besides rehabilitation, activity modifications to avoid any arm positions that provoke symptoms can be helpful.[366]

Sprained Conoid and Trapezoid Ligaments

A sprain of these ligaments can result from a clavicular fracture, but it can also occur in sports that require the arm to be pulled into the extremes of extension or ER. Pain is felt at the extremes of all passive arm and scapula movements. Forced ER with the arm in horizontal abduction will usually be the most painful test, and differentiation between the two structures is made by palpation of the coracoid process. No limitation of active shoulder range is usually found and resistive movements are painless.

Interventions for these ligament sprains include electrotherapeutic modalities and physical agents, transverse friction massage (TFM), and progression of ROM of the shoulder complex and strengthening of the G-H muscles and scapular pivoters.

TABLE 16-37 Exercise Modification According to the Direction of Glenohumeral Instability

Direction of Instability	Position to Avoid	Exercises to Modify or Avoid
Anterior	Combined position of external rotation, extension, and abduction	Chest press, pull-down, push-up, bench press, military press, flyes
Posterior	Combined position of horizontal adduction, internal rotation, and flexion	Chest press, push-up, bench press, flyes, weight-bearing exercises
Inferior	Full elevation, dependent arm	Shrugs, elbow curls, incline press, military press

Acromioclavicular Joint sprain

An injury to the A-C joint, which can be categorized as either acute traumatic or chronic, is reported to be present in 31% of all patients with shoulder pain.[204,512] The majority of acute traumatic injuries occur from a fall onto the shoulder with the arm adducted at the side. The ground reaction force (GRF) produces displacement of the scapula in relation to the distal clavicle. The chronic disorder may be atraumatic or posttraumatic, with the former being attributed to generalized osteoarthritis, inflammatory arthritis, or mechanical problems of the meniscus of this joint.[70] Injuries to the A-C joint were originally classified by Tossy et al.[513] and Allman et al.[87] as incomplete (grades I and II) and complete (grade III). This classification has been expanded to include six types of injuries based on the direction and amount of displacement (Table 16-38).[81,514–516] As with the S-C joint, A-C joint injuries are classified according to ligamentous injury rather than injury to the joint itself:

- *Type I.* Tenderness and mild pain at the A-C joint. Sometimes there is a high, painful arc (160–180 degrees), and resisted adduction is painful.
- *Type II.* Moderate to severe local pain with tenderness in the coracoclavicular space. The clavicle may appear to be slightly higher than the acromion, although in reality the opposite is true. All passive motions are painful at the end of ROM, and usually both resisted adduction and abduction are painful. Passive posteroanterior translation at the A-C joint is greater than that of the opposite joint.
- *Type III.* The patient usually holds the arm against the body in a slightly adducted position and exerts an upward axial pressure through the humerus. An obvious gap is visible between the acromion and the clavicle. All active motions are painful, especially abduction. The piano key phenomenon is present; after pushing the clavicle inferiorly, it springs back to its original position.
- *Type IV.* Similar findings as those of type III, except the pain is severe and the clavicle is displaced posteriorly.
- *Type V.* There is a large distance between the clavicle and coracoid process and there is tenderness to palpation over the entire lateral half of the clavicle.
- *Type VI.* The superior aspect of the affected shoulder is flatter than the noninvolved side. Often there are associated fractures of the clavicle and upper ribs, as well as injury to the brachial plexus.

Types I–III and V all involve inferior displacement of the acromion with respect to the clavicle. They differ according to the severity of ligamentous injury and the amount of resultant displacement.[517]

Types I and II typically result from a fall or a blow to the point on the lateral aspect of the shoulder, or a FOOSH injury.

Types III and IV usually involve a dislocation (commonly referred to as an A-C separation) and a distal clavicle fracture, both of which commonly disrupt the coracoclavicular ligaments.[70] In addition, damage to the deltoid and trapezius fascia, and rarely the skin, can occur.[70]

Type IV injuries are characterized by posterior displacement of the clavicle.

Type VI injuries have a clavicle inferiorly displaced into either a subacromial or subcoracoid position. These types (IV, V, VI) also have complete rupture of all the ligament complexes and are much rarer injuries than types I through III.[70]

In the pediatric patient, A-C sprains are usually grade I or II and may occur without clavicular fracture.[494] Grade III sprains in this population commonly rupture the posterior (dorsal) clavicular periosteum. However, the coracoclavicular ligaments and A-C ligaments remain intact.[494]

The clinical findings are based on injury severity (Table 16-38). Patients who have suffered an injury to the joint typically present with a history of either a distinctive, traumatic mechanism of injury or a more insidious type of onset that began with pain and dysfunction.[72] The joint is quite superficial and direct palpation is accomplished easily. The patient may report that the arm feels better with a superiorly directed support on the arm, such as a sling. Pain is typically reproduced at the end range of passive elevation, passive ER and IR, and especially with passive horizontal adduction, across the chest. This is cross-arm test compresses the A-C joint and is highly sensitive for A-C joint pathology.[70,75,81,518] The ROM available depends on the stage of healing and severity. In the very acute stage, range may be limited by pain, whereas the less acute stage will be painful at the end of range in full elevation or horizontal adduction. Pain, crepitus, or hypermobility may be encountered with mobility testing. Resistive movements are usually painless. It is important to assess for secondary injury to the surrounding soft tissues and to the other three articulations of the shoulder complex when there is a history of trauma to the A-C joint.

A complete radiographic examination including a 15-degree-superior A-P view, a lateral Y view, and an axillary film should confirm the diagnosis.[70]

The intervention for A-C joint sprains depends on the severity of the injury and the physical requirements of the patient.

- *Types I and II.* These patients will usually recover full and painless function with conservative intervention.[75] Although adhesive taping devices and orthotics have been used in the early phase after injury to attempt reduction of the clavicle in the type II injury, they have not demonstrated efficacy in any good experimental trials.[70] Ice, nonsteroidal anti-inflammatories, and analgesics should be used judiciously. Most physicians prescribe a sling for 1–2 weeks. Gentle ROM exercises and functional rehabilitation are started immediately following immobilization, and then isometric exercises are prescribed for those muscles with clavicular attachments. These exercises are progressed to PREs for the muscles that attach to the clavicle and the scapular pivoters. A graduated return to full activity is very important. Most patients will be back to full sport/occupation participation within 12 weeks, although they may have a slight cosmetic deformity.[70]
- *Type III.* The intervention for type III injuries is controversial.[70] A survey of orthopaedic residency programs in 1992 revealed that 86.4% preferred conservative intervention.[519] The natural history of this injury with conservative intervention suggests that patients have no long-term difficulty with pain or

TABLE 16-38	Classification of A-C Injuries and Clinical Findings
Type I	Isolated sprain of acromioclavicular ligaments Coracoclavicular ligaments intact Deltoid and trapezoid muscles intact Tenderness and mild pain at A-C joint High (160–180 degrees) painful arc Resisted adduction is often painful Intervention is with TFM, ice, and pain-free AROM
Type II	A-C ligament is disrupted Sprain of coracoclavicular ligament A-C joint is wider; may be a slight vertical separation when compared to the normal shoulder Coracoclavicular interspace may be slightly increased Deltoid and trapezoid muscles intact Moderate-to-severe local pain Tenderness in coracoclavicular space PROM all painful at end range with horizontal adduction being the most painful Resisted abduction and adduction are often painful Intervention initiated with ice and pain-free AROM/PROM; TFM introduced on day 4
Type III	A-C ligament is disrupted A-C joint dislocated and the shoulder complex displaced inferiorly Coracoclavicular interspace 25–100% greater than normal shoulder Coracoclavicular ligament is disrupted Deltoid and trapezoid muscles are usually detached from the distal end of the clavicle A fracture of the clavicle is usually present in patients under 13 yr of age Arm held by patient in adducted position Obvious gap visible between acromion and clavicle AROM all painful; PROM painless if done carefully Piano key phenomenon (clavicle springs back after being pushed inferiorly) present
Type IV	A-C ligament is disrupted A-C joint dislocated and the clavicle anatomically displaced posteriorly into or through the trapezius muscle Coracoclavicular ligaments completely disrupted Coracoclavicular interspace may be displaced but may appear normal Deltoid and trapezoid muscles are detached from the distal end of the clavicle Clavicle displaced posteriorly; Surgery indicated for types IV–VI
Type V	A-C ligaments disrupted Coracoclavicular ligaments completely disrupted A-C joint dislocated and gross disparity between the clavicle and the scapula (300–500% greater than normal) Deltoid and trapezoid muscles are detached from the distal end of the clavicle Tenderness over entire lateral half of the clavicle
Type VI	A-C ligaments disrupted Coracoclavicular ligaments completely disrupted A-C joint dislocated and the clavicle anatomically displaced inferiorly to the clavicle or the coracoid process Coracoclavicular interspace reversed with the clavicle being inferior to the acromion or the coracoid process Deltoid and trapezoid muscles are detached from the distal end of the clavicle Cranial aspect of shoulder is fatter than opposite side; Often accompanied with clavicle or upper rib fracture and/or brachial plexus injury

AROM, active range of motion; PROM, passive range of motion; TFM, transverse friction massage.
Data from Allman FL. Fractures and ligamentous injuries of the clavicle and its articulation. J Bone Joint Surg Am. 1967;49:774–784; Rockwood CA Jr, Young DC. Disorders of the acromioclavicular joint. In: Rockwood CA Jr, Matsen FA III, eds. The Shoulder. Philadelphia, PA: WB Saunders; 1990:413–468.

loss of function.[520–524] A more recent study[525] found no strength deficits at follow-up, although discomfort at higher levels of activity was more pronounced. There is a reported high complication rate with attempts at surgical stabilization.[526,527] Citing the concern regarding greater displacement, some authors have proposed surgical intervention, but there have been several controlled comparative studies[518,526,527] that suggest that conservative intervention gave results comparable to those of surgically treated patients, but without surgical complications.[70]

A reasonable approach would be to initially treat all types conservatively with sling immobilization, followed by supervised rehabilitation.[70] Once the sling is removed, pendulum exercises can be initiated. PROM in the extremes of motion are avoided for the first 7 days, but the goal should be for full PROM after 2–3 weeks. A graduated resistance exercise program is initiated once pain is improved and AROM is full. These exercises should emphasize strengthening of the deltoid and upper trapezius muscles and promote dynamic stabilization of the shoulder complex.[208] Full return to sport is expected by 6–12 weeks.[70] If patients are still functionally limited after more than 3 months, a secondary reconstructive procedure may be necessary.[70]

- *Types IV, V, and VI.* These types of displacement all require surgical intervention as failure to reduce these and repair them may lead to chronic pain and dysfunction.[70,75,70] The greater displacement and injury includes damage to the deltoid and trapezius muscle and fascia. The most common operative approach is a distal clavicle excision, or Mumford procedure. The postsurgical progression involves gaining pain-free ROM prior to advancing to exercises to regain strength, manual techniques to normalize arthrokinematics, and functional training to improve neuromuscular control of the shoulder complex.

Late complications, including degenerative changes of the distal clavicle, can develop with a subluxed clavicle.[70] Symptoms may be treated with the selective use of modalities and steroid injections. If this conservative approach fails, then the patient should be considered as a surgical candidate.[70]

Acromioclavicular Joint Arthrosis

A-C joint arthrosis may be degenerative or posttraumatic. It is most commonly seen in middle-aged patients, either as an isolated entity or in combination with rotator cuff tendinopathy and impingement syndrome.[70,75]

A-C joint arthrosis is diagnosed by the history and physical examination. Patients typically complain of pain locally or distributed to the anterolateral neck, the trapezius–supraspinatus region, and the anterolateral deltoid.[528] This pain is usually exacerbated with overhead and/or flexed and adducted positions of the arm.[70] Direct palpation to the A-C joint will sometimes reproduce the patient's pain. Impingement of the rotator cuff must be ruled out. The selective use of cortisone injections into the A-C joint or the subacromial space can be applied to help differentiate A-C pain from rotator cuff tendinopathy and treat both of these conditions.[70,75]

Conservative intervention consists of rest, modification of activity, and NSAIDs. Electrotherapeutic modalities and cryotherapy may be used to control pain and the active inflammation. Joint mobilizations of grade I or II may also be used to decrease pain. Once pain and inflammation are under control, the rehabilitation progresses to strengthening of the dynamic restraints of the A-C joint (primarily the deltoid, trapezius, and pectorals).[75,208] Any activities involving raising the arm above the level of the shoulder or reaching across the chest should be avoided as these will tend to aggravate the A-C joint.[204]

sternoclavicular Joint sprain

The S-C joint can sustain sprains, dislocations, or other injuries, but is less involved than the A-C joint with osteoarthritis or mechanical conditions.[204] Posterior S-C dislocations, although rare, are frequently delayed in their diagnosis, and can even be life-threatening due to the pressure placed on many vital structures lying between the sternum and the cervical spine such as the trachea, esophagus, and major blood vessels.[195] However, most of these dislocations occur anteriorly and are more obvious.

Any trauma to the shoulder girdle may cause an S-C dislocation, although the joint is most commonly injured through motor vehicle accidents, followed by sports.[529] In sports, the mechanism of injury is usually secondary to a FOOSH with the arm in either a flexed and adducted position, or extended and adducted position.[486] The well-developed interarticular meniscus can be torn and can lead secondarily to degenerative changes. Irritation of this joint may also occur in inflammatory conditions, such as rheumatoid arthritis or repetitive microtrauma.[197] Infection of this joint usually indicates a systemic source, such as bacterial endocarditis.[204]

An injury to the S-C joint can be significant because the joint plays an integral role in scapular motion through the clavicle's articulation with the scapula. Subjectively, the patient reports discomfort with end-range movement of the shoulder. S-C injuries are graded according to severity of injury to the ligament supporting the joints rather than injury to the joint itself.[65]

- *Type I.* Sprain of S-C ligament.
- *Type II.* Subluxation, partial tear of capsular ligaments, disk, or costoclavicular ligaments.
- *Type IIA.* Anterior subluxation; this is the most common grade.
- *Type IIB.* Posterior subluxation.[197]
- *Type IIIA.* Anterior dislocation.
- *Type IIIB.* Posterior dislocation.
- *Type IV.* Habitual dislocation (rare).

The clinical presentation for S-C sprains are characterized by deformity, local pain or tenderness, and subsequent ecchymosis. With a posterior dislocation or subluxation, some shortness of breath or even venous congestion in the neck may be seen, with decreased circulation sometimes evident in the arm.[72]

Chronic subluxation or damage to the intra-articular disk can produce long-term discomfort with repetitive strong movements of the upper limb and therefore may require surgical stabilization of the S-C joint.[72]

T e conservative intervention for first- or second-degree sprains (providing that the joint is deemed stable) is aimed at addressing the function of the shoulder complex, particularly the end ranges, and is dependent on the cause. Typically the shoulder is immobilized for 3–4 days, as pain dictates. In more severe sprains (second- or third-degree sprain with instability following reduction), a shoulder sling or figure-8 strap is worn for 2–3 weeks to minimize stress on the joint, and then the arm may be protected for a further 2 weeks.

- Appropriate modalities are used to control pain and the inflammatory process.
- ROM exercises are initiated early, and care is taken to avoid excessive movement at the S-C joint. Initially, until the pain and inflammation is under control, activities should be limited to midrange. ROM is increased based on patient tolerance.
- Any hypomobilities of the neighboring joints are addressed using specific mobilizations of an appropriate grade.
- In cases with residual ligamentous laxity, stabilization exercises should focus on strengthening those muscles that attach to the clavicle (pectoralis minor, sternal fibers of the pectoralis major and upper trapezius), performed within ranges that do not stress the joint. Exercises include incline bench, shoulder shrugs, and the seated push-up.[530] T e scapular pivoters should also be strengthened. For example, exercises such as Superman, bent over row, rhomboids, and push-ups with a plus should be included.[530]
- Return to normal activity is permitted when the patient no longer has associated pain with movements of the shoulder complex, and the rehabilitation program has been progressed to the appropriate level of stress for the specific demands of the patient's activity.

Complications of anterior S-C dislocation include cosmetic deformity, recurrent instability, and late osteoarthrosis.[72] Complications of posterior dislocation include all of these plus pressure or rupture of the trachea, pneumothorax, rupture of the esophagus, pressure on the subclavian artery of brachial plexus, voice changes, and dysphagia.[72]

Total shoulder Arthroplasty

A total shoulder arthroplasty (TSA), in which the glenoid and humeral surfaces are replaced, is a surgical option typically reserved for elderly patients with cuff-deficient arthritic shoulders.[531] Other patients who may require a TSA include those with bone tumors, rheumatoid arthritis, Paget's disease, osteonecrosis of the humeral head, fracture dislocations, and those who incur recurrent dislocations.[532,533] A reverse TSA (rTSA), is designed to reverse the ball and socket location of the native shoulder, and is typically used when the rotator cuff integrity is compromised. A hemireplacement arthroplasty (hemiarthroplasty), is used when one surface, the humeral head, is replaced.

T e primary indication for surgical intervention is complaints of unremitting pain, rather than decreased motion, and a failure of conservative measures. Additional considerations include patient age, activity level, job requirements, and general health.[531]

A course of preoperative intervention is recommended. T is should include an assessment of ROM, scapular mobility, muscle imbalances, and pain. T e key muscles to examine preoperatively for strength include the rotator cuff, deltoid, trapezius, rhomboids, serratus anterior, latissimus dorsi, teres major, and pectoralis major and minor.[261] T e patient should be provided with exercise instruction and patient education on postsurgical precautions. A course of shoulder stretching before a prosthetic arthroplasty may improve postsurgical function.[534]

T e TSA is a very difficult procedure, and the outcome depends on the skill of the reconstruction, the sof -tissue repair, the orientation of the implants, and the success of the rehabilitation.[420,532,535,536] T e total shoulder replacement provides significantly greater pain relief than hemiarthroplasty, with approximately 80% of patients reporting pain relief af er hemiarthroplasty versus more than 90% af er shoulder replacement.[536]

Four types of replacement components have traditionally been used:

1. Unconstrained. T is is the most widely used component and consists of a modular inert humeral component that exists with a high-density polyethylene glenoid component.
2. Constrained. T is type, in which the glenoid and humeral components are coupled and fixed to bone, was designed for patients who had severe deterioration of the rotator cuff but with a functioning deltoid. However, due to the high rate of associated complications, it is rarely, if ever, used nowadays.
3. Reversed ball and socket. T is design consists of a small humeral socket that slides on a larger ball-shaped glenoid component.
4. Semiconstrained. T is type involves the use of a smaller and spherical humeral head with a head–neck angle of 60 degrees, which reportedly permits increased ROM.

Although surgical techniques vary, most involve the dissection of the subscapularis or a rotator cuff repair, or a combination of both. T e patient is usually placed in a sling or an elastic shoulder immobilizer following the operation that positions the humerus in adduction, IR, and slight forward flexion. An abduction splint may be issued if a rotator cuff repair is performed and is worn for 4–6 weeks, according to the surgeon's instructions. Goals for postoperative ROM are based on intraoperative ROM measurements.

T e long-term outcome following shoulder arthroplasty depends on many factors including the quality of the sof tissue (especially the integrity of the rotator cuff), the quality of the bone, the type of implant and fixation used, the patient's expectations, and the quality of the rehabilitation program.[261] Most surgeons have their own postsurgical rehabilitation protocols—only the surgeon knows the extent of sof -tissue damage and repair, and any guidelines communicated to the clinician must be strongly adhered to. Typically, the only motions not allowed in the early weeks are active IR and active and passive ER beyond 35–40 degrees.

PATTeR N 4e: imPAir eD JOiNT mOBiLiTY, mOTOr FUNCTiON, mUs CLe Per FOr mANCe, r ANGe OF mOTiON WiTh LOCALiZeD iNFLAmmATiON

In addition to those conditions producing impaired ROM, motor function, and muscle performance attributed to inflammation, this pattern includes conditions that cause pain and muscle guarding without the presence of structural changes. Such conditions include rotator cuff tears, tendinopathy, bursitis, capsulitis, and tenosynovitis.

r otator Cuff Pathology

Fif y to seventy percent of shoulder issues seen by clinicians are related to conditions of the rotator cuff (RC).[537,538] T e frequency of RC problems is not surprising as these structures play an essential role in supporting the shoulder capsule and holding the humeral head in proper alignment in the glenoid cavity. Problems can occur from a number of sources including trauma, attrition, and the anatomical structure of the subacromial space. T e supraspinatus is the tendon most of en affected because of its location beneath the anterior acromion, and its extensions into the infraspinatus tendon that may also become involved.[539,540] Significant tears of the RC rarely involve the subscapularis tendon.[539,540]

A number of mechanisms are recognized and include compression, tensile overload, and macrotrauma.

- Compression. Compression of the RC can either be primary or secondary. Primary compression is due to a reduction in the size of the subacromial space (e.g., a type III hooked acromion process or a congenitally thick coracoacromial ligament in younger patients, or an osteophyte on the undersurface of the acromion process in the older patient). Secondary compression occurs as a result of a decrease in G-H joint stability that allows the humeral head to compress the RC.
- Tensile overload. Tensile overload can also be either primary or secondary. Primary tensile overload occurs when the RC attempts to resist horizontal adduction, IR, anterior translation, and distraction forces during such activities as throwing (the deceleration phase) and hammering. Secondary tensile overload occurs as a result of G-H instability that places greater distractive and tensile forces on the RC, and eventual failure of the tendon.
- Macrotrauma. Macrotrauma and subsequent tearing of the tendon results when the forces generated by the trauma exceed the tensile strength of the tendon. RC tears are not as common in the skeletally immature athlete as in the elderly athlete. Indeed, the incidences of RC tear increases with age. Approximately 50% of individuals older than 55 years demonstrated an arthrographically detectable RC tear.[541] Although cadaver studies of individuals older than 40 years have generally shown a prevalence of full-thickness RC tears between 5% and 20%,[542] the prevalence of partial-thickness RC tears has been shown to be in the 30–40% range in adult cadavers.[542]

A detailed history is important to diagnose an RC injury and the cause, and it can help to determine whether the patient's symptoms are related to repetitive motion, following a specific injury or event, or are of a more insidious onset (e.g., referred symptoms of cardiac origin, or referred symptoms from the cervical spine). Activities and arm positions that increase or decrease symptoms are also helpful in diagnosing and guiding treatment. Prior episodes of similar symptoms may give a useful clue to the patient's present condition. A social history should include the patient's occupation and sport (including position), and level of athletic participation. T e presence of associated symptoms (e.g., loss of motion, weakness, instability, numbness, swelling, catching of the shoulder) also provides helpful information.

Pain, weakness, and loss of shoulder motion are common symptoms reported with RC pathology. T e patient complains initially of a dull ache radiating into the upper and lower arm. T is ache is worse af er activity, at night when the patient lies on the affected shoulder, and with actions such as reaching above the head or putting on a coat. T e characteristic physical finding is the painful arc. T e pain may begin around 50–60 degrees of abduction in patients with shoulder immobility.

In elderly patients, symptoms are of en insidious and with no specific injury.

T e clinician can of en determine the involved tendon by resisting the AROM of each tendon.

Palpable anterior tenderness over the coracoacromial ligament is common with impingement.[28,543] Tenderness of the biceps tendon and at the supraspinatus insertion is also commonly found.

Patients with a painful arc and the above history, but no pain to resisted shoulder movements, are likely to have subacromial–subdeltoid bursitis.[204]

A study by Park et al.[324] evaluated eight physical examination tests for RC pathology (the Neer impingement sign, Hawkins–Kennedy impingement sign, painful arc sign, supraspinatus muscle strength test, Speed's test, cross-body adduction test, drop-arm sign, and infraspinatus muscle strength test) to determine their diagnostic values, including likelihood ratios and posttest probabilities, for three degrees of severity in RC disease: bursitis, partial-thickness RC tears, and full-thickness RC tears. T e sensitivity, specificity, positive predictive value, negative predictive value, and overall accuracy of the eight tests varied considerably—the combination of the Hawkins–Kennedy impingement sign, the painful arc sign, and the infraspinatus muscle test yielded the best posttest probability (95%) for any degree of impingement syndrome. T e combination of the painful arc sign, drop-arm sign, and infraspinatus muscle test produced the best posttest probability (91%) for full-thickness RC tears.[324] T e study concluded that the severity of the impingement syndrome affects the diagnostic values of the commonly used clinical tests and that the variable accuracy of these tests should be taken into consideration when evaluating patients with symptoms of RC disease.[324]

RC tears are described by size, location, direction, and depth.

Weakness to some extent always accompanies RC tears. T e amount of weakness is directly related to the size of the tear.[1] For example, with small tears, the weakness may not be

detected and the patient may have full ROM, although there may be a painful arc. Massive tears of the RC present with sudden profound weakness with an inability to raise the arm overhead, and exhibit a positive "drop-arm" sign (see "Special Tests" section).[544] In this situation, infiltration of the subacromial space with a local anesthetic may eliminate the pain and allow more accurate testing of the muscle–tendon unit. The use of corticosteroid injections for RC tears to promote healing is controversial because of their association with weakening the integrity of tendons with repeated use. Some studies have supported this belief,[38,545–547] although only one case of RC rupture following steroid injection has been reported in the literature.[545] Two recent studies have demonstrated that corticosteroid injections are more effective than anti-inflammatory drugs in the management of RC problems.[548,549] However, if the patient has not responded to 1–2 well-placed injections, either other intervention modalities should be considered or the diagnosis questioned.

Acute massive tears require prompt evaluation for surgical repair because little is known about the efficacy of conservative intervention.[1,304,550–557] However, the patient may decide against surgery for various reasons, including concerns about a successful repair, surgical risks, or lack of functional improvement.[558] The conservative program for full-thickness RC tears is directed toward stretching and strengthening the remaining RC, deltoid, pectoralis major, and trapezius muscles.[538,559] The postsurgical approach is initiated with some form of immobilization that restricts positions based on the surgical repair, and promotes pain control. For example in open repairs, flexion, and abduction might be restricted for as long as 4 weeks, or if the capsulolabral complex has been repaired the patient might spend up to 2 weeks in an airplane or ablation splint.[530] Exercises in the early phase include shoulder shrugs, isometrics, and then AAROM exercises. Once the subacute stage of healing has been achieved, the focus of the rehabilitation program is to regain full ROM and to gradually increase the stress to healing tissue. At this stage, AROM exercises are initiated before progressing to gradual resistance using surgical tubing with a focus on the restoration of normal arthrokinematics and a normal scapulothoracic rhythm.[530] The rehabilitation during the final stage of healing mirrors that of conservative management.

The conservative intervention for patients with a partial tear varies. If the symptomatic tear is partial, then a period of conservative intervention should be attempted.[538,560–562]

- Stage I. The focus of early rehabilitation is the reduction of pain and inflammation through modalities, activity modifications, and NSAIDs prescribed by the physician. Jobe and Nuber[165] describe a program of kinesiologic repair that strengthens the RC (to increase the depressor effect on the humeral head) and the scapular pivoters, but avoids any increase in the elevating effect of the deltoid. The mainstays of this strengthening program are the IR and ER exercises (Table 16-39).[259] These are initially performed as isometric exercises at various parts of the range. Once these are tolerated well, concentric exercises of the scapular pivoters are introduced beginning with manual resistance and progressing to free weights (see "Intervention Strategies" section). Care should be taken with exercises that involve the use of weights with the arm flexed or abducted away, or overhead, as these may exacerbate supraspinatus impingement and tendinopathy symptoms if performed in the early stages of rehabilitation. The exercises prescribed should be as specific as possible, and tailored to the patient's functional and athletic goals. The lower extremity and trunk muscles that provide core stability should also be strengthened. Deficits in strength, strength imbalances, and flexibility in the legs, hips, and trunk should be addressed. This is particularly so in throwing athletes, where restrictions of the hip and back motion are common.[34,47,142,146]

Manual techniques can be used to address any tightness in the capsule (usually the posterior and inferior aspects) or motion restrictions of the S-C or A-C joints (see "Therapeutic

TABLE 16-39 Specific Strengthening Exercises for the Shoulder Girdle

Muscle	Exercise
Middle trapezius	Prone row Prone horizontal abduction with the arm and 90-degree abduction with ER
Lower trapezius	Prone horizontal at 90-degree abduction with ER Prone full can Prone ER at 90-degree abduction Bilateral ER
Upper trapezius	Shoulder shrugs Prone row Prone horizontal abduction at 90-degree abduction with ER
Supraspinatus	Full can Prone full can
Infraspinatus and teres minor	Sitting, external rotation of the arm with a towel roll Sidelying external rotation Prone ER at 90-degree abduction
Rhomboids and levator scapulae	Prone row Prone horizontal abduction at 90-degree abduction hip ER Prone extension with ER
Serratus anterior	Dynamic hug Push-up with plus Serratus punch 120 degrees
Subscapularis	Lift-off (Gerber) IR at 0-degree abduction IR at 90-degree abduction IR diagonal exercise Shoulder dumps
Deltoid	Sidelying, 45-degree abduction

TABLE 16-40 Classification of Different Shoulder Impingement Syndromes

Based on the Stage of Pathology[a]	Based on Direction of Instability	Based on Progressive Microtrauma[b]
Stage I. Edema, hemorrhage (patient usually <25 yr) Stage II. Tendinitis/bursitis and fibrosis (patient usually 25–40 yr) Stage III. Bone spurs and tendon rupture (patient usually >40 yr)	Unidirectional instability (anterior, posterior, or inferior) with or without impingement Multidirectional instability with or without impingement	Group IA: This group, typically found in the older population, encompasses those patients with pure and isolated impingement and no instability Group IB: This group, typically found in the older population, encompasses those patients with instability secondary to mechanical trauma Group II. Patients in this group, who are usually young (<35 yr) overhead athletes, demonstrate instability with impingement secondary to microtrauma that comes from overuse Group III. Patients in this group, who are also typically young overhead athletes, demonstrate atraumatic, generalized ligamentous laxity Group IV. Patients in this group are young (<35 yr) who have experienced a traumatic event, resulting in instability in the absence of impingement

[a]Neer C. Impingement lesions. Clin Orthop Relat Res. 1983; 173:71–77.
[b]Kvitne RS, Jobe FW, Jobe CM. Shoulder instability in the overhead or throwing athlete. Clin Sports Med. 1995;14:917–935.

Techniques" section). The patient should be instructed on how to perform an isolated posterior capsule stretch.

- Stage II. Restoration of ROM using exercises, stretching techniques, and self-mobilization. During this stage, the patient should be exercising with free weights, with an emphasis on eccentric exercises of the RC. Concentric exercises for the upper trapezius and deltoid are added. These include shoulder flexion and reverse flyes. The serratus anterior is strengthened using push-ups and the push-up plus. Neuromuscular retraining exercises for the shoulder complex include rocking on all fours, and the Fitter board, as appropriate. Plyometric exercises using small medicine balls and push-ups with a hand clap are also included during this stage as appropriate. Neuromuscular techniques can also be applied manually and include quick reversals during PNF patterns. Other manual techniques include stretching of the capsule and any other pericapsular structures that appear tight.
- Stage III. PNF diagonal patterns are initiated in this stage in addition to eccentric exercises of the RC. Typical exercises performed in this stage include the military press, reverse flies, and push-ups.
- Stage IV. Plyometric strengthening and sport/activity specific training with a gradual return to normal activity.

subacromial impingement syndrome

SIS is a recurrent and troublesome condition closely related to RC disease.[563] In the presence of a normal RC, normal scapular pivoters, and no capsular contractures, the humeral head translates less than 3 mm superiorly during the midranges of active elevation, whereas at the end ranges, A-P and superoinferior translations of 4–10 mm do occur, all of which are coupled with specific motions of IR or ER.[19,47,139,260,288,564–567] An increase in superior translation with active elevation may result in encroachment of the coracoacromial arch.[39,564] This encroachment produces a compression of the suprahumeral structures against the anteroinferior aspect of the acromion and coracoacromial ligament. Repetitive compression of these structures, coupled with other predisposing factors, results in a condition called SIS. SIS was first recognized by Jarjavay[568] in 1867, and the term impingement syndrome was popularized by Neer[39] in the 1970s.

Both intrinsic and extrinsic factors have been implicated as etiologies of the impingement process, and a number of impingement types have evolved (Table 16-40). Two of those types include the outlet (intrinsic/internal) impingement and the nonoutlet (extrinsic/external) impingement (Fig. 16-63).

Outlet impingement

This type of impingement occurs as a result of abnormal contact between the RC undersurface and the posterosuperior glenoid rim (Fig. 16-63). The etiology of posterosuperior glenoid impingement has been a source of much debate. Neer[39] proposed that a tight or crowded subacromial space (e.g., one in which the space is compromised by an anterior acromial osteophyte) could cause a mechanical abrasion of the RC against the acromion with abduction above 80–90 degrees without concomitant ER. Others have attributed internal impingement secondary to anterior microinstability and tightness of the capsule posteriorly.

Whatever the underlying cause, the abrasion of the soft-tissue structures located between the head of the humerus and the roof of the shoulder during elevation of the arm produces an irritation, inflammation, and tearing of the RC muscles, an irritation of the LHB, and subacromial bursitis.[57,569,570]

This type of impingement is known as an outlet impingement because it occurs at the supraspinatus outlet formed by the coracoid process, the anterior acromion, the A-C joint, and the coracoacromial ligament. It clinically manifests as a "painful arc." A painful arc describes a region of pain in a particular motion, which has pain-free areas on either side of it.[326] For example, during abduction the patient may feel an onset of pain at 80 degrees, which then disappears at 100 degrees. The general cause of a painful arc is impingement of a tender subacromial structure during motion, although loose bodies and instabilities may also cause a painful arc.

Although Neer and Poppen[571] reported that 90–95% of RC tears were the result of the outlet subacromial impingement, the role of age-related or senescent degeneration and

tensile overload has been emphasized more recently (see later).[569,570,572–576]

CLiNiCAL PeAr L

Kennedy and Hawkins[201] originally described the term "swimmer shoulder" as an outlet impingement, as they thought it was caused by impingement of the rotator cuff tendons under the coracoacromial arch. However, further analysis indicated that the course of this condition is multifactorial including [200]

1. Stroke biomechanics, and/or
2. Overuse and fatigue of muscles of the shoulder, scapular, and upper back, and/or
3. Glenohumeral laxity with subsequent shoulder instability

Nonoutlet impingement

Nonoutlet impingement, sometimes referred to as posterior internal impingement, in which the subacromial space appears to be normal, occurs in the younger patient performing repetitive overhead motions. T e mechanism in this condition appears to be an impingement of the RC against the posterior superior glenoid labrum and the humeral head during forced humeral elevation and IR. T is can eventually result in posterior superior tears in the glenoid labrum, and lesions in the posterior humeral head (Bankart lesion).

Primary and secondary extrinsic impingements

T ree other types of impingement, which relate to chronic disorders of the RC, have been proposed.

- Primary extrinsic impingement refers to an intrinsic degenerative process in the structures occupying the subacromial space that occurs when the lesser tuberosity of the humerus encroaches on the coracoid process due to hypertrophic degenerative changes at the A-C joint, or other trophic changes in the coracoacromial arch or humeral head, all of which decrease the subacromial space. Eventually, the superior aspect of the RC is compressed and abraded by the surrounding bony and sof tissues due to anatomical crowding, posterior capsular tightness, and/or excessive superior migration of the humeral head.[577] Patients with primary impingement are typically over the age of 40 and present with limited horizontal abduction (as compared with the uninvolved side), and limited IR (< 50 degrees). T is condition is commonly treated operatively.
- Secondary extrinsic impingement occurs when the static and dynamic stabilizers of the shoulder become compromised and fail to protect the joint. T is results in mechanical compression of the suprahumeral tissues due to hypermobility or instability of the joint and increased translation of the humeral head. T e instability can be unidirectional with or without impingement, or multidirectional. Although some degree of hypermobility can be controlled by a healthy rotator cuff, weakness or fatigue can eventually lead to inflammation of the suprahumeral tissues through repetitive trauma (see Glenohumeral Instability).

CLiNiCAL PeAr L

It is recognized that primary impingement syndrome conditions can lead to secondary impingement if not managed appropriately.[578,579]

- Internal extrinsic impingement. T e primary cause of internal extrinsic impingement is G-H instability and/or tensile overload of the RC resulting in poor control of the humeral head during throwing activities involving forward flexion, IR, and abduction. Patients in this group are usually younger, have a history of traumatic anterior instability, a posterior defect of the humeral head, and damage to the posterior glenoid labrum. T ese individuals typically present with limited IR, excessive ER, and anterosuperior humeral head migration (see Scapular Dyskinesis).[193]

T us, the pathophysiology of SIS and RC disorders may have both intrinsic and extrinsic factors. In addition to the shape and form of the acromion, the amount of vascularization to the RC, the correct functioning of the dynamic stabilizers, and the condition of the A-C joint, a number of other intrinsic and extrinsic factors have been found to predispose an individual to SIS, including the following[38,40,55,62,580]:

1. Age. T e age of the patient appears to be an important etiologic factor in the development of subacromial impingement in association with repetitive motion.[541,581–584] In the absence of repetitive motion as a causative factor, SIS is more common af er the third decade of life and is uncommon in individuals younger than 30 years.[38,39] In addition, there is a normal age-related increase in asymptomatic RC defects.[581–583,584,585] Constant and Murley[586] have also shown that there is an age-related decrease in shoulder function in healthy volunteers.
2. Position of the arm during activities. T e arm position adopted during activities may contribute to the development of subacromial impingement significantly.[210] Because of the tangential vector of deltoid contraction, the tendency for superior translation of the humeral head is greatest between 60 and 90 degrees of elevation[43,564,587] T us repetitive activities in this range of elevation place a high demand on the RC to counteract this tendency. In addition, repetitive activities that occur during higher levels of elevation of the arm bring the greater tuberosity and supraspinatus insertion into close proximity to the coracoacromial arch.[43,564,587]
3. Muscle imbalances. Sustained or repetitive overhead activity requires the scapular pivoters to constantly maintain appropriate scapular rotation.[38,108,121] Fatigue of the scapular pivoters may lead or contribute to relative subacromial impingement because of poor or asymmetric scapular rotation.[38,108,121] Secondary impingement can occur because of serratus anterior dysfunction, resulting in the anterior and inferior movement of the coracoacromial arch, which reduces available clearance for the RC and greater tuberosity as the shoulder is flexed forward.[4,108] Scapular lag from dysrhythmic scapulothoracic motion can also contribute to subacromial impingement because

the acromion fails to rotate with the humerus, thereby producing a relative decrease in the acromiohumeral interval.[4,108] Defects in proprioception and motor coordination of the RC and the deltoid muscle were recently discussed as playing a major role in the development of SIS.[588,589] In swimming, the greatest propulsive force is generated by adduction and IR of the upper extremity with the pectoralis major and latissimus dorsi providing most of the force. T us, training induced adduction and IR strength can lead to an imbalance and reduced glenohumeral stability.

4. Capsular tightness.[590] Capsular tightness is a common mechanical problem related to primary impingement syndrome and has been reported to occur at the posterior,[108] anterior,[43] and inferior[452,551] portions of the capsule. Individuals who avoid painful overhead activity, or who are predisposed to motion imbalances because of their work or sport, can develop capsular tightness.[591] During the period of pain avoidance or unbalanced movement, the capsular connective tissue may lose the ability to lengthen due to decreased critical fiber distance and abnormal collagen fiber cross-linking. T is in turn can lead to capsular tightness, joint stiffness, painful or limited function, and to an earlier onset or greater degree of subacromial compression, particularly in elevated planes of movement.[38,252,407,592] T is is particularly true with a posterior capsular contracture, which commonly coexists with SIS and RC disease. Posterior capsular contracture may add to the abnormal subacromial contact by producing an anterosuperior translation during active elevation.[37,38] Tightness of the posterior capsule can also cause a decrease in IR of the G-H joint, which leads to an increase in the anterior and superior migration of the humeral head. In contrast, tightness of the anteroinferior capsule results in limited ER, preventing the greater tuberosity from sufficient ER to "clear" the coracoacromial arch.[117] T us, the restoration of capsular mobility is an important component in the rehabilitation process.
5. Postural imbalance. Postural imbalance, particularly scapulothoracic dysfunction in relation to the FHP, has been implicated as an etiologic factor in secondary impingement syndrome.[38,291] T e FHP, which is associated with an increase in the thoracic kyphosis angle, a forward shoulder posture, and a scapula that is positioned in relatively more elevation, protraction, downward rotation, and anterior tilt has been cited as a potential etiologic factor in the pathogenesis of SIS.[593] T e effect of these changes leads to a loss of G-H flexion and abduction range, compression and irritation of the uppermost (bursal) surface of the supraspinatus tendon, resultant changes in the activation patterns of the length-dependent force couples, and a reduction in the range of G-H elevation.[593] However, the evidence for this is limited, with research studies reporting equivocal findings.[225,231,243,258,594] Postural imbalance can also occur as a secondary development in primary SIS.[590]
6. Repetitive overhead activities. Repetitive activities that involve humeral flexion have been reported to predispose individuals to RC disorders.[40,260] In fact, any repetitive elevation beyond 90 degrees has the potential to provoke RC disorders.[43] As the shoulder is an inherently unstable joint, muscle forces are critical for maintaining stability, correct motion, and painless function. For example, in swimming, the serratus anterior (a major scapular stabilizer) and subscapularis (an internal rotator of the shoulder) are active throughout the entire swimming stroke and are therefore prone to fatigue.[595]
7. Structural asymmetry. Scapular asymmetry and its role in impingement have been widely reported by investigators of upper extremity pathology.[108,231,496,596] Warner et al.[496] determined that 57% of their subjects with impingement syndrome demonstrated static scapular postural asymmetry, and all demonstrated weakness of the scapular pivoters (rhomboids, serratus anterior, lower trapezius, deltoid, and RC).
8. T e position of the humerus at rest. T is can affect the healing process of patients with primary shoulder impingement syndrome. T e work of Rathburn and Macnab[56] illustrated the deleterious "wringing out" effect on RC tendon vascularity with an adducted dependent posture of the humerus.
9. Impaired scapular kinematics. Many researchers have studied the scapular kinematics in patients with SIS, but results of these studies to date have been largely variable, because of en control subjects were included who were not matched to the subjects with SIS, or because the studies compared shoulder motion of the affected shoulder with the asymptomatic side only.[597]

A study by McClure et al.[168] included a matched control group as well as measurements of several physical characteristics of patients with SIS, including kinematics of the scapula, shoulder ROM, shoulder muscle force, and both upper thoracic spine and shoulder resting posture. All subjects were examined with the following tests and measures: (1) goniometric measurement of shoulder ROM, (2) assessment of upper thoracic spine and scapular resting posture, (3) measurement of shoulder isometric muscle force with a handheld dynamometer, and (4) assessment of shoulder kinematics with an electromagnetic motion analysis system during three active shoulder motions (shoulder flexion, scapular plane elevation, and ER at 90 degrees of abduction). T e study had the following findings:[168,597]

- T ere were no differences in resting posture between the subjects with and without SIS.
- T e SIS group demonstrated less ROM of the shoulder in all directions assessed, and less isometric muscle force for shoulder ER and scapular plane elevation.
- T e subjects with SIS demonstrated slightly greater upward rotation of the scapula and elevation of the clavicle with shoulder flexion and slightly more posterior tilt and retraction of the clavicle with scapular plane elevation compared with those who did not have SIS.

Given the limited mobility and decreased shoulder muscle force identified in the SIS group and the kinematic differences identified between the two groups, it is tempting to conclude that the weakness of the shoulder musculature, or loss of mobility of the shoulder, or both, cause compensatory scapulothoracic movement strategies. However, further research

is needed to determine whether a management strategy that specifically addresses the identified impairments of reduced muscle force, ROM, and altered kinematics results in greater improvements in pain, activity, and participation than competing noninvasive management strategies.[168,597]

If SIS is allowed to progress, the patient moves the shoulder less frequently due to the pain. The lack of movement increases the potential of developing adhesive capsulitis (frozen shoulder), particularly in the older patient. Neer[40] divided the impingement process into three stages, although the condition is a continuum of symptoms with overlap at the margins of each stage.[76] Each impingement stage is managed based on the specific findings and the intrinsic or extrinsic factors contributing to the problem, whether they result from compression, tensile overload, or macrotrauma.

Stage I. This stage consists of localized inflammation, slight bleeding, and edema of the RC. This stage is typically observed in patients younger than 25 years of age, although it can also be seen in older populations due to overuse. The patient reports pain in the shoulder and a history of acute trauma or repetitive microtrauma.

The physical examination during this stage reveals tenderness at the supraspinatus insertion and anterior acromion, a painful arc, and weakness of the RC secondary to pain, particularly when tested at 90-degree abduction or flexion. Acromial elevation and scapular stabilization are often jeopardized early in the injury process due to pain-based inhibition of the serratus anterior and lower trapezius, and due to subclinical adaptations altering the position of the scapula to accommodate injury patterns in subluxation or impingement.[139,143] Stage I is a reversible condition.

The subacromial space can be identified as a source of impingement by using the Neer impingement test supplemented with the Hawkins–Kennedy impingement test (see "Special Tests" section).

The emphasis during the intervention of this phase is to control the pain and inflammation. The pain from subacromial impingement usually resolves with a period of rest and activity modification. Rest is advocated to prevent further trauma to the area and reduce excessive scar formation.[598] In addition to the rest and modification of activities, pain and inflammation may be controlled with the use of electrotherapeutic modalities, cryotherapy, and NSAIDs prescribed by the physician.

Stage II. Stage II represents a progressive process in the deterioration of the tissues of the RC. This stage is generally seen in the 26–40-year-old age group. Irritation of the subacromial structures continues as a result of the abnormal contact with the acromion. The subacromial bursa loses its ability to lubricate and protect the underlying RC, and tendinopathy of the cuff develops. The patient often reports that a specific activity brings on their symptoms, especially an overhead activity. Pain is generally located on the top of the shoulder and will radiate to the midbrachium in the region of the deltoid insertion. The physical examination reveals crepitus or catching at approximately 100 degrees and restriction of PROM (due to fibrosis). This stage is no longer reversible with just rest. Although this stage often responds to long-term conservative care, it can progress to a partial-thickness tear. If the level of symptoms is severe enough, surgery is often required. Conservative intervention during this stage involves a progressive strengthening program as described in the "Intervention Strategies" section.[599,600]

CLiNiCAL PeArL

A study by Bang and Deyle[601] determined that a combination of manual therapy applied by experienced clinicians and supervised exercise was better than exercise alone to increase strength, decrease pain, and improve function in patients with SIS.

Fifteen to twenty-eight percent of those patients diagnosed with SIS may eventually require surgery.[407,554] Surgical intervention is usually reserved for those who have failed to make satisfactory improvement over a period of 6 months. However, at least two randomized controlled clinical trials that examined the efficacy of conservative intervention with SIS have found that exercise supervised by a physical therapist was superior to placebo and was as effective as surgical subacromial decompression combined with postoperative rehabilitation in the intervention of patients with stage II primary impingement.[601,602] Another randomized controlled study[603] reported improved ROM, decreased pain, and increased function in patients with shoulder pain who underwent a program of individualized muscle stretching, strengthening, and retraining versus surgery.[603]

Stage III. Stage III is the end stage, common in the over-40 age group, where destruction of the soft tissue and rupture, or macrotrauma of the RC, is seen (see "Rotator Cuff Pathology" section). Localized atrophy can occur with this stage. Osteophytes of the acromion and A-C joint develop. The wear of the anterior aspect of the acromion on the greater tuberosity and the supraspinatus tendon eventually results in a full-thickness tear of the RC. The physical examination reveals atrophy of the infraspinatus and supraspinatus, and more limitation in AROM and PROM than the other stages.

Posterior superior Glenoid impingement

Posterior superior glenoid impingement is newly recognized as a source of RC pathology in athletes. This type of impingement is thought to result from an impingement of the RC between the greater tuberosity and the posterior superior glenoid labrum, although the actual cause has yet to be determined.[604,605]

intervention

Several evidence-based medical approaches to treat RC pathology exist, including arthroscopic acromioplasty,[606] and corticosteroid injection.[607] Although an arthroscopic rotator cuff repair appears to be a relatively minor procedure, postsurgical rehabilitation is long and intensive.[608] Several factors can affect the extent to which a person will recover after rotator cuff repair including demographics (age, gender), clinical variables (bone mineral density, diabetes mellitus, level of sports activity, preoperative shoulder ROM, and obesity), cuff integrity (sagittal size of the cuff lesion, retraction of the cuff, fatty infiltration, and multiple tendon involvement), and surgical procedure (concomitant biceps/A-C joint procedures).[608]

In addition, a number of evidence-based PT approaches have also been recognized including posterior shoulder stretch,[273] joint mobilization,[609] and strengthening and neuromuscular reeducation.[610]

CLiNiCAL PeArL

Acontrolled laboratory study by Muth et al.[611] that assessed pain, range of motion, function, scapular kinematics, and electromyographic signal amplitude of the shoulder musculature before and after thoracic spine manipulation in subjects with rotator cuff tendinopathy found immediate improvement in shoulder pain and function postmanipulation. However, it is unclear whether the manipulations altered neurophysiological processes, neuromotor control, or segmental spine kinematics.

A progression from isometric exercises to close chain, and finally to open-chain activities beginning with scapulothoracic strengthening and scaption retraining, and then proceeding to RC strengthening, is generally recommended (see "Intervention Strategies" section).

- Scapulothoracic strengthening and scaption retraining exercises include isometric scapular pinches and shrug exercises, rowing, press-ups, and the push-up plus. Exercises to improve the scapulohumeral rhythm include the PNF D2 pattern, alternating serratus punches with tubing, and latissimus dorsi pull downs.
- Rotator cuff strengthening exercises include the empty can, biceps curl, IR and ER of the shoulder against resistive tubing, elbow extension, prone ER of the shoulder, and shoulder flexion and abduction (performed below 90 degrees).

Periarticular syndromes

T e historical features of all these syndromes are similar. Pain is increased af er exercise and is usually worse at night, of en waking the patient from sleep. Certain movements, such as reaching above the head or putting on a coat, will produce pain. ER and IR motions are usually within normal limits when compared with the uninvolved side, but abduction and flexion are painful between 70 and 110 degrees. Disorders of the periarticular inert structures, such as the bursae, are characterized by a noncapsular pattern. T ese can be divided into two subgroups. One group has a restricted range of passive movement, and the other has an unrestricted range. Two common periarticular syndromes that affect the shoulder in older patients are subacromial–subdeltoid bursitis and bicipital tendinopathy.

According to Nevasier,[612] primary shoulder bursitis is seen only in gout, rheumatoid arthritis, pyogenic infections, and tuberculosis.[613] Secondary bursitis, due to the proximity of the bursae to an inflamed tendon, is far more common.

Calcified Bursitis

Etiology of this condition is a result of decreased vascularization, cuff degeneration, and/or increased levels of the HLA-1 antigen. T ere are three recognized stages:

- Precalcific—calcium deposits in the matrix of vesicles
- Calcific—continued calcium deposition and increased pressure
- Postcalcific—the body decreases its blood supply to the area in an attempt to get rid of the calcium, producing severe pain (comparable to kidney stones)

T e condition produces a limitation of ROM in all directions, and the area is very tender to touch or compression.

Conservative intervention consists of an intramuscular steroid injection to decrease pain and inflammation, ice applications, and Codman's exercises to relieve pressure. Typically, the pain decreases with an increase in ROM in 48–72 hours. Af er 72 hours, the bursitis is treated as a traumatic bursitis (see next).

Traumatic Bursitis and hemorrhagic Bursitis

Traumatic bursitis is the result of direct trauma. But it can also be secondary to a degenerative rotator cuff. T e patient of en complains of pain at night. Pain is typically felt over the deltoid and its insertion, with the arm in extension. T e patient demonstrates limited AROM and PROM in a noncapsular pattern, and an empty end-feel at approximately 70–80 degrees with G-H abduction.

T e condition responds well to a conservative regimen of pain and inflammation control, capsular stretching (especially posteriorly), Codman's exercises, manual techniques to increase the acromiohumeral interval (scapula down and back, inferior glide), postural reeducation, restoration of normal synergy patterns for the G-H depressors, and functional restoration.

Calcific Tendinopathy

Calcific tendinitis or, more accurately termed calcific tendinopathy, is characterized by a reactive calcification that affects the rotator cuff tendons. It is a common cause of shoulder pain.[614] Frequently, such calcifications are incidental radiographic findings in asymptomatic patients.[615] Approximately 50% of patients with calcific tendinopathy have shoulder pain,[616,617] with associated acute or chronic painful restrictions of shoulder ROM, impacting ADLs.

T e cause and pathogenesis of calcifications of the rotator cuff are unclear.[56,618] Ischemia as a result of hypovascularization in the so-called critical zone of the rotator cuff,[56] degeneration of the tendons,[618] and metabolic disturbances[619] have all been suggested as possible causes. According to Uhthoff et al.,[620,621] fibrocartilaginous transformation of the tendon tissue leads to calcium deposits. T e course of the disease may be cyclic, with spontaneous resorption and reconstitution of the tendon.[620,621] T e factor that triggers metaplasia has not yet been determined, although tissue hypoxia is thought to be the primary factor.[619] Clearly, degeneration of the rotator cuff tendons is a precursor for calcification.[204] Both shoulders are involved at 20–30% of patients with calcific tendinopathy of the shoulder.[616,617] Calcific tendinopathy is observed infrequently in people under age 40.[204] T e prevalence of calcific tendinopathy has been reported to be between 3%[616] and 7%.[622] Calcific tendinopathy can be acute or chronic.[621] In general, the condition is found more frequently in women than men.[616] A relationship

to occupation must be considered because there is a high incidence among clerical workers.[621]

The course of calcific tendinopathy is variable. In most cases, the deposits are located 1–2 cm from the insertion of the supraspinatus tendon on the greater tuberosity.[615] In some patients, the deposits are absorbed spontaneously with limited pain. Chronic calcific tendinopathy generally presents with impingement symptoms of pain with overhead motion. Other patients have persistent and recurring episodes of severe pain.

Uhthoff et al.[621] suggest dividing calcific tendinopathy into a formative phase and a resorptive phase. In the formative phase, calcium deposits crystallize with minimal inflammation. Pain is usually mild and self-limiting during this phase. In the later, resorptive phase, the calcific material changes consistency from a solid to a paste or liquid. Shoulder pain is seen more often in this phase. This pain can be severe and develop abruptly. During these acute episodes of shoulder pain, the physical examination is often difficult due to pain limiting AROM and PROM.

Management of calcific tendinopathy is often conservative, consisting of ice applications and pendulum exercises (prescribed in the acute phase) to prevent the development of adhesive capsulitis.[76]

Promising results have been reported for shock-wave therapy.[623,624] Ultrasound therapy, using a wide intensity range is commonly used as an intervention for painful musculoskeletal disorders.[625] The way in which ultrasound stimulates resorption of calcium deposits has not been established.[615] It may stimulate the accumulation of peripheral-blood mononuclear cells by activating endothelial cells. It may also act indirectly by increasing the intracellular calcium levels.[626] At higher intensities, ultrasound may trigger or accelerate the disruption of apatite-like microcrystals. The appearance of these smaller calcium crystals may then stimulate macrophages to remove calcifications by phagocytosis.[627,628] Finally, the increases in the temperature of tissue exposed to ultrasound may increase blood flow (i.e., induce hyperemia) and metabolism, thus facilitating the disintegration of calcium deposits.[615]

Invasive interventions directed at the calcium deposits, such as open surgical removal of the deposits, percutaneous needle aspiration and closed lavage of the deposits with lidocaine reduce pain and restore shoulder function in some patients, but not in all.[204,617,629–631]

Acute subacromial–subdeltoid Bursitis

This is an extremely uncomfortable condition. Active elevation is very painful and greatly restricted, and can be accompanied by a painful arc. While most patients with subacromial–subdeltoid bursitis describe a mechanical mechanism, bilateral bursitis is often seen in patients with inflammatory arthritis.[204] A differential diagnosis should be made between gouty arthritis, septic arthritis, a pathologic fracture, or a dislocation of the shoulder, and these can be differentiated from one another by their accompanying symptoms. Regardless of the severity of the pain, other conditions need to be ruled out. These include subscapular tendinopathy, a pectoralis major lesion, a sprain of the conoid–trapezoid ligament, or early G-H arthritis. The pain of bursitis is usually reproduced with passive abduction at 180 degrees, passive IR, and passive horizontal adduction. Resistive testing may also produce pain. Associated and predisposing findings may also be noted. These include winging of the scapula, and forward head and rounded shoulder posture.

With the shoulder positioned in extension to expose more of the bursa, palpation of the shoulder region can elicit tenderness of the rotator cuff tendons and tenderness of the subacromial–subdeltoid bursa over the anterior humeral head.

Conservative intervention for this condition involves the use of modalities to help control the pain and inflammation, and patient education to avoid exacerbation.

Primary Chronic subacromial–subdeltoid Bursitis

Two types of primary chronic bursitis are defined:

1. The type caused by degenerative changes, especially of the supraspinatus and A-C joint. This can produce a reduced space for the bursa and cause an inflammatory reaction of the bursa.
2. The type caused by a systemic disease such as rheumatoid arthritis.

With primary chronic bursitis, pain develops gradually. The pain is usually localized to the shoulder and lateral deltoid area, but it can spread into the upper arm. Findings from the objective examination include a positive painful arc into abduction or forward flexion, but full movement in other directions. One or more resisted tests are often painful, but may be negative if repeated with an inferior pull on the arm.

The intervention of choice is a course of local anesthetic injections.

secondary Chronic subacromial–subdeltoid Bursitis

Secondary chronic bursitis is more common than the primary type and results from other shoulder pathologies, including a rupture of the medial coracohumeral ligament. Similar to primary chronic bursitis, the pain develops gradually in the shoulder and lateral deltoid region, but can radiate into the upper arm.

The objective findings are the same as those for the primary chronic bursitis. However, the exception is that other pathologies are present and make a specific diagnosis more difficult.

The intervention of choice is similar to primary chronic bursitis, although the primary lesion should be sought and treated.

Bicipital Tendinopathy

Tendinopathy of the LHB occurs more often as a secondary condition related to an impingement syndrome.[442,612] Slatis and Aalto[632] described a three-part classification for biceps lesions:

- Type A: Impingement tendinopathy, which occurs secondary to impingement syndrome and rotator cuff disease. Since the tendon passes beneath the anterior edge of the acromion, impingement can cause biceps tendinopathy as well as rotator cuff problems.

- Type B: A subluxation of the biceps tendon.
- Type C: Attrition tendinopathy, commonly associated with spurring and fraying.

In addition, the biceps tendon sheath is a direct extension of the G-H joint, and inflammatory conditions such as rheumatoid arthritis can involve the biceps tendon.

Other researchers[633] have proposed two main categories related to age with younger patients developing problems due to repetitive trauma and anomalies of the bicipital groove, and the older age group developing problems associated with degenerative changes in the tendon.

The pain associated with inflammation of the LHB is typically felt along the anterior lateral aspect of the shoulder with radiation into the biceps muscle, and tenderness is noted directly over the bicipital groove.

Objective findings for this condition include the following:

- Full AROM and PROM, although pain is often reported at the end range of flexion and abduction.
- Normal accessory glides at the G-H joint (negating the need to use joint mobilizations).[442,612]
- Pain on palpation of the bicipital groove while the arm is positioned at 10 degrees of IR.
- Pain with resisted elbow flexion or resisted forward flexion of the shoulder.
- Pain on passive stretch of the biceps tendon.
- Positive Speed's test.

Every attempt must be made to identify associated lesions (e.g., those affecting the glenoid labrum and rotator cuff) or to note any contributing factors (e.g., a poorly stabilized scapular, the hypomobile cervical and/or thoracic spine, or altered muscle recruitment patterns).[72]

The conservative intervention for biceps tendinopathy secondary to chronic impingement is similar to that described for rotator cuff tendinopathy. These include electrotherapeutic modalities, physical agents, NSAIDs, TFM, and gentle stretching of the contractile tissues. Care must be taken with the TFM so as to not exacerbate the acutely or chronically inflamed tissue. Once the pain and inflammation are under control, the patient is progressed through ROM exercises within the pain-free ranges. Intensive strengthening is initiated when full pain-free AROM has been restored.

subluxing Biceps Tendon

The LHB tendon, with its proximal point of exit at a 30–40-degree angle from the straight line of the tendon and the tunnel, swings from one side of the groove to the other during the motions of IR and ER of the humerus.[29] If the groove is shallow, the tendon may force its way over the lesser or greater tuberosity, tearing the transverse humeral ligament in the process. Repeated subluxation wears down the tuberosity and increases the frequency of the subluxation.

If the groove is narrow and tight, the constant pressure of the tendon has the potential to cause tendinopathy or even rupture of the tendon.[29]

The pain, not often severe, has the same referral pattern as that of bicipital tendinopathy. A click is typically felt during abduction and ER motions, with reduction of the tendon occurring with adduction and IR. There is tenderness over the bicipital groove, which follows the groove as the arm is rotated. On IR, the groove is under the coracoid, and during ER it is at the anteromedial line.[29]

The intervention depends largely on how important athletics is to the participant. Conservative intervention involves the temporary avoidance of the pain and click-provoking movements and the application of TFM. In severe cases, surgical intervention may be indicated, which offers excellent results.[29]

rupture of the Long head of Biceps

A total rupture of the LHB is usually seen in middle-aged patients, resulting from repeated injections of steroid into the bicipital groove or in cases of chronic impingement.[204] The tendon is avascular, and as it weakens, it tears with a minimal amount of force.

Patients usually report hearing or feeling a "snap" at the time of the injury. Typically, rupture is followed by a few weeks of mild-to-moderate pain, followed by resolution of the pain and restoration of normal function.[204] When attempts are made to contract the biceps, the muscle belly rolls down over the distal humerus, producing a swelling close to the elbow instead of in the middle of the arm: the so-called "Popeye" sign. Functional limitations are unusual after this rupture, especially in the older population, because the short head of the biceps remains intact.[634] Typically, there is a negligible loss of elbow flexion and supination strength.

Surgical repair is rarely indicated except in the younger, active population (<50 years). With or without surgery, a rupture of the LHB increases the risk of developing an SIS. This results from the short head of the biceps pulling the humeral head upward, without the presence of the long head to hold the humeral head downward.

PATTERN 4G: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, RANGE OF MOTION WITH FRACTURES

Atraumatic Osteolysis of the Distal Clavicle

Atraumatic osteolysis of the distal clavicle (AODC) was first described in 1959 by Ehricht.[635]

The etiology is thought to be a stress failure of the distal clavicle due to an initial stress fracture, followed by cystic and erosive changes secondary to bone resorption.[70] Subsequent bone formation and remodeling cannot occur because of continued stress on the joint.[70]

It is most common in athletes involved in prolonged weight training and appears to be on the increase. The recent increase in incidence may be due to the emphasis on strength training regimens in sport. In a group of Danish weightlifers, the prevalence was found to be 27% compared with a normal (non–weight-lifing) control group.[636]

The symptoms usually begin insidiously. They are usually described as a painful, dull ache localized to the A-C

joint. T e ache, which tends to be worse at the beginning of exercise, may radiate into the deltoid and trapezius. Bench presses, dips, and push-ups are usually the most painful exercises. Abduction of the arm beyond 90 degrees causes pain. T rowing is also painful. On examination, there is point tenderness at the A-C joint and forced arm adduction across the chest increases the symptoms. Symptoms are bilateral in 20% of cases.

T e most common differential diagnoses to be considered are cervical spondylosis and rotator cuff disease. AODC can be distinguished from rotator cuff tendinopathy by selective injection of anesthetic into the A-C joint. An abolishment of the pain with the provocative maneuvers subsequent to the injection helps confirm the diagnosis.

T e majority of patients with this condition respond to conservative management and activity modification, with most improving by reducing or eliminating their strength training activities.[636] However, even af er several years' layoff, if strength training is reinstituted at the same level, the symptoms will commonly recur.[637,638] Other aspects of conservative intervention involve heat, NSAIDs, ROM, and stretching and strengthening exercises. T e exercises should be performed below 90 degrees of abduction. Ultrasound has also been advocated.[636] Although a consideration, intra-articular injection of steroid does not provide long-lasting success. It is more helpful to aid in the diagnosis and predicting surgical success.

Conservative intervention failure is an indication for surgical management. T is consists of resection of the distal clavicle, either open or arthroscopic.

Clavicle Fractures

Fractures of the clavicle account for 5–10% of all fractures and 35–40% of shoulder girdle injuries in adults. T e clavicle is the most commonly fractured bone in childhood.[87] Fractures of the clavicle usually result from a FOOSH, a fall or blow to the point of the shoulder, or less commonly from a direct blow.

T e classic presentation following a clavicular fracture is guarded shoulder motions and difficulty elevating the arm beyond 60 degrees. A clavicular deformity may also be observable. T ere is also exquisite tenderness to palpation or percussion (bony tap) over the fracture site. Horizontal adduction is painful. T e diagnosis is confirmed by radiograph.

T e conservative intervention for clavicle fractures includes approximation of the fracture ends followed by immobilization with a sling and figure-8 strap for 3–6 weeks. AAROM and then AROM exercises for the shoulder can be initiated once clinical union has been established (in 2–3 weeks). Due to the importance of the clavicle in shoulder function, joint mobilizations are started immediately af er the period of immobilization and strengthening exercises for the deltoid, pectoralis major, and upper trapezius muscles are prescribed when appropriate. As with all shoulder injuries, the clinician should ensure that the scapulohumeral rhythm is normal and symmetrical and that the essential stabilizing musculature of the G-H joint is intact. Normal healing times for clavicular fracture are 6 weeks in young children in 8 weeks in adults.[639] Surgical intervention is reserved for those cases involving neurovascular compression, an open fracture, associated fractures, and marked displacement.

Proximal humeral Fractures

A proximal humeral fracture, involving the proximal third of the humerus, is the most common fracture of the humerus in the young and the elderly. In the skeletally immature patient, the fracture frequently presents as an epiphyseal fracture of the proximal humeral growth plate as the result from a direct blow to the anterior, lateral, or posterolateral aspect of the humerus, or a FOOSH injury.[640] In the elderly, the fractures usually occur through osteopenic bone following minimal trauma.

T e majority of proximal humeral fractures are stable with no significant displacement of the fracture. T is type is typically treated conservatively, with an emphasis on controlling distal edema and stiffness, and early motion at the shoulder to prevent the development of arthrofibrosis secondary to prolonged immobilization.[641]

T e arm is usually immobilized in a sling until pain and discomfort subsides, of en af er 2 weeks if the fracture is classified as nondisplaced and stable. If the fracture is classified as nondisplaced, it is considered unstable and the immobilization period is typically approximately 4 weeks. AROM exercises for the wrist and hand are initiated immediately following immobilization. Typically, passive and active-assisted exercises for the shoulder can be initiated approximately 1 week af er injury. Clinical unity of the fracture usually occurs af er 1–4 weeks. T is can be tested by having the patient stand with the involved arm at their side with the elbow flexed. T e clinician places one hand on the humeral head, and then gently rotates the humerus with the other. Clinical unity is established when the fracture fragments move in unison, and the movement is free of crepitation. At this point, gentle AROM exercises are initiated for the shoulder and elbow. Once clinical union is confirmed by radiograph (usually at around 6 weeks), full PROM exercises to the shoulder and elbow are performed, with PREs typically initiated at 6–8 weeks.

scapular Fractures

Scapular fractures are not common, accounting for only 1% of all fractures, 3% of all shoulder injuries and 5% of fractures involving the entire shoulder.[642] T e anatomic features of the scapula provide insight into the mechanisms of injury and offer a convenient classification system (Table 16-41)[643]:

- Injuries to the body or the spine of the scapula typically result from a direct blow with significant force, such as from a motor vehicle accident or a fall.
- Acromion injuries usually result from a direct downward force to the shoulder.
- Scapular neck fractures most frequently result from an anterior or posterior force applied to the shoulder.
- Glenoid rim fractures most of en result from force transmitted along the humerus af er a fall onto a flexed elbow.
- Stellate glenoid fractures usually follow a direct blow to the lateral shoulder.
- Coracoid process fractures may result from either a direct blow to the superior aspect of the shoulder or a forceful muscular contraction that causes an avulsion fracture.

TABLE 16-41 Classification of Glenoid Cavity Fractures

Type	Description
IA	Anterior rim fracture
IB	Posterior rim fracture
II	Fracture line through the glenoid fossa exiting at the lateral border of the scapula
III	Fracture line through the glenoid fossa exiting at the superior border of the scapula
IV	Fracture line through the glenoid fossa exiting at the medial border of the scapula
VA	Combination of types II and IV
VB	Combination of types III and IV
VC	Combination of types II, III, and IV
VI	Comminuted fracture

In addition to a history of trauma, the most common findings are tenderness, edema, and ecchymosis over the affected area. In addition, the upper extremity is held in adduction, and any attempt to abduct the extremity increases pain.

Most scapular fractures, depending on location and classification, can be treated successfully without surgical intervention. Conservative intervention consists of approximately 7–10 days of sling immobilization, followed by a progressing regimen of pendular and gentle PROM exercises as comfort and control allow.[72] Once sufficient healing has been demonstrated radiographically, the patient is encouraged to discontinue immobilization and proceed with AAROM and AROM exercises. Exercises that strengthen the muscles that attach to the scapula and those that arise from the scapula must be introduced at the earliest opportunity.

s capular Dyskinesis

Strengthening and stretching exercises for scapular muscles are a common part of rehabilitation programs designed for people with shoulder dysfunctions. Scapular dyskinesis is an alteration in the normal position or motion of the scapula that occurs during coupled scapulohumeral movements as a response to shoulder dysfunction.[644] T e causes are many (Table 16-42). It should be suspected in patients with shoulder injury and can be identified and classified by specific physical examination. T ere are three types of scapular dyskinesis:

TABLE 16-42 Potential Causes of Scapular Dyskinesis

Potential Causes	Examples
Abnormality in bony posture or injury	Excessive scapular protraction and acromial depression in all stages of motion which increases the risk for impingement Excessive resting kyphosis Forward head posture creates tightness to the anterior neck musculature, which again in turn facilitates the abnormal scapula position
AC joint injuries or instabilities	Can alter the center of rotation of the scapula, leading to faulty mechanics
Muscle function alterations	Alterations involving the serratus anterior and lower trapezius are a common source of dysfunction, especially in cases of secondary impingement Microtrauma due to excessive strain in the muscles, fatigue, and inhibition due to pain
Nerve damage	A rare cause
Contractures	Especially of the anterior musculature that attaches to the coracoid process (pectoralis minor and short biceps head) can create an anterior tilt and forward lean to the scapula, as can tightness to the posterior capsule and latissimus

Data from Kibler WB, McMullen J. Scapular dyskinesis and its relation to shoulder pain. J Am Acad Orthop Surg. 2003;11:142–151.

- Type I is characterized by prominence of the inferior medial scapular border. In throwers, this type may be referred to as a SICK scapula (malposition of the Scapula, prominence of the Inferior medial border of the scapula, Coracoid pain, and malposition, and scapular dyskinesia).[269] A thrower with this syndrome presents with an apparent "dropped" scapula in the symptomatic shoulder compared with the contralateral shoulder's scapular position. Viewed from behind, the inferior medial scapular border appears very prominent, with the superior medial border and acromion less prominent. When viewed from the front, this tilting (protraction) of the scapula makes the shoulder appear to be lower than the opposite side.[269] T e pectoralis minor tightens as the coracoid tilts inferiorly, and shif s laterally away from the midline, and its insertion at the coracoid becomes very tender.[269]
- Type II is characterized by protrusion of the entire medial border.
- Type III involves superior translation of the entire scapula and prominence of the superior medial border.

Evaluation of the patient should include the trunk segments, hip and lower extremity function, and scapular position and movement analysis. T ere may be pain at the coracoid process, and the entire medial border may be tender with trigger points found in the upper trapezius. T ere may even be painful scar tissue found in the musculature due to

long-standing dyskinesis. Motion about the scapulothoracic joint should be smooth with no catching or rapid movements, which are more of en seen during the lowering phase of the arm. Strength testing can include the isometric scapular pinch, the SAT, the scapular retraction test, and the LST. Once all the factors involved in the dysfunction of the shoulder are identified, treatment can begin on restoring normal scapular position and movement. More extensive therapy, including strengthening, should not occur until this step is accomplished; otherwise the shoulder is being worked in a faulty position.

T e intervention of scapular dyskinesis is directed at managing underlying causes and restoring normal scapular muscle activation patterns by kinetic chain-based rehabilitation protocols. Leg, back, and trunk flexibility and strength should be normalized, and exercises that emphasize kinetic chain activation of the leg, trunk, and scapula should be instituted. Useful combinations of movements to allow activation include trunk extension and scapular retraction, trunk rotation and scapular retraction, and one-legged stance and diagonal trunk rotation and scapular retraction. All of these exercises facilitate lower trapezius muscle activation.

snapping scapular

T e term snapping scapula has been used to describe the clinical scenario of tenderness at the superomedial angle of the scapula, painful scapulothoracic motion, and scapulothoracic crepitus.[92,645–648] Infrequently, an underlying cause for the scapulothoracic dyskinesia is identified. T e uncommon etiologies of snapping scapula include scapular exostoses, malunited scapular or rib fractures, and Sprengel's deformity.[646,649–651] Pain is usually reported at the superomedial angle of the scapula, with or without scapulothoracic crepitus.

T e intervention for this condition is based on the cause. Common causes for this condition are an inflammation of the bursa between the scapula and thorax (scapulothoracic bursitis), prominence of the superomedial angle of the scapula, and muscular imbalance of the scapular pivoters.[92,646–648,652–655]

impaired Posture

Patients with impaired posture have functional limitations associated with muscle imbalances, repetitive altered joint mobility, and pain. Impaired posture is commonly associated with referred pain to the shoulder. T e most common posture referring pain to the shoulder is a FHP with rounded shoulders. T is posture is characterized by hypertrophy of the anterior chest and cervical musculature (including the pectoralis minor muscle and the anterior and medial scalene muscles). T e position adopted in the FHP can compromise the space in the scalene triangle and cause compression of the neurovascular structures, resulting in a condition called TOS (see Chapter 23).[464]

T is posture can also lead to sof -tissue restrictions of the anterior shoulder muscles, suboccipital muscles, and shoulder rotators.[464]

T e intervention includes a conservative regime of postural reeducation and exercises to restore the normal synergy patterns for G-H depressors, to increase shoulder stability, and facilitate functional restoration (see Chapter 25). Cervical and thoracic stabilization exercises may be introduced in addition to the correction of any muscle imbalances.

r eferred Pain

See Chapter 5.

scapulocostal syndrome

Although this syndrome has been documented,[656–658] it is poorly understood. Scapulocostal syndrome (SCS) is an enthesopathy (a disorder of the attachment of a ligament, tendon, joint capsule, or muscle to bone) of the origin of the serratus posterior superior muscle. Clinically, it appears that SCS is a distinct variety of fibromyalgia.[658]

SCS has been postulated to have many causes including[658]

- ischemia[659]
- trigger point[656]
- postural degeneration[660,661]
- physical sloth[662]

Clinical findings for this syndrome include the following[658]:

- Pain of a cervicobrachial nature, described as burning and aching, is the most common presenting symptom.
- Active and passive motions of the shoulder girdle are usually full and pain free.
- Poor overall physical conditioning.

Conservative intervention, which includes intralesional injections and physical rehabilitation involving ROM, strengthening, and conditioning exercises, was shown in one study[658] to be successful in 95.9% of 201 patients.

subclavian steal syndrome

See Chapter 5.

myofascial Pain syndrome

Shoulder pain can of en be caused by myofascial dysfunction. T e following muscles are most commonly involved. T e intervention strategies for myofascial trigger points are described in Chapter 10.

infraspinatus

The infraspinatus is a frequent cause of myofascial shoulder pain, with the trigger points in this muscle commonly referring pain deep into the shoulder joint. Due to the severity of the referred pain from this muscle's trigger points, it is often misdiagnosed as subdeltoid bursitis or supraspinatus tendinopathy.

Pain can also be felt in the anterior shoulder and anterior upper arm. In extreme cases, the pain may refer to the extensor area of the forearm and into the hand.

Clinical findings can include the following:[663]

- A history of sleeping difficulty on the involved side because of pressure on trigger points. Sleeping on the uninvolved side can also produce pain because of stretching of the muscle. Supporting the involved arm on a pillow while sleeping on the uninvolved side is a significant help.
- Limited IR and adduction of the shoulder, including horizontal adduction in severe cases.
- Shoulder girdle muscle fatigue rather than weakness. Pain is elicited on resisted testing of the infraspinatus and middle and posterior deltoid muscles.
- Decreased grip strength.
- Positive signs of subacromial impingement due to dysfunction of the infraspinatus.

Anterior Deltoid

Anterior deltoid trigger points typically refer pain and tenderness in the area of the muscle itself. Clinical findings include decreased ER and extension of the shoulder.

Posterior Deltoid

Trigger points in this muscle (located posterior to the humeral head) and in the levator scapulae are the most frequent cause of myogenic posterior shoulder pain.[663] Pain is elicited on resisted testing, reaching across to the opposite shoulder anteriorly and toward the end of ER while the arm is abducted at 90 degrees because of the shortening action in the muscle.[663]

Levator scapulae

This muscle is one of the most frequent myofascial sources of shoulder and neck pain. Pain reference is to the base of the neck, the posterior shoulder joint over the area of the humeral head, and along the medial scapular border.

Clinical findings include the following:

- painful ipsilateral rotation of the neck,
- a limitation of full shoulder abduction accompanied by reproduction of posterior shoulder pain.[663]

These trigger points are activated by holding a telephone receiver between the shoulder and ear; sleeping on a sofa with the head on the armrest, which causes prolonged stretching deformation of the muscle; postural stress due to shoulder girdle asymmetry; and psychologic distress.[663]

scalenes

The pain pattern is similar for all three scalenes and can include the anterior chest, the upper arm both anterolaterally and posteriorly, the thumb and index finger, and the medial scapular area.[663] Tenderness is referred to the infraclavicular fossa and disappears immediately after inactivation of the trigger points.

supraspinatus

Rarely occurring in isolation, supraspinatus trigger points refer pain around the shoulder area, particularly to the middeltoid region, and the lateral epicondyle of the humerus. When the muscle is less severely involved, the patient will have difficulty fully abducting the shoulder.

As described previously, supraspinatus dysfunction can have wide-ranging consequences in shoulder biomechanics.

subscapularis

Pain from subscapularis trigger points is felt at rest or on motion over the posterior shoulder. The pain may also extend over the scapula and posteromedial arm as far as the wrist.

Clinical findings include the following:

- painful and limited shoulder abduction, especially if ER of the arm is added to the movement,
- painful resisted shoulder adduction and IR,
- decreased posterior glide of the G-H joint,
- positive subacromial impingement signs.

Trapezius

The trigger points of the trapezius are usually found in the upper trapezius near the distal clavicle and in the lower border of the lower trapezius near the medial scapular border. Both areas refer pain and tenderness to the top of the shoulder over the acromion.[663] These trigger points may cause tenderness of the A-C joint ligaments. Trigger points in the lower trapezius can refer pain into the ipsilateral posterior neck and suboccipital region.[663]

Thoracic Outlet syndrome

The chief complaint of TOS is one of diffuse arm and shoulder pain, especially when the arm is elevated beyond 90 degrees. Potential symptoms include pain localized in the neck, face, head, upper extremity, chest, shoulder, or axilla; and upper extremity paresthesias, numbness, weakness, heaviness, fatigability, swelling, discoloration, ulceration, or Raynaud's phenomenon. TOS is described in Chapter 25.

Brachial Plexus Neuropathy

Brachial plexus neuropathy, also known as idiopathic brachial neuritis, acute shoulder neuritis, neuralgic amyotrophy, or Parsonage–Turner syndrome is a condition that is often misdiagnosed as it has a similar clinical presentation to other pathologies such as cardiac disease, cervical radiculopathy, shoulder impingement, a rotator cuff tear, adhesive capsulitis, and calcific tendinopathy.[664–667]

The typical clinical presentation of this condition is an acute onset of sharp, severe pain in the upper extremity, which often awakes the patient at night and last for a few days to weeks. Soon after, when the pain lessens, the patient

notices weakness in the involved extremity and, with strength testing, moderate weakness to total paralysis of the shoulder girdle may be present.[668] Diagnostic testing may include EM, and nerve conduction studies.

In the acute stages, NSAIDs can be used to control the pain. Once the pain level is tolerable, PT is advocated to restore/maintain full ROM and to regain strength.[669] In addition, a sling can be used to support the weight of the arm when sitting, standing, and walking to support the scapular stabilizing muscles against the weight of the arm.[670]

Crutch Palsy

Crutch palsy, a type of brachial plexus neuropathy, which commonly follows the use of axillary crutches is rare but well recognized. T ere are a number of documented reports of compressive neuropathies stemming from the incorrect use of axillary crutches, the so-called "crutch palsy."[671–673] T e incorrect use of axillary crutches, with excessive weight bearing on the axillary bar, leads to a sevenfold increase in force on the axilla.[677] T is type of palsy can also be caused by an individual leaning over the back of a chair so that the axilla is compressed for a prolonged period of time. T e diagnosis of crutch palsy is usually made clinically by taking a careful history and performing a physical examination. T is includes observation of the patient during ambulation using crutches and looking at the axilla for such signs of chronic irritation as hyperpigmentation and skin hypertrophy. A detailed neurologic examination is usually sufficient to determine the cord or terminal branch(es) involved and the level of the involvement.[671]

Complex r egional Pain (shoulder/h and) syndrome

T is condition is described in detail in Chapter 18.

Cervical r adiculitis

T e onset of cervical radiculitis (see Chapter 25) can be insidious or traumatic, or secondary to shoulder disease such as adhesive capsulitis.[216,675]

T e patient reports a wide range of symptoms. T ese range from mild discomfort to severe pain that is associated with neck motion restrictions, particularly hyperextension and rotation.[71,676]

Objectively, there may be a loss of cervical lordosis with associated paravertebral muscle spasm. Palpation may reveal tenderness over the posterior aspect of the neck, which can exacerbate the radicular symptoms in the arm.[677] T e testing of muscle strength, sensation, and muscle stretch reflexes should help confirm the diagnosis.

Conservative intervention consists of the control of pain and inflammation through rest and activity modification. T e patient is educated on positions to avoid, including rotation toward the involved side and neck extension. Once the pain is controlled, the program is progressed to cervical ROM and strengthening exercises, postural education, and general strengthening and conditioning of the upper extremities.

Peripheral Nerve entrapment

T ere are a number of common peripheral nerve neuropathies in the shoulder region (see Chapter 3), which are being recognized with increasing frequency. T e nerves that can be injured in the region include the suprascapular, accessory, long thoracic, axillary, posterior (dorsal) scapular, and musculocutaneous.

Quadrilateral space syndrome

Idiopathic quadrilateral space syndrome, a compression of the axillary nerve as it passes with the posterior circumflex artery through the quadrilateral space, is rare.

T e typical clinical presentation includes:[658]

- Vague, poorly localized shoulder discomfort,
- Pain with fatigue when the patient attempts to maintain the arm above shoulder level,
- Paresthesias in a nondermatomal pattern,
- Tenderness to palpation in the quadrilateral space can occur.[678]

T e initial intervention is conservative and includes rest, muscle relaxants, and NSAIDs. Surgery may be required if there is no improvement in 3–6 months.[678]

Adverse Neural Tension

An abnormal response to mechanical stimuli of neural tissue is termed adverse neural tension (see Chapter 12).[679,680] T e G-H joint can be the source of neurologic tension due to multidirectional instability, direct trauma, or poor posture and resultant tension on the brachial plexus.[216,681] T e movements of shoulder ER and depression stretch the brachial plexus. Side flexion of the cervical spine away from the tested side also stretches the brachial plexus. Of en the patient adopts postures to compensate for tight neurologic structures and relieve the tension on the brachial plexus. One of the most common of these adaptive postures is elevation of the shoulder girdle.

Adhesions of the brachial plexus can be detected using the upper limb tension tests 1 and 2 (refer to Chapter 12).[680]

Axillary Web syndrome

Axillary web syndrome (AWS), or lymphatic cording, is a complication of breast cancer that impacts the musculoskeletal and lymphatic systems. AWS typically follows surgery for breast neoplasia. Although the etiology and pathogenesis of AWS has not been completely determined, there is a growing consensus that the cause is due to a hypercoagulation and fibrosis in and around the lymphatic vessels in the axilla.[682] More specifically, AWS consists of one or more (frequently two or three) cords of subcutaneous tissue that originate from the axilla, spread to the anteromedial surface of the arm down to the elbow and then move into the anteromedial aspect of the forearm and sometimes into the root of the thumb.[683]

T e classic clinical findings with AWS is a significant limitation in shoulder abduction range of motion, and this is of en the primary reason the patient seeks treatment.[684] T e patient may also report symptoms of pain, numbness, or pulling, that are felt throughout the arm and forearm, sometimes

extending into the hand. Since the symptoms of AWS can develop years af er an axillary node dissection, it is important for the clinician to include the differential diagnosis of AWS in any patient who has a history of lymph node dissection with the aforementioned findings.[684]

Although there have only been a few studies regarding the PT intervention for AWS, it would appear that the recommended treatment plan would include manual lymph drainage, neural mobilizations of the upper extremity, manual therapy (sof -tissue techniques),[685] patient education, and ROM exercises.[685]

Th er APeUTiC TeCh NiQUes

Techniques to increase Joint mobility

With some slight variations, the same techniques that are used to examine the joint glides of the shoulder complex (see "Passive Accessory Motion Tests" section) can be used to mobilize the joints, with the clinician varying the intensity of the mobilizations based on the intent of the treatment, patient response, and the stage of tissue healing. Unlike the testing positions, where the joint is placed in the resting position, the joint position for mobilization techniques varies:

- T e resting position is used if gentle techniques are to be used.
- T e restricted ROM is approximated if more aggressive techniques are to be used.
- T e purposes of joint mobilization include the following:
  - to increase accessory motion;
  - to increase ROM;
  - to decrease pain;
  - to improve periarticular muscle performance.

Joint mobilization may be preferable to stretching at the shoulder because it provides a precise stretch to a specific part of the capsule. It also can be performed with less pain, reduced load on other periarticular structures, and less compressive force on articular structures[438,687] as compared with physiologic stretching.[1] A number of studies[291,688,689] have examined the efficacy of passive joint mobilization and/or PROM. T ey found this mode of intervention to be effective for enhancing ROM in the patient with SIS. Investigators have suggested that joint mobilization, especially posterior gliding, may have an important role in restoring capsular extensibility in primary SIS[452,496] by preventing or stretching abnormal collagen cross-linkage,[253] rupturing adhesions,[690] reducing edema,[691] or reducing pain.[692] In addition to the G-H joint, the clinician should also ensure that the mobility at the A-C, S-C, and scapulothoracic joints are normal.

Kaltenborn[294] stressed the importance of promoting joint glides for increasing capsular mobility and prevention of joint compression and periarticular sof -tissue injury that may occur with long lever angular mobilizations.[447] Sustained manual capsule stretches are particularly effective in regaining motion.[1,693,694] Low load, prolonged stretching produces plastic elongation of tissues as opposed to the high tensile resistance seen in high load, brief stretching.[459,695] (i.e., the arm is brought to end range, pushed slightly beyond that range, and held in that position for 10–20 seconds).

Glenohumeral Joint

Distraction of the G-h Joint

T is is a general technique to stretch G-H capsule.

inferior Glide of the G-h Joint

T is technique can be used to increase G-H abduction

Posterior Glide of the G-h Joint

T is technique can be used to increase G-H IR, flexion, and horizontal adduction.

Anterior Glide of the G-h Joint

T is technique can be used to increase G-H ER, extension, and horizontal abduction. Caution must be used when using this technique in patients with a history of G-H subluxation/dislocation.

scapulothoracic Joint

Distraction

T is technique is a general technique to apply a stretch to the serratus anterior and to break up adhesions at the scapulothoracic joint.

superior Glide

T is technique is applied to increase ROM into scapulothoracic joint elevation and ER.

inferior Glide

T is technique is applied to increase ROM into scapulothoracic joint depression and IR.

medial Glide

T is technique can be used for increasing ROM into scapulothoracic joint retraction, depression, and IR.

Lateral Glide

Although this technique can be used for increasing ROM into scapulothoracic joint protraction, elevation, and ER, it should be used with caution in patients with posture impairments involving shoulder as this motion might already be hypermobile.

sternoclavicular Joint

T e S-C joint rarely needs mobilizing as it is of en hypermobile.

Acromioclavicular Joint

Anterior and Posterior r otation of the Clavicle

T is technique can be used to help with the overall motion of the clavicle, although these motions may already be hypermobile.

Superior Glide of the Acromion on the Clavicle

This technique can be used as a general mobilization technique and is particularly useful if the patient's A-C joint is tender to palpation.

Specific Passive Physiologic Mobilization: Humerus and Scapula

Quadrant Technique

The quadrant technique previously described as the Lock test (special tests of the shoulder) can also be used as a mobilization technique. This is done by adjusting the intensity according to the irritability of the condition. If the pain is severe, grade IV (small oscillatory techniques just into the tissue resistance) are used. If this technique decreases the pain, the technique is reapplied and reassessed. If the intervention produces no change in the symptoms, the clinician increases the grade slightly or increases the vigor and reassesses. If the intervention produces an increase in pain, the clinician continues with the same intervention but at a lesser grade.

Scapular Assist

The clinician stands behind the patient. The scapula is stabilized with one hand and, as the patient raises the arm, the scapula motion is assisted by applying a compressive force over the scapula with one hand while stabilizing the A-C joint with the other hand (Fig. 16-19). A similar technique may be used for increasing motion at the end range of arm elevation. This is a good technique to gain ROM during the period when the scapular controllers are being strengthened but have not reached the point when they are able to work independently.

Posterior Capsule (sleeper) stretch

The patient is in sidelying with the affected shoulder toward the table and the arm at 90 degrees of forward flexion.[166] The patient is asked to roll forward to approximately 45-degree angle. At this point scapular winging should be noticeable. The clinician stands behind the patient and applies pressure with the palm of the hand onto the medial border of the scapular.[193] The scapula is then depressed down toward the posterior thorax reversing the scapular winging, with the amount of scapula pressure gauged by the clinician's position in relation to the patient. The amount of forward roll and the degree of forward flexion of the involved extremity are important variables in adjusting the technique.

Specific Passive/Active Physiologic Mobilization of the Shoulder

Elevation through Abduction

The patient lies in the supine position with his or her head supported. The patient's upper extremity is adducted across his or her abdomen. The clinician palpates the posterior aspect of the patient's wrist with one hand and the proximal forearm with the other. The motion barrier is localized by instructing the patient to elevate the arm in the scaption plane to the limit of the physiologic ROM.[696] From this position, the patient is instructed to hold still while the clinician applies a gentle resistance into further elevation. The contraction is held for 3–5 seconds, after which the patient is instructed to relax completely. The new barrier of elevation/abduction is located and the mobilization is repeated.

Elevation through Adduction

The technique is identical to the one already described with the exception that the abduction component is replaced by one of adduction so that the patient performs a combination of elevation and adduction.[696]

Mobilizations With Movement

Decreased elevation

The patient is seated and the clinician stands on his or her uninvolved side. The clinician places one hand over the scapula of the involved side. Using the other hand, the clinician reaches around the front of the patient to place the thenar eminence or a belt (Fig. 16-136) on the anterior aspect of the head of the humerus of the involved shoulder. The patient is asked to elevate his or her arm while the clinician applies a posterior glide to the humeral head (avoiding pressure over the sensitive coracoid process).[697] If this technique is successful, the patient is asked to hold a weight while elevating the arm (Fig. 16-136).

Decreased internal rotation

The patient is seated with his or her hands as far behind the back as possible. The clinician stands facing the patient on the involved side. The clinician places one hand on the patient's

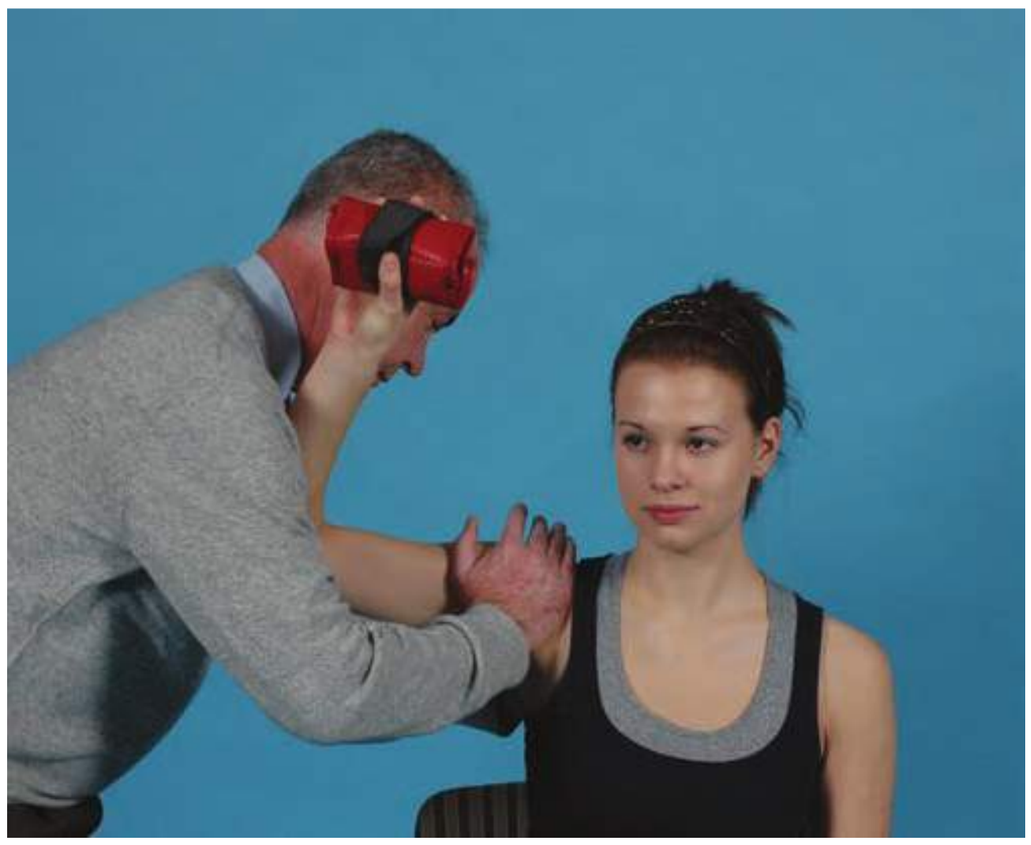

FIGURE 16-136 Mobilization with movement to increase elevation.

FIGURE 16-137 Mobilization with movement to increase IR.

forearm and the web space of other hand in the patient's axilla to stabilize the scapula by using a lumbrical grip (Fig. 16-137).[697] While maintaining the stabilization of the scapula, the clinician glides the humerus inferiorly in the glenoid fossa using the hand at the elbow and applies an adduction force by pressing their abdomen against the patient (see Fig. 16-137) as the patient internally rotates the shoulder (using their other hand to help if necessary). The technique can also be performed using a belt (Fig. 16-138).

Transverse Friction massage

Deep TFM is a good treatment adjunct for tendon and ligament injuries of the shoulder. Since the procedure needs to be performed at a specific area, the examination must accurately determine which structure is involved.

Biceps

The patient is positioned with the shoulder abducted to 30 degrees and the elbow flexed. The clinician stands at the patient's side and supports the arm (Fig. 16-139). The clinician places his or her fingers on the biceps tendon and alternately applies a medial and lateral glide motion to the tendon to create gentle friction.

FIGURE 16-138 Mobilization with movement to increase IR using belt.

FIGURE 16-139 Transverse friction massage of biceps tendon.

supraspinatus

The supraspinatus tendon is located just distal to the anterolateral corner of the acromion. It can become more discernible by positioning the patient's arm in slight extension behind the back (Fig. 16-140). The massage is applied perpendicular

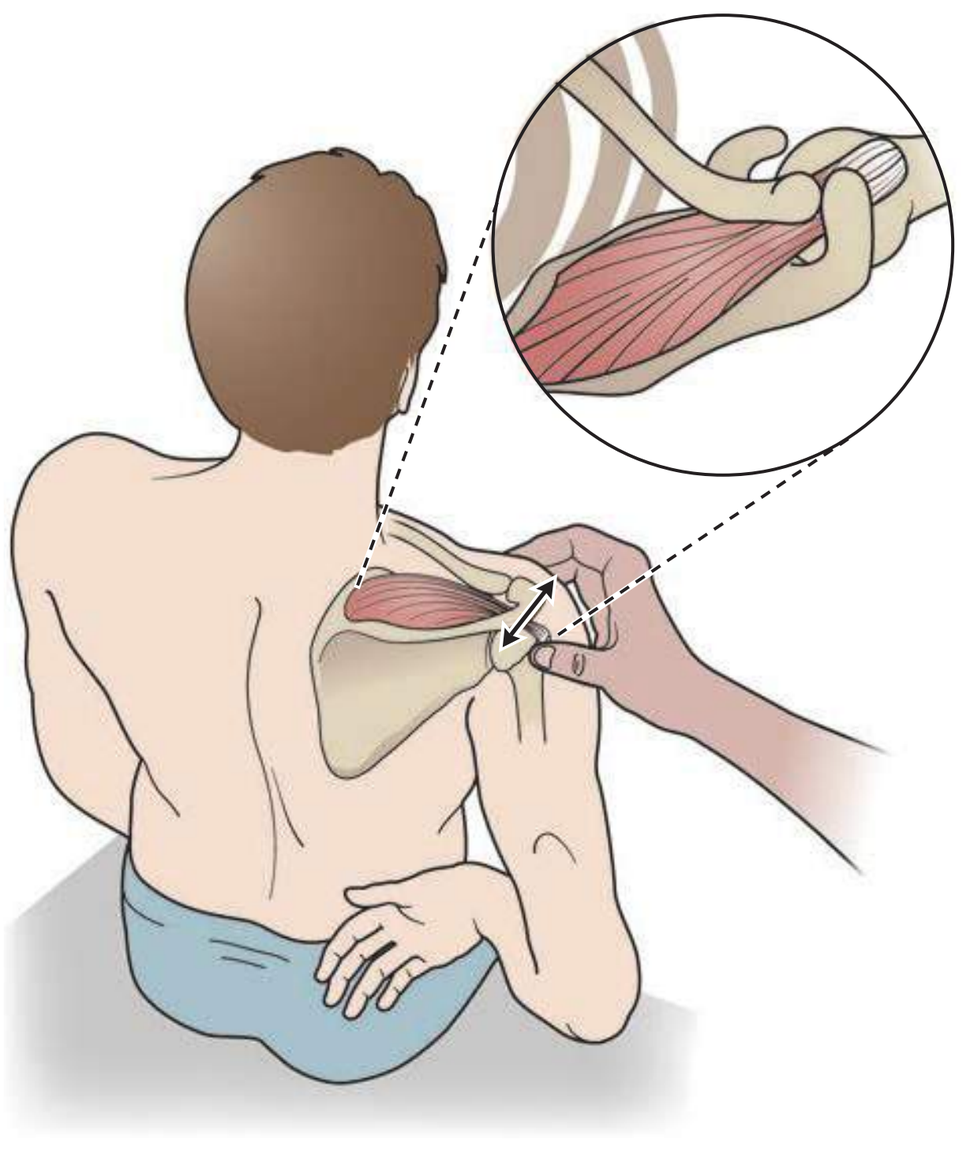

FIGURE 16-140 Transverse friction massage of the supraspinatus tendon.

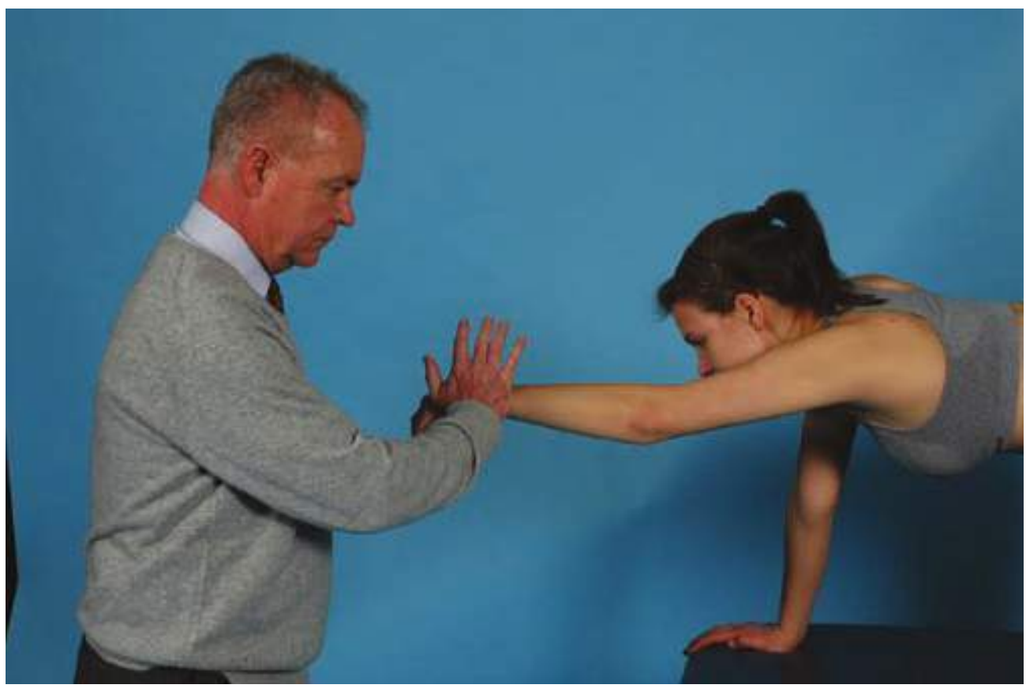

FIGURE 16-141 Rhythmic stabilization in quadruped.

to the tendon at the point of relative hypovascularity, which is located approximately 1 cm proximal to its insertion into the greater tuberosity of the humerus.[60]

rhythmic stabilization

The patient is positioned on all four limbs. The patient raises the involved arm to approximately 90 degrees of flexion and is asked to hold this position (Fig. 16-141) while the clinician applies a series of controlled alternating isometric contractions of the agonist and antagonist muscles to stimulate movement of the agonist, and develop stability, while monitoring scapular muscle activity.

The same exercise can be performed in a variety of positions.

self-stretches

The "saw"

This exercise can be used to stretch the anterior capsule when motion above 90 degrees is restricted. The patient can be in the standing or sitting position. Maintaining his or her arm in approximately 90 degrees of elbow flexion, the patient is asked to perform a sawing motion as though cutting through wood (Fig. 16-142).

Wall Walking

Wall walking can be used when attempting to regain full-range elevation. Clock exercises are a variation of wall walking. The hand is moved to the various positions on an imaginary clock face on the wall, ranging from 8 o'clock, through 12 o'clock, to 4 o'clock. This allows for rotation of the humerus throughout varying degrees of flexion or abduction to replicate rotator cuff activity. This exercise is first performed against a fixed resistance such as a wall or a countertop, and then can be moved to moveable resistance such as a ball or some other moveable implement.

Pulleys

Pulley exercises are commonly used as an active-assisted exercise to help regain full overhead motion. However, it is recommended that pulley exercises not be used until the patient has at least 120 degrees of elevation, and then only used in a pain-free arc to decrease the potential for impingement.

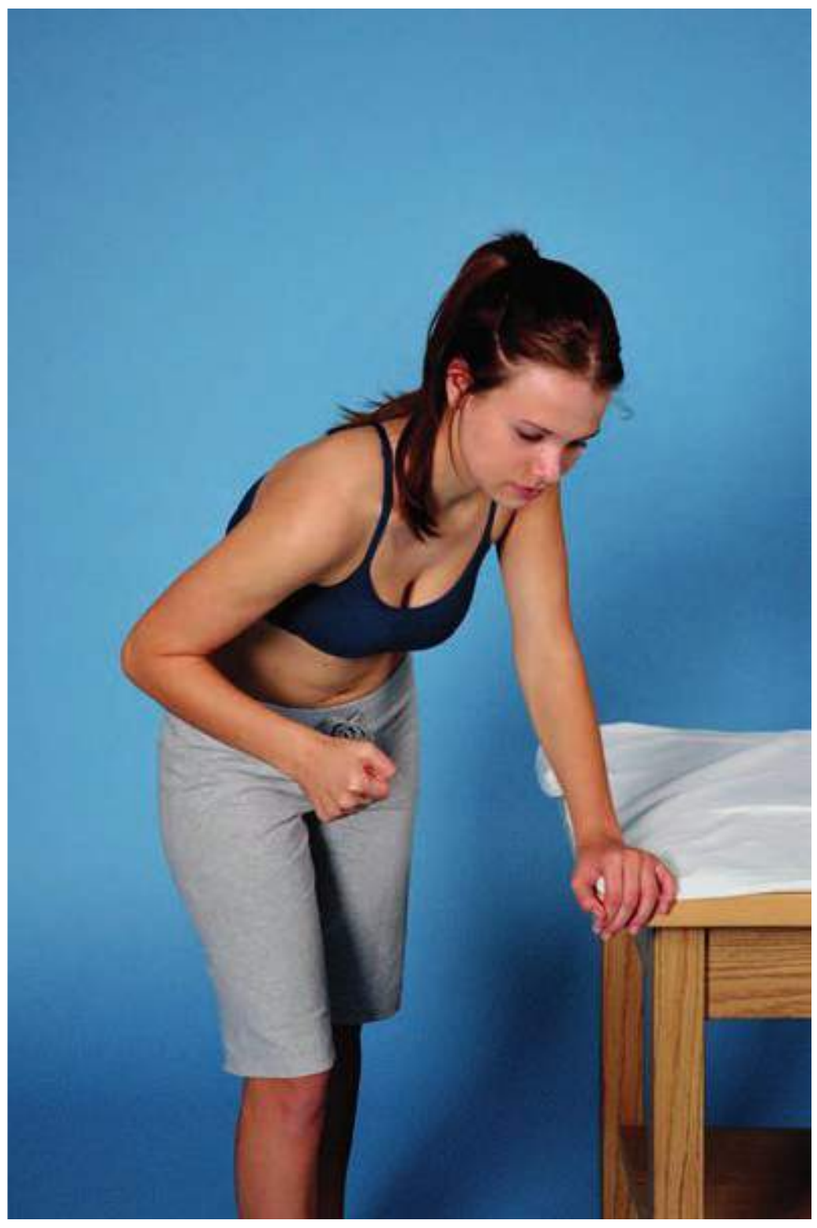

FIGURE 16-142 The saw.

Wall Corner stretch

This stretch is used to increase the flexibility of the anterior joint capsule, pectoralis major and minor, anterior deltoid, and coracobrachialis. The patient stands in a corner and places both hands and forearms on the wall, so that the upper arms are level with the shoulders. The stretch is applied by moving the trunk toward the wall, while keeping it perpendicular to the floor. The exercise can be modified to stretch one shoulder by performing the exercise in a doorway.

horizontal Abductors and Posterior Capsule

The horizontal abductors (posterior deltoid, infraspinatus, teres minor, rhomboids, and middle trapezius) and the posterior joint capsule are stretched by having the patient pull the arm across the front of their body (Fig. 16-143). This exercise should be used with caution for those patients with an impingement syndrome or A-C dysfunction.

inferior Capsule

The inferior capsule stretch is performed by placing the arm in the fully elevated overhead position (Fig. 16-144).

Pectoralis minor

The pectoralis minor can be stretched by asking the patient to clasp his or her hands behind the head (Fig. 16-145). From this position, the patient attempts to move the elbows in a posterior direction. Initially, the clinician can monitor the exercise to ensure that the stretch is occurring in the correct region.

FIGURE 16-143 Horizontal adduction stretch.

FIGURE 16-144 Inferior capsule stretch.

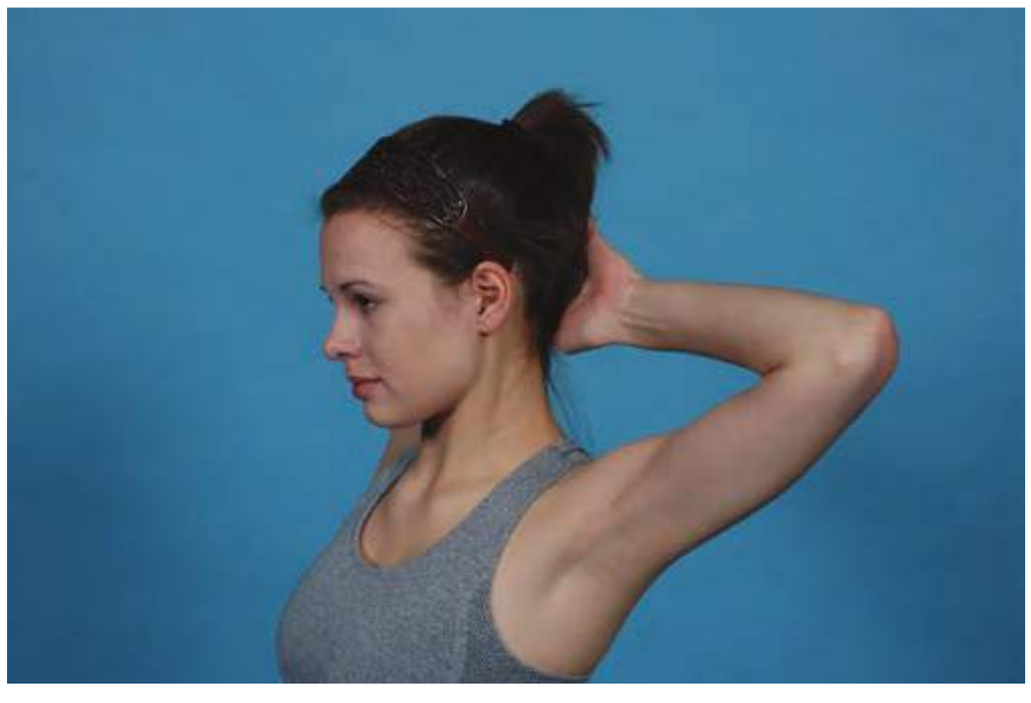

FIGURE 16-145 Pectoralis minor stretch.

FIGURE 16-146 T-bar exercise for flexion.

Shoulder Flexors

A T-bar or L-bar is used for this exercise. Two positions are used depending on the intent of the stretch.

To stretch the latissimus dorsi, teres major and minor, the posterior deltoid, triceps, and inferior joint capsule, the patient lies in supine position with the arm overhead (Fig. 16-146). Overpressure can be applied with the bar.

To stretch the anterior deltoid, coracobrachialis, pectoralis major, biceps, and anterior joint capsule, the patient's arm is positioned out to the side in approximately 90 degrees of abduction. The patient extends the arm as far as is comfortable (Fig. 16-147). The bar can be used to apply overpressure into further shoulder extension.

FIGURE 16-147 T-bar exercise for extension.

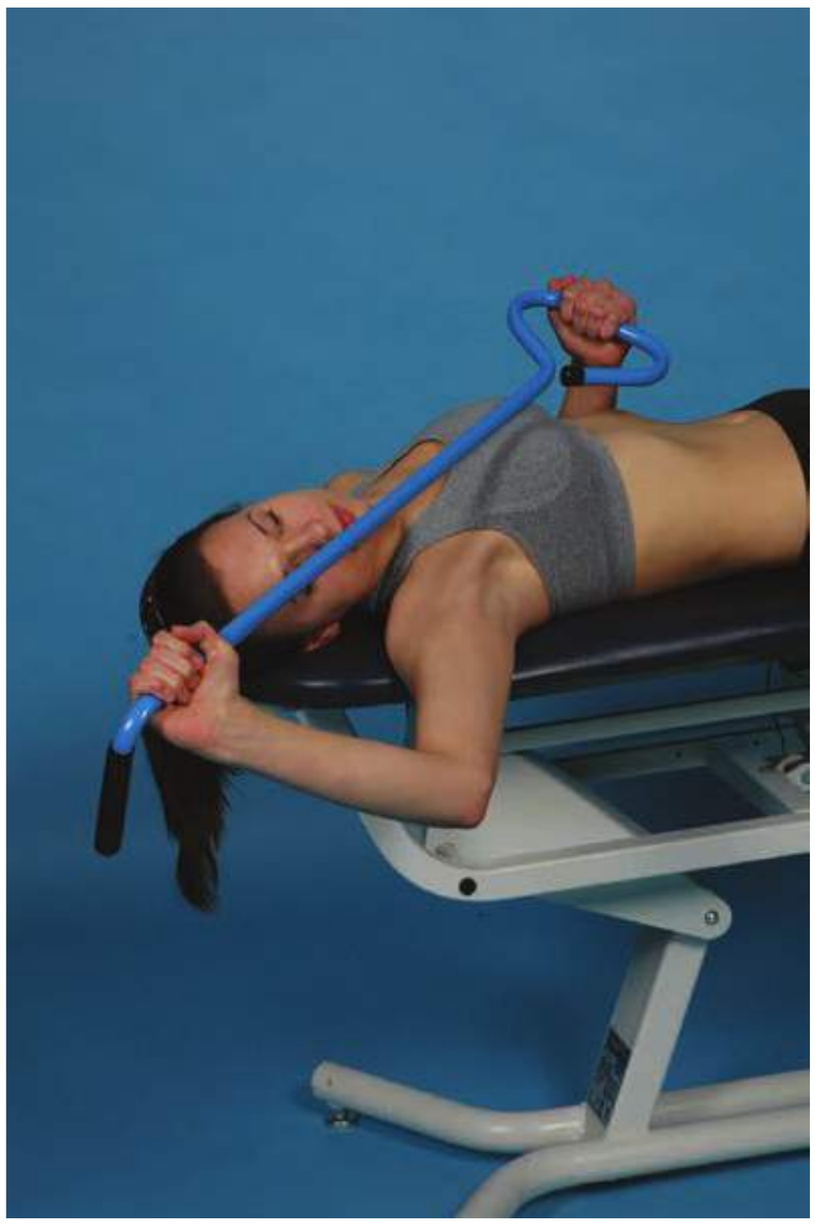

FIGURE 16-148 T-bar exercise for external rotation.

FIGURE 16-149 Towel stretch.

shoulder internal rotators

A T-bar or L-bar is used for this exercise. The patient lies in supine position. The arm is flexed at the elbow and in one of the three positions of abduction at the shoulder: 0 degrees, 90 degrees (see Fig. 16-148), and 130 degrees. For each of the three positions, the shoulder is externally rotated as far as is comfortable. Overpressure is then applied by the bar to stretch the subscapularis, pectoralis major, anterior deltoid, latissimus dorsi, and the anterior joint capsule.

shoulder external rotators

A T-bar or L-bar is used for this exercise. The patient lies in supine position. The elbow is flexed and the arm is abducted into one of the three positions at the shoulder: 0 degrees, 90 degrees, and 130 degrees. For each of the three positions, the shoulder is internally rotated as far as is comfortable. Overpressure can then be applied using the bar to stretch the infraspinatus, teres minor, posterior deltoid, and posterior joint capsule.

Alternatively, the patient can sit sideways to a table. The entire upper arm is placed on the table top, bending the trunk as necessary. The elbow is flexed to approximately 90 degrees. Using the other arm, the patient grasps the forearm of the involved arm and moves it into IR as far as is comfortable. Rhythmic oscillations, or hold–relax techniques, can be applied at the end of range.

Towel stretch

The towel-stretch exercise (Fig. 16-149) combines the motions of ER and IR and stretches the capsule accordingly.

AUTOMOBILIZATION TECHNIQUES

inferior Distraction

This is a good technique if the patient's shoulder abduction range is limited to below 90 degrees. The patient sits sideways next to a table. The involved arm is comfortably positioned using a towel roll or pillow in as much abduction as can be tolerated painlessly. The elbow is in full extension (Fig. 16-150). Using the uninvolved hand, or a towel wrapped around the humerus, the patient grasps the superoanterior aspect of the proximal humerus of the involved arm (see Fig. 16-150). From this position, an inferior glide is produced by pushing the humerus directly downward, or pulling the towel toward the floor. Rhythmic oscillations can be used.

FIGURE 16-150 Self-inferior distraction.

If the patient has more than 90 degrees of abduction, another technique is preferable. The patient stands against a wall with the involved shoulder positioned comfortably into abduction. The elbow is flexed to approximately 90 degrees and the fleshy part of the forearm rests against a wall. The other hand grasps the superoanterior aspect of the proximal humerus of the involved arm and applies an inferior glide by pushing the humerus downward toward the floor.

Inferior Distraction with Adduction

The patient stands or sits on a stool. A towel roll is placed under the axilla, and the arm to be mobilized is positioned across the chest. Using the uninvolved hand, the patient grasps the involved forearm just above the styloid processes and pulls the arm rhythmically across the chest into G-H adduction, and downward toward the floor (Fig. 16-151).

FIGURE 16-151 Inferior distraction with adduction.

CASE STUDY

Shoulder PAIN WITH CERTAIN MOTIONS

HISTORY AND SYSTEMS REVIEW

General Demographics

The patient is a 22-year-old male who lives at home with his parents.

History of Current Condition

Insidious onset of intermittent left shoulder pain began 2 weeks ago, with a report of occasional referral of pain into the upper left arm. The patient denies numbness or tingling into the left upper extremity. Pain increased sufficiently the past week to prompt the patient to see a physician, who diagnosed the condition as rotator cuff impingement and prescribed PT and NSAIDs. The patient was also placed on work restrictions; maximum lift limited to 10 lb.

History of Current Condition

No history of left shoulder pain.

Medical and Surgical History

Unremarkable.

Medications

Ibuprofen, 800 mg daily.

Functional Status and Activity Level

The patient reported stiffness and soreness of the left shoulder on arising in the morning and again at the end of the day after working. Difficulty was also reported with putting on a jacket, driving to work which takes 45 minutes, and the use of a hedge trimmer. The patient reported that the shoulder pain interrupts his sleep two to three times every night and that he was having difficulty combing his hair, brushing his teeth, or lifting his arm without pain. He also reported that he enjoyed swimming but cannot swim the crawl or backstroke because of the pain. The patient described "cracking" and "popping" of the shoulder with activity.

Health Status (Self-Report)

Generally in good health but pain interferes with tasks at home and at work.

Questions

1. What structure(s) do you suspect to be involved in this patient?
2. What could the history of pain with certain overhead movements indicate?
3. Why do you think the patient's symptoms are worsened with certain functional and recreational activities?
4. What additional questions would you ask to help rule out cervical involvement or pain referred from a visceral structure?
5. What is your working hypothesis at this stage? List the various diagnoses that could present with these signs and symptoms, and the tests you would use to rule out each one.
6. Does this presentation/history warrant a Cyriax upper quarter/quadrant scanning examination? Why or why not?

STiFF ANd PAiNFul Shoulder

HISTORY AND SYSTEMS REVIEW

General Demographics

The patient is a 55-year-old female who lives alone.

History of Current Condition

The patient reports a 7-month history of unilateral shoulder girdle stiffness, pain, and weakness with a diagnosis from the physician of "right frozen shoulder." There was no history of trauma, but the patient reported an abrupt onset of very severe pain 7 months prior. Within several days, she also had right forearm and thumb pain of lesser severity, and weakness of the right shoulder.

The forearm and thumb pain had since resolved, and although there was some restricted motion of the shoulder, the more marked painful stiffness of the shoulder did not occur until 2 or 3 months after the onset of symptoms. After 3 months, she was having difficulties performing her job functions and sought medical attention. Thus far, she had been treated with a series of two corticosteroid injections, both of which had given her short-term relief.

History of Current Condition

Non–work-related right shoulder injury 5 years ago, which resolved in 2 months with a course of PT, including ROM and strengthening exercises, which she followed for 1 month after discharge from PT.

Medical and Surgical History

Unremarkable. Gall bladder surgery 2 years ago.

Medications

Daily 800 mg ibuprofen and high blood pressure medication.

Other Tests and Measures

None.

Occupational, Employment, and School

Patient was a mail reception clerk for the postal service, and her job involved monitoring incoming mail, which required repeated opening and lifting of mail packages.

Functional Status and Activity Level

Stiffness/soreness occurs at the first hour in the morning, and again at the end of the day after working. Pain interferes with sleep two times per night, especially with rolling in bed or driving to work, which takes 30 minutes. The patient discontinued her normal three-times-a-week aerobic workout and upper and lower body resistance exercises approximately 3 months ago.

Health Status (Self-Report)

In general, the patient is in good health, except for a minor heart problem (congestive heart failure) and high blood pressure.

Questions

1. At this point in the examination, is it possible to determine the patient's diagnosis? Why or why not?
2. What does the history of pain with sleeping on the shoulder and pain/stiffness in the morning tell the clinician?
3. Why do you think the patient s symptoms are related to time of day?
4. What additional questions would you ask to help rule out pain referred from a visceral structure given the patient's medical history?
5. Do you have a working hypothesis at this stage? List the various diagnoses that could present with these signs and symptoms, and the tests you would use to rule out each one.
6. Does this presentation/history warrant a scan? Why or why not?
7. Do you think the patient's age is a factor?

CHAPTER 17 Elbow

CHAPTER OBJECTIVES

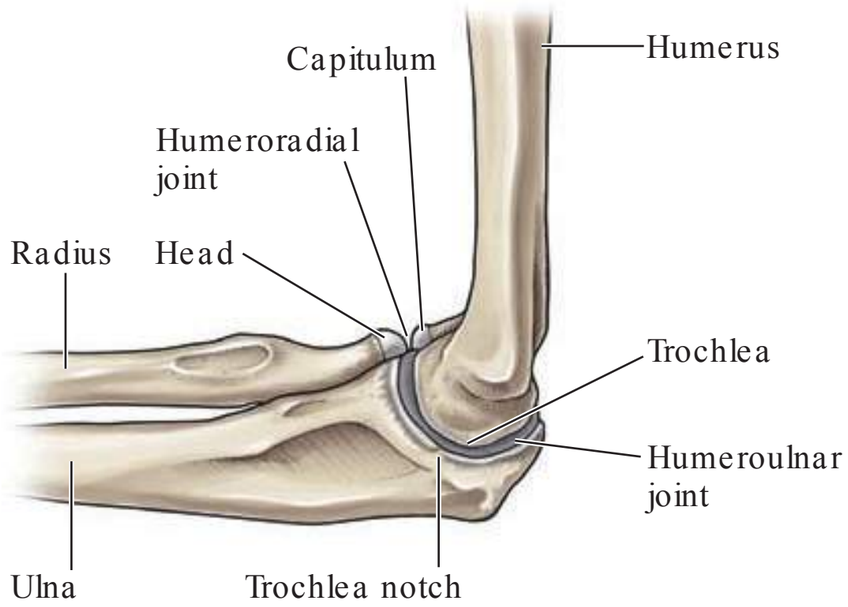
At the completion of this chapter, the reader will be able to:

1. Describe the anatomy of the joints, ligaments, muscles, and blood and nerve supply comprising the elbow complex.
2. Describe the biomechanics of the elbow complex, including open- and close-packed positions, normal and abnormal joint barriers, force couples, and stabilizers.
3. Describe the purpose and components of the tests and measures for the elbow complex.
4. Perform a comprehensive examination of the elbow complex, including palpation of the articular and soft-tissue structures, specific passive mobility, and passive articular mobility tests, and stability tests.
5. Evaluate the total examination data to establish a prognosis.
6. Describe the relationship between muscle imbalance and functional performance of the elbow.
7. Outline the significance of the key findings from the tests and measures and establish a diagnosis or working hypothesis.
8. Summarize the various causes of elbow dysfunction.
9. Develop self-reliant intervention strategies based on clinical findings and established goals.
10. Describe and demonstrate intervention strategies and techniques based on clinical findings and established goals.
11. Evaluate the intervention effectiveness in order to progress or modify an intervention.
12. Plan an effective home program and instruct the patient in same.

OVERVIEW

The elbow serves an important linkage function that enables proper positioning of the hand and the transmission of power from the shoulder to the hand, thus augmenting the versatility and agility of the upper extremity. Unlike the shoulder, the elbow complex is an inherently strong and stable joint, because of the interrelationship of its articular surfaces and ligamentous constraints. However, the stability of the elbow complex allows little in the way of compensatory adjustments, making it particularly vulnerable to overuse injury from repetitious muscle activity and sudden movements of acceleration and deceleration. Appropriate diagnosis and treatment require a detailed understanding of the normal anatomy of the elbow.

ANATOMY



The elbow complex, enclosed within the capsule of the cubital articulation, is composed of three distinct articulations: the humeroulnar joint, the humeroradial joint, and the proximal radioulnar joint. The anterior joint capsule of the elbow originates from the distal humerus proximal to the radial and coronoid fossa, from where it then inserts distally into the rim of the coronoid and the annular ligament (AL).[1] Posteriorly, the capsule incorporates the area proximal to the olecranon process; it attaches distally along the articular margin of the sigmoid notch and the proximal aspect of the olecranon fossa.[2]

CLINICAL PEARL

The joint capsule of the elbow complex is thin but strong and is reinforced medially and laterally by ligaments. Anteriorly, the capsule contributes 38% of the resistance to valgus force and 32% of the resistance to varus force in full extension.[3] The capsule of the joint does not respond well to injury or prolonged immobilization and often forms thick scar tissue, which may result in flexion contractures of the elbow.[4–6]

HUMEROULNAR JOINT

The humeroulnar (trochlear) joint is a uniaxial hinge joint formed between the incongruent saddle-shaped joint surfaces of the spool-shaped trochlea of the humerus and the trochlear

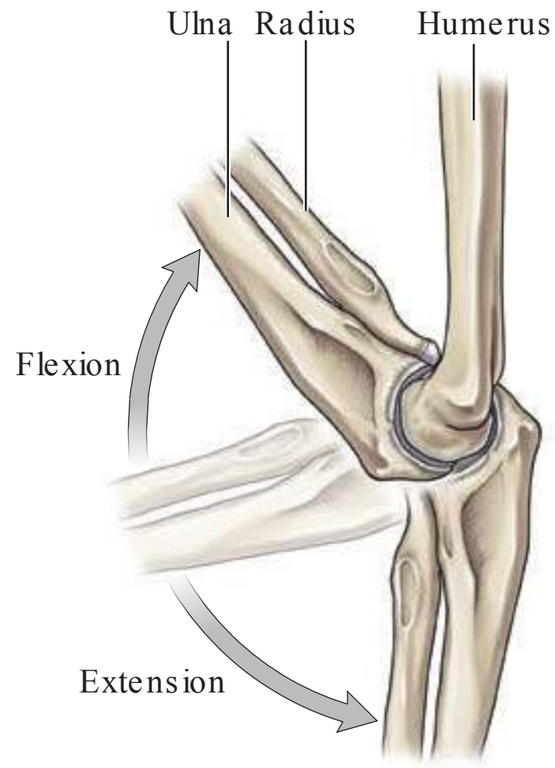


FIGURE 17-1 The bony structures of the elbow complex. (Reproduced, with permission, from Chapter 31. Arm. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

notch of the proximal ulna (Fig. 17-1). Anteriorly, the humeral trochlear groove is vertical and parallel to the longitudinal groove, while, posteriorly, the groove runs obliquely lateral and distal, forming an acute angle of about 15 degrees with the longitudinal axis of the humerus.[7] T is valgus angulation is referred to as the "carrying angle" of the elbow. T ree hundred degrees of the articular surface of the trochlea is covered with hyaline cartilage, compared with only 180 degrees on the trochlear notch.[8]

CLINICAL PEARL

The carrying angle serves to direct the ulna laterally during extension and increase the potential for elbow flexion motion, as the offset allows room anteriorly for approximation of the muscles of the arm and forearm. The carrying angle is approximately 11–14 degrees in males and 13–16 degrees in females.[9–11]

The resting or open-packed position for the humeroulnar joint is 70 degrees of flexion with 10 degrees of forearm supination. The close-packed position is full extension and maximum forearm supination. For the part of the joint between the coronoid process and the humerus, the close-packed position is maximum flexion. The capsular pattern is much more limitation of flexion than extension.[12]

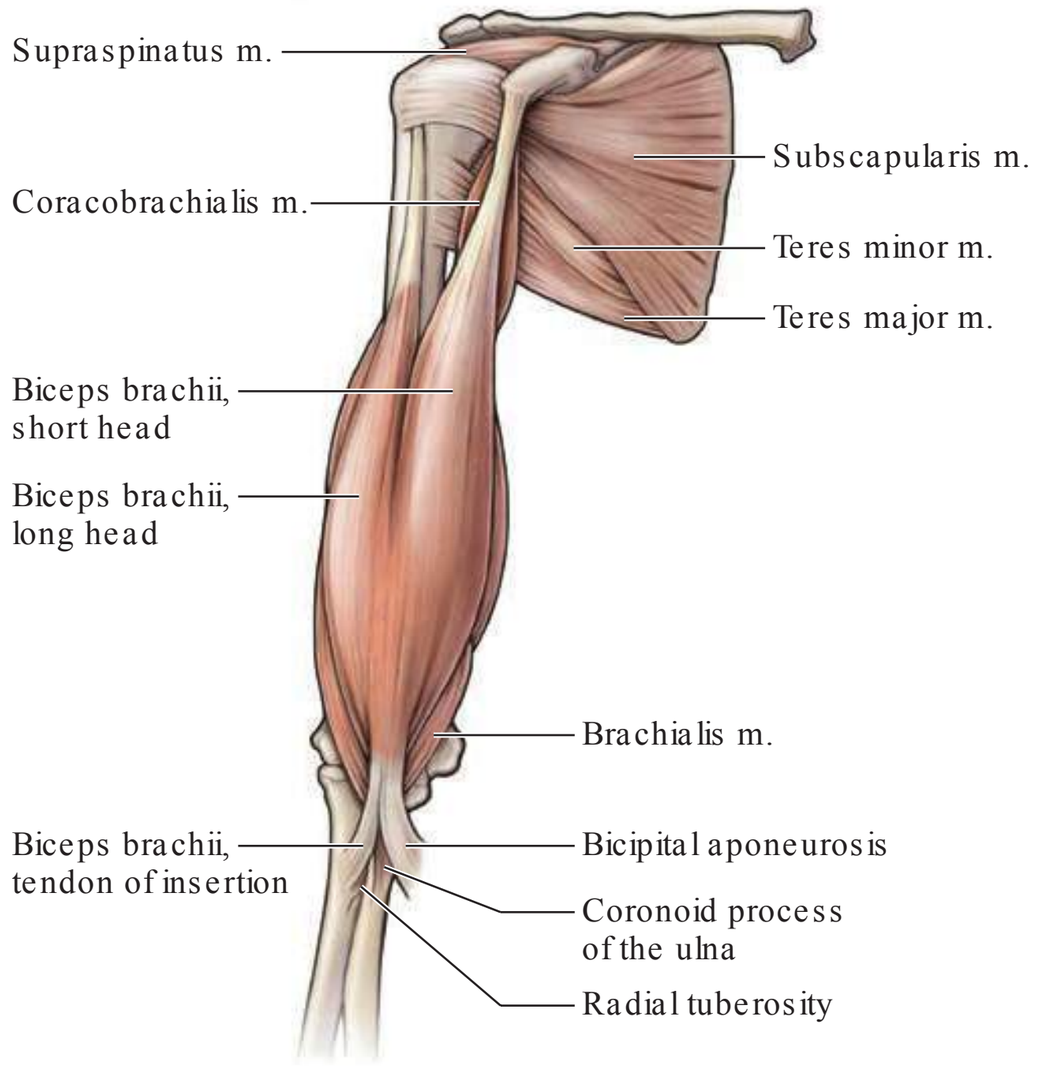

FIGURE 17-2 The biceps. (Reproduced, with permission, from Chapter 31. Arm. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

HUMERORADIAL JOINT

T e humeroradial (radiocapitellar) joint is a uniaxial hinge joint formed between the spherical capitellum of the humerus and the concave fovea of the radial head (see Fig. 17-1). T e design of this joint allows the elbow to flex and extend and for the radius to rotate. T e superior surface of the proximal end of the radius is biconcave while the head of the radius is slightly oval. T e radial tuberosity (see Fig. 17-2) serves as a site of attachment for the biceps brachii (see Fig. 17-2). T e humerus widens at the elbow and forms the medial and lateral epicondyles.

CLINICAL PEARL

The resting, or open-packed, position of the humeroradial joint is extension and forearm supination. The close-packed position is approximately 90 degrees of elbow flexion and 5 degrees of supination. There is no true capsular pattern at this joint, although clinically an equal limitation of pronation and supination is observed.

PROXIMAL RADIOULNAR JOINT

T e radius and the ulna lie side by side, with the radius being the shorter and more lateral of the two forearm bones. T e proximal or superior radioulnar joint is a uniaxial pivot joint. It is formed between the periphery of the convex radial head, and the fibrous osseous ring formed by the concave radial notch of the ulna (see Fig. 17-3), which lies distal to the trochlear notch, and the AL. T e AL (Fig. 17-4) forms 80% of the articular surface of the proximal radioulnar joint (see AL later).

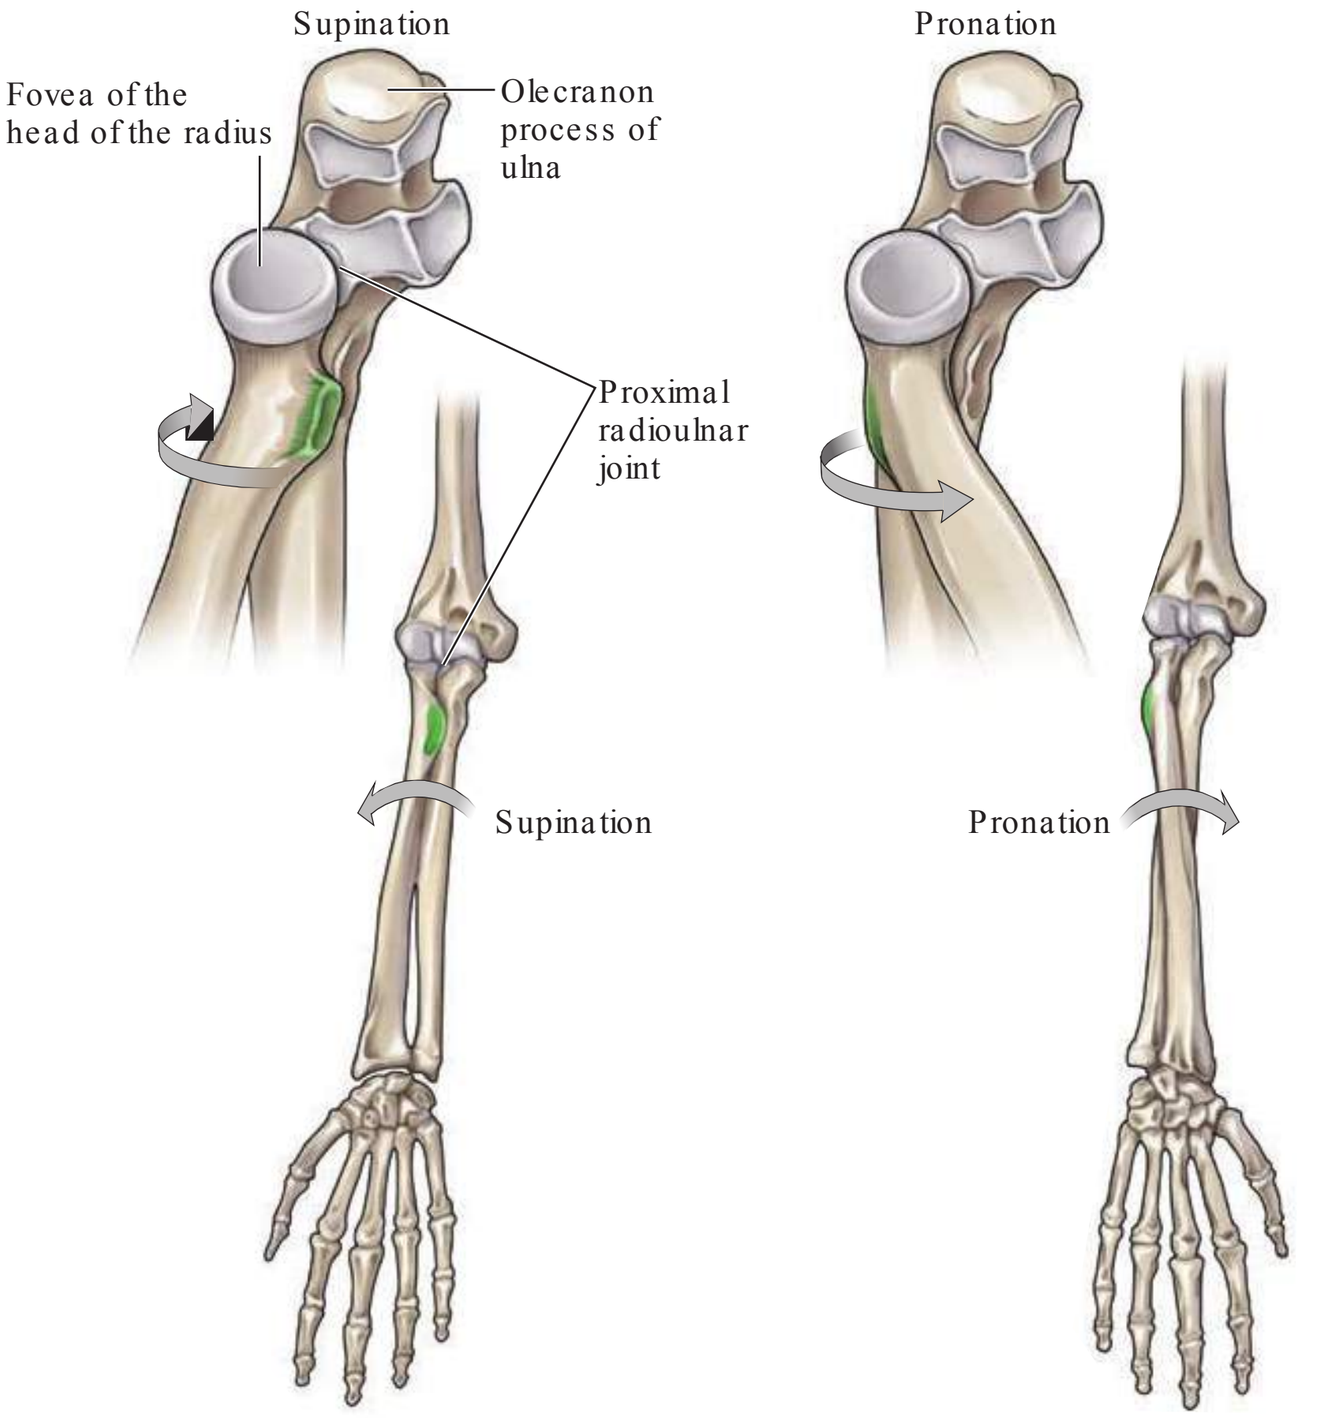

FIGURE 17-3 The proximal radioulnar joint, and the two major movements: (A) supination, and (B) pronation. (Reproduced, with permission, from Chapter 31. Arm. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

CLINICAL PEARL

The resting, or open-packed, position for the proximal radioulnar joint is 70 degrees of flexion and 35 degrees of forearm supination. The closed-packed position is 5 degrees of forearm supination. The capsular pattern is minimal to loss of motion, with pain at the end ranges of pronation and supination.[12]

The proximal and distal radioulnar joints together form a bicondylar joint. An interosseous membrane sometimes

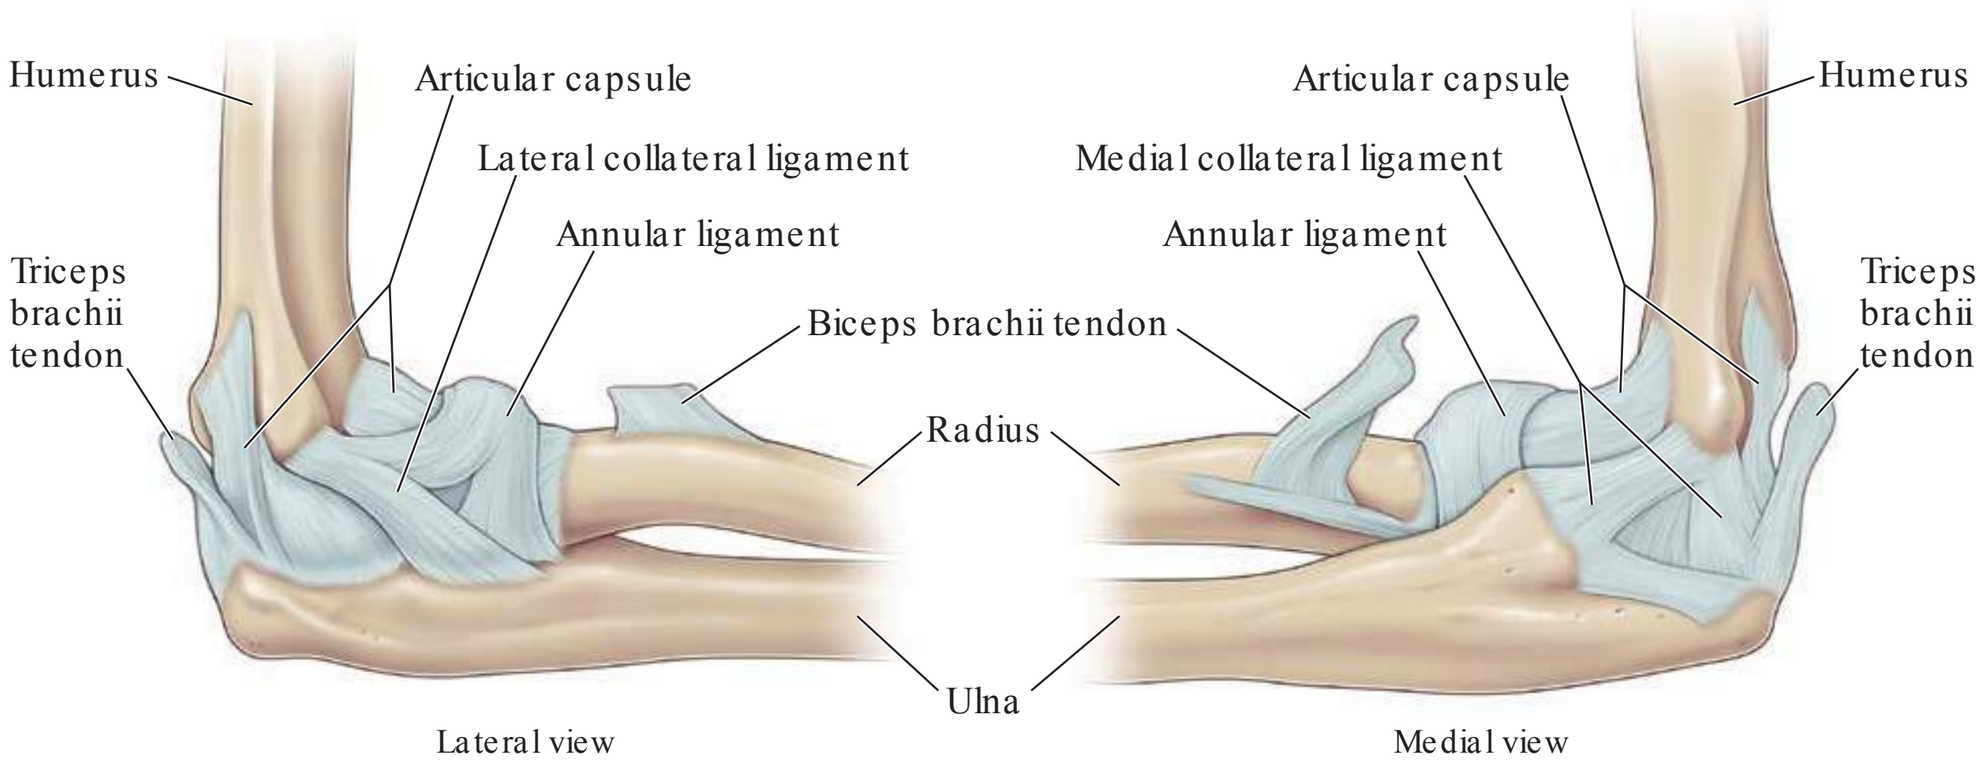

FIGURE 17-4 Elbow joint with ligaments detailed. (Reproduced, with permission, from Chapter 31. Arm. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

referred to as the middle radioulnar articulation and located between the radius and the ulna, serves to help distribute forces throughout the forearm, and provide muscle attachment. Most of the fibers of the interosseous membrane of the forearm are directed away from the radius in an oblique medial and distal direction.[8] Approximately 8% of the compression force due to bearing weight to the forearm crosses the wrist between the lateral side of the carpus and the radius.[8] The remaining 20% of the compression force passes across the medial side of the carpal bones and the ulna.[8] Because of the fiber orientation of the interosseous membrane, some of the proximally directed force through the radius is transferred across the membrane to the ulna.[13]

LIGAMENTS

Support for the elbow complex is provided through strong ligaments (Fig. 17-4).

Medial Ligament Complex

The ulna collateral ligament (UCL) or medial collateral ligament (MCL) extends from the central two-thirds of the anteroinferior surface of the medial epicondyle to the proximal medial ulna, from just posterior to the axis of the elbow medial epicondyle,[14–16] to just distal to the tip of the coronoid (see Fig. 17-4).[17,18]

The fan-shaped MCL is the most important ligament in the elbow for providing stability against valgus stress, particularly in the range of 20–130 degrees of flexion and extension,[19] with the humeroradial joint functioning as a secondary stabilizer to valgus loads.[20,21] The MCL achieves this stability through almost the total range of flexion and extension due to its eccentric location with respect to the axis of elbow motion.[22–25] In full elbow extension, valgus stability of the elbow is provided equally by the MCL, the joint capsule, and the joint interactions.[5]

There are three distinct components of the MCL[14,17,26,27]: the anterior bundle, the transverse bundle, and the posterior bundle (Fig. 17-4).

Anterior Bundle

The anterior bundle of the MCL is the strongest and stiffest of the elbow collateral ligaments, with an average load to failure of 260 newtons (N).[19] The anterior bundle of the MCL inserts an average of 18 mm distal to the coronoid tip, and is composed of two other components, the anterior band and the posterior band, which perform reciprocal functions:[17,22,26]

- The anterior band of the anterior bundle is the most important component of the ligamentous complex, because it primarily stabilizes the elbow against valgus stress in the ranges of 0–60 degrees of flexion, and becomes a secondary restraint with further flexion.[3,14,17,20–22,24,26,28] The anterior band is primarily responsible for stability against valgus stresses at 30, 60, and 90 degrees of flexion, making it the most important component in resisting the valgus forces associated with overhead sports activities.[1] Recently, Ochi et al.[15] determined that the deep middle portion of the anterior band, previously described as the "guiding bundle,"[27] is a prime limiting factor in humeroulnar motion.[22,29]
- The posterior band is taut from 60 to 120 degrees of elbow flexion and is a secondary restraint to valgus stress at 30 degrees and 90 degrees of flexion, but a primary restraint to valgus at 120 degrees of elbow flexion.[26] The posterior band functions as an equal co-restraint with the anterior band at terminal elbow flexion,[3,19,22,26,28] and also acts as a primary restraint to passive elbow extension. In the higher degrees of flexion, the posterior band is nearly isometric and is thus functionally important in the overhead athlete in counteracting valgus stresses.[30]

Oblique (Transverse) Bundle

The oblique bundle, also known as Cooper's ligament, is variably present.[14,17,31] It does not cross the elbow joint and comprises fibers running along the medial joint capsule from the tip of the olecranon to the medial ulna, just distal to the coronoid.[14,32] The transverse fibers have little role in elbow stability due to the fact that they both originate and insert on the ulna.

Posterior Oblique Bundle

The posterior bundle of the MCL originates from the medial epicondyle and inserts onto the medial margin of the semilunar notch, forming the floor of the cubital tunnel and a thickening of the posterior elbow capsule.[32,33] Being thinner and weaker than the anterior bundle, the posterior bundle becomes taut at 60 degrees of elbow flexion but provides only secondary restraint to valgus stress at flexion beyond 90 degrees.[22,23]

Lateral Ligament Complex

Unlike the medial ligament complex, the lateral ligamentous complex (see Fig. 17-4) is less discrete, and individual variation is common. The lateral complex consists of the AL, the lateral-radial collateral ligament (LCL), and the lateral ulnar collateral ligament (LUCL).[19] The LCL courses distally and forms a broad conjoint insertion onto the proximal ulna.[34,35] The proximal margin of this conjoined insertion begins at the proximal aspect of the radial head, just inferior to the radial notch. From here, it progresses along a rough ridge in line with the supinator crest of the ulna.[19] The LCL is closely associated with the insertions of the extensor carpi radialis brevis (ECRB) and the supinator, with the latter muscle crossing this ligament complex obliquely from distal to proximal at its ulnar attachment and becoming confluent with the underlying AL and LCL more proximally at its humeral origin.[19] The LUCL originates from the lateral epicondyle from where it passes over the AL and then begins to blend with it distally where it inserts onto the supinator crest of the ulna.[14] It is unclear as to how much stability is provided by the LUCL, but it may help prevent posterolateral rotary instability.[36]

As a unit, the lateral ligament complex functions to maintain the ulnohumeral and radiohumeral joints in a reduced position when the elbow is loaded in supination. More specifically, the anterior portion of the LCL stabilizes the proximal radioulnar joint during full supination; the posterior portion

stabilizes the joint during pronation. As the axis of rotation passes through the origin of the LCL, the various fibers of this ligament maintain consistent patterns of tension whether varus, valgus, or no force is applied to the elbow throughout the arc of flexion.[14,28] The LCL contributes only 9% of the restraint to varus stress at 90 degrees of flexion. In extension, the LCL contributes 14% of this restraint.[28]

Insufficient lateral support of the elbow complex results in lateral gapping at the ulnohumeral joint and posterior translation of the radial head in relation to the capitellum.[19] However, the proximal radioulnar relationship remains undisturbed.

CLINICAL PEARL

As much as 50% of elbow stability is the result of the joint capsule, MCL, and the LCL. The remaining 50% is associated with the bony structure of the joint. Other structures also provide passive support to the elbow complex. Secondary restraints of the lateral elbow consist of the bony articulations, and the extensor muscles with their fascial bands and intermuscular septa (see "Force Couples of the Elbow"). Secondary restraints of the lateral elbow consist of the bony articulations, the joint capsule (see Fig. 17-4), and the extensor muscles with their fascial bands and intermuscular septa. These independently support the forearm unit from laterally rotating away from the humerus by virtue of their anatomic arrangement, and provide a secondary static and dynamic vector supporting the lateral joint.[35]

Annular Ligament

The AL (Fig. 17-4), which is wider proximally and distally, runs around the radial head from the anterior and the posterior margin of the radial notch, to approximate the radial head to the radial notch and enclose the radial circumference. The AL forms a band that encircles 80% of the radial head and functions to maintain the relationship between the head of the radius and the humerus and ulna. The internal circumference of the AL is lined with cartilage to reduce the friction against the radial head during pronation and supination.[8] The external surface of the ligament receives attachments from the elbow capsule, the LCL, and the supinator muscle.

Quadrate Ligament

The quadrate ligament is a short, stout ligament that arises just below the radial notch of the ulna and attaches to the medial surface of the neck of the radius.[8] This ligament lends structural support to the capsule of the proximal radioulnar joint.[8]

BURSAE

There are numerous bursae in the elbow region.[23] The olecranon bursa is the main bursa of the elbow complex and lies posteriorly between the skin and the olecranon process. Under normal conditions, the bursa does not communicate with the elbow joint, although its superficial location puts it at high risk of injury from direct trauma to the elbow.

Other bursae in the posterior elbow region include the deep intratendinous bursa and a deep subtendinous bursa, which are present between the triceps tendon and olecranon. Anteriorly, the bicipitoradial bursa separates the biceps tendon from the radial tuberosity. Along the medial and lateral aspects of the elbow are the subcutaneous medial epicondylar bursa and the subcutaneous lateral epicondylar bursa.[37]

Muscles

A summary of the muscles of the elbow is outlined in Table 17-1. The muscles of the forearm are contained within three major fascial compartments, the anterior forearm, the posterior forearm, and the compartment referred to as the mobile wad (Table 17-2).

Elbow Flexors

Anatomic, biomechanic, and electromyographic (EMG) analyses have demonstrated that the prime movers of elbow flexion are the biceps, brachialis, and brachioradialis (see Table 17-1).[38] The pronator teres, flexor carpi radialis (FCR), flexor carpi ulnaris (FCU) (Fig. 17-5), and the extensor carpi radialis longus (ECRL) muscles are considered to be weak flexors of the elbow.[37] Most elbow flexors, and essentially all the major supinator and pronator muscles, have their distal attachments on the radius.[8] Contraction of these muscles, therefore, pulls the radius proximally against the humeroradial joint.[39,40] The combined efforts of all the elbow flexors can create large amounts of elbow flexion torque. The interosseous membrane transfers and dissipates a portion of this muscle force to the radius and to the ulna.[8] The reverse action of the elbow flexors can be used in a closed-chain activity by bringing the upper arm closer to the forearm such as when performing a pull-up.[41]

Biceps Brachii

The biceps is a two-headed muscle that spans two joints. The short head of the biceps arises from the tip of the coracoid process of the scapula where it meshes with the coracobrachialis and pectoralis minor tendon, whereas the long head arises from the supraglenoid tuberosity of the scapula (Fig. 17-2). The biceps has two insertions: a common tendinous insertion at the radial tuberosity and by the lacertus fibrosus (bicipital aponeurosis) that emanates from the biceps muscle belly at the level of the musculotendinous junction and crosses distally and medially to insert along the subcutaneous border of the ulnar (see Fig. 17-2).[42]

At the elbow, the biceps is a dominant flexor, but its secondary function is supination of the forearm.[43] The supination action of the biceps increases the more the elbow is flexed and is maximal at 90 degrees. It diminishes again when the elbow is fully flexed. No,[44] or limited,[45] biceps muscle activity has been demonstrated during elbow flexion, with the forearm pronated.[37] The biceps, via its long head, also functions as a shoulder flexor (see Chapter 16).

Brachialis

The brachialis (Fig. 17-6) originates from the lower two-thirds of the anterior surface of the humerus and inserts on the ulnar tuberosity and the coronoid process. The brachialis is the workhorse of the elbow and functions to flex

TABLE 17-1 Muscles of the Elbow, Forearm, Wrist, and Hand: Their Actions, Nerve Supply, and Nerve Root Derivation

Muscles	Nerve Supply	Nerve Root Derivation	Action
Triceps	Radial	C7–8	Elbow extension
Anconeus	Radial	C7–8, (T1)	
Brachialis	Musculocutaneous	C5–6, (C7)	Elbow Flexion
Biceps brachii	Musculocutaneous	C5–6	
Brachioradialis	Radial	C5–6, (C7)

Flexor carpi ulnaris	Ulnar	C7–8	
Flexor carpi ulnaris	Ulnar	C7–8	Ulnar deviation of the wrist
Extensor carpi ulnaris	Posterior interosseous (radial)	C7–8	
Flexor carpi radialis	Median	C6–7	Radial deviation of the wrist
Extensor carpi radialis longus	Radial	C6–7	
Abductor pollicis longus	Posterior interosseous (radial)	C7–8	
Extensor pollicis brevis	Posterior interosseous (radial)	C7–8	
Extensor digitorum communis	Posterior interosseous (radial)	C7–8	Extension of the fingers
Extensor indicis	Posterior interosseous (radial)	C7–8	
Extensor digiti minimi	Posterior interosseous (radial)	C7–8	
Flexor digitorum profundus	Lateral: anterior interosseous (median) Medial: Ulnar	C8, T1 C8, T1	Flexion of the fingers (lateral aspect flexes the second and third digits; medial aspect flexes the fourth and fifth digits
Flexor digitorum superficialis	Median	C7–8, T1	Flexion of the fingers

the elbow regardless of the degree of pronation and supination of the forearm,[45] It is the most powerful flexor of the elbow when the forearm is pronated.[46]

Brachioradialis

The brachioradialis (Fig. 17-5) arises from the proximal two-thirds of the lateral supracondylar ridge of the humerus and the lateral intermuscular septum. It travels down the forearm and inserts on the lateral border of the styloid process on the distal aspect of the radius.

The brachioradialis appears to have a number of functions, two of which occur with rapid movements of elbow flexion. Initially it functions as a shunt muscle, overcoming centrifugal forces acting on the elbow, and then by adding power to increase the speed of flexion.[43]

The brachioradialis also functions to bring a pronated or supinated forearm back into the neutral position of pronation and supination. In the neutral or pronated position, the muscle acts as a flexor of the elbow, an action that diminishes when the forearm is held in supination.[45,47]

Pronator Teres

The pronator teres (see Fig. 17-5) has two heads of origin: a humeral head and an ulnar head. The humeral head arises

TABLE 17-2	Muscle Compartments of the Forearm

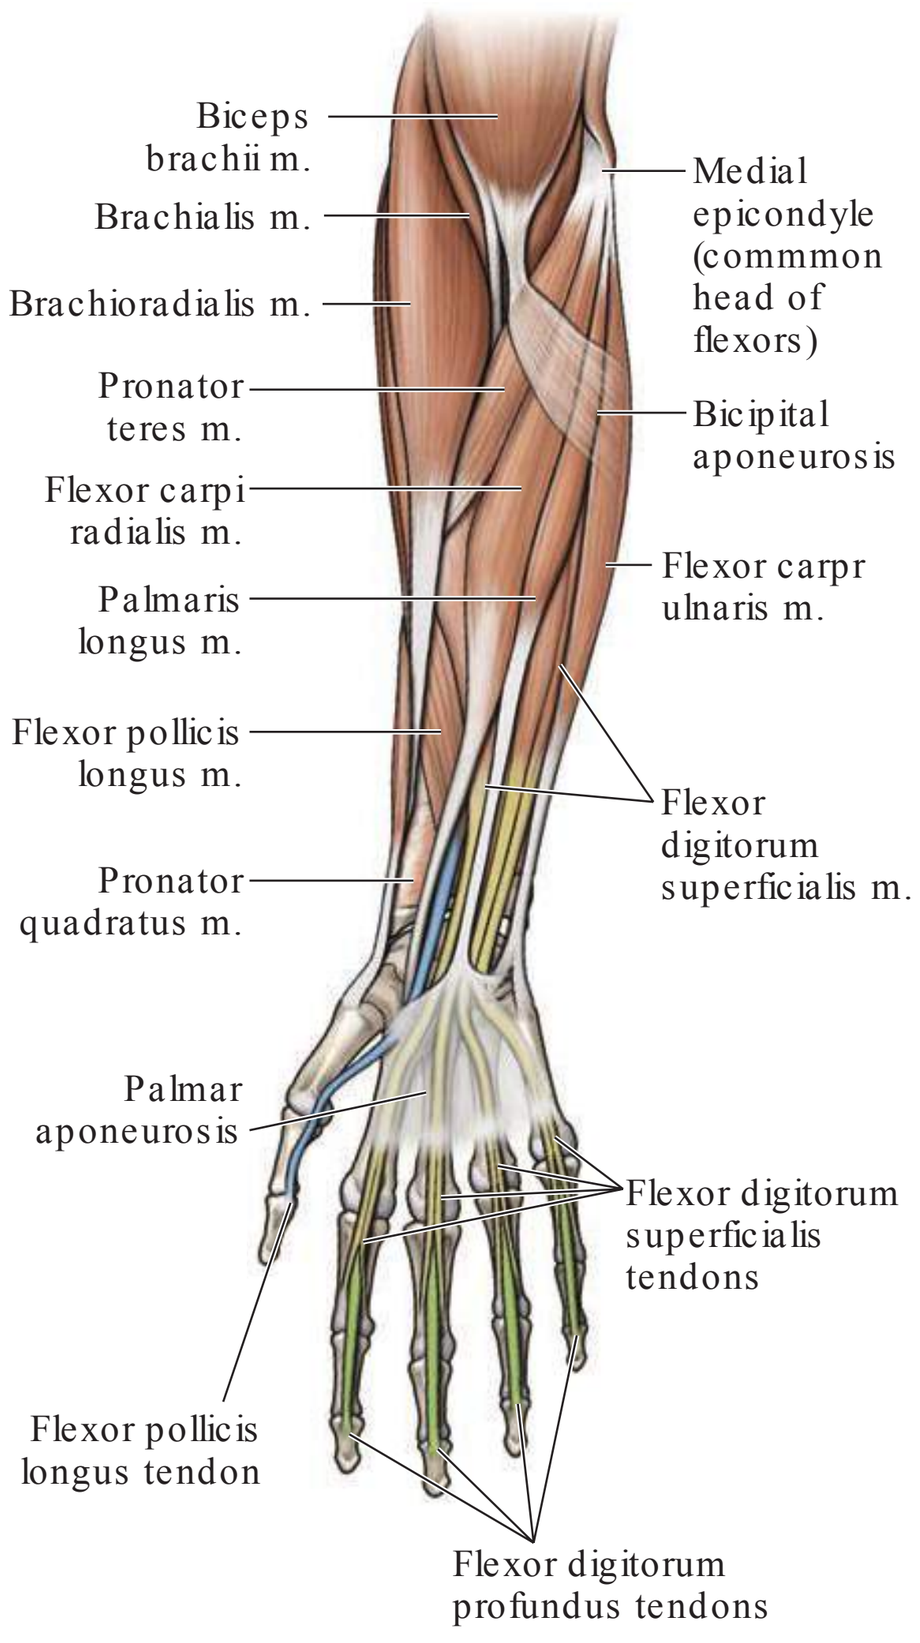

FIGURE 17-5 Muscles of the anterior forearm. (Reproduced, with permission, from Chapter 32. Forearm. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

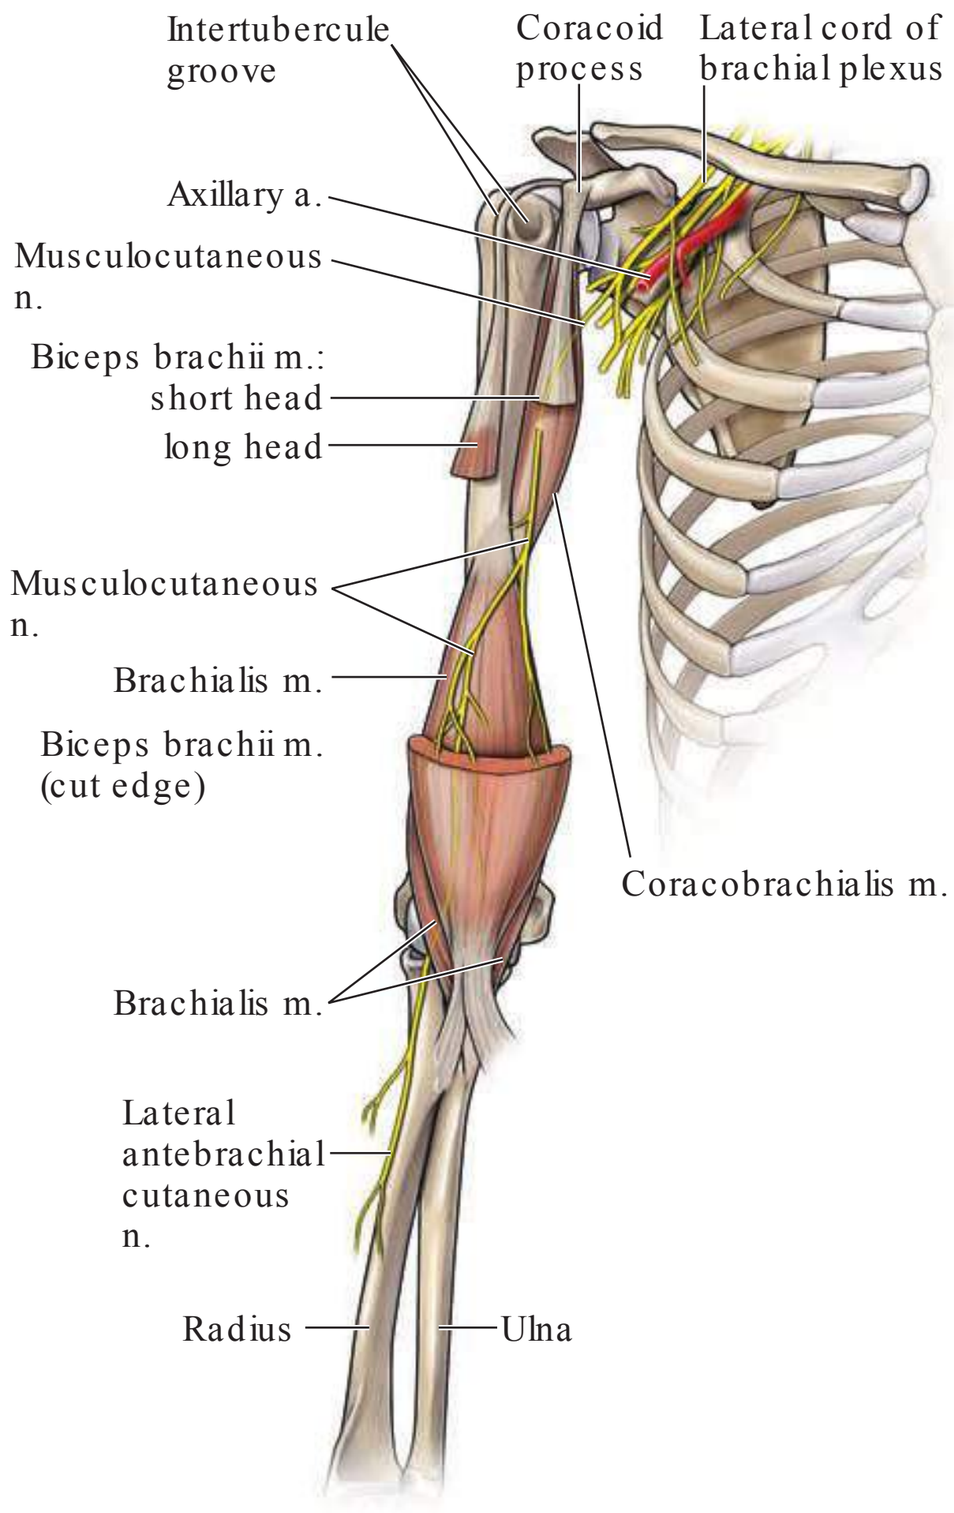

FIGURE 17-6 The brachialis muscle. (Reproduced, with permission, from Chapter 31. Arm. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

from the medial epicondylar ridge of the humerus and common flexor tendon, whereas the ulnar head arises from the medial aspect of the coronoid process of the ulna. The pronator teres inserts on the anterolateral surface of the midpoint of the radius. The muscle functions predominantly to pronate the forearm, but can also assist with elbow flexion.[5,46,47]

Extensor Carpi Radialis Longus

The ECRL arises from a point superior to the lateral epicondyle of the humerus on the lower third of the supracondylar ridge, just distal to the brachioradialis. It travels down the forearm to insert on the posterior surface of the base of the second metacarpal. The muscle functions as a weak flexor of the elbow, as well as assisting with wrist extension and radial deviation.

Flexor Carpi Radialis

The FCR (see Fig. 17-5) arises from the common flexor tendon on the medial epicondyle of the humerus and inserts on the base of the second and third metacarpal bones. The FCR functions to flex the elbow and wrist but also assists in pronation and radial deviation of the wrist.

Flexor Carpi Ulnaris

The FCU (see Fig. 17-5) has two heads of origin. The humeral head arises from the common flexor tendon on the medial

epicondyle of the humerus. It inserts on the pisiform, hamate, and fifth metacarpal bones. The FCU functions to assist with elbow flexion in addition to flexion and ulnar deviation of the wrist.

Forearm Pronators

Pronator Teres

See above.

Pronator Quadratus

The fibers of the pronator quadratus run perpendicular to the direction of the arm, running from the most distal quarter of the anterior ulna to the distal quarter of the anterior radius (see Fig. 17-5). It is the only muscle that attaches only to the ulna at one end and the radius at the other end.

The pronator quadratus is the main pronator of the hand.

Flexor Carpi Radialis

See above.

Forearm Supinators

Biceps

The effectiveness of the biceps as a supinator is greatest when the elbow is flexed to 90 degrees, placing the biceps tendon at a 90-degree angle to the radius. In contrast, with the elbow flexed only 30 degrees, much of the rotational efficiency of the biceps is lost.[41]

Supinator

The supinator originates from the lateral epicondyle of the humerus, LCL, the AL, the supinator crest, and the ulnar fossa. It inserts on the superior third of the anterior and lateral surface of the radius. The supinator muscle is a relentless forearm supinator, similar to the brachialis during elbow flexion. The supinator functions to supinate the forearm in any elbow position, while the previously mentioned ECRL and brevis work as supinators during fast movements, and against resistance.

The nervous system usually recruits the supinator muscle for low-power tasks that require a supination motion only, while the biceps remains relatively inactive—a fine example of the law of parsimony (see Chapter 3).[8]

CLINICAL PEARL

The muscles about the elbow help provide stability by compressing the joint surfaces through muscular contraction.[48] The flexor and pronator muscles, which originate at the medial epicondyle, provide additional static and dynamic support to the medial elbow,[5] with the FCU and flexor digitorum superficialis being the most effective in this regard.[49]

Elbow Extensors

There are two muscles that extend the elbow: the triceps and the anconeus (see Table 17-1).

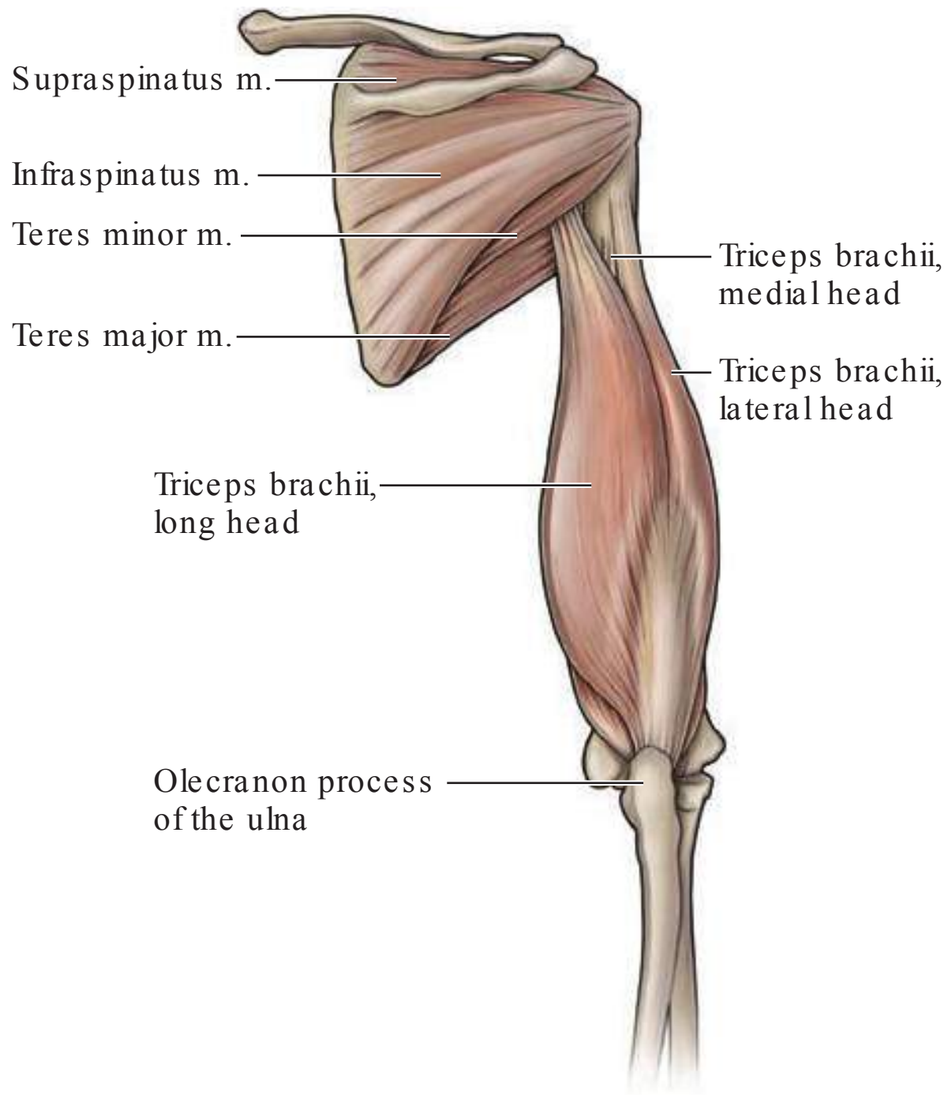

FIGURE 17-7 The triceps. (Reproduced, with permission, from Chapter 31. Arm. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

Triceps Brachii

The triceps brachii (Fig. 17-7) has three heads of origin. The long head arises from the infraglenoid tuberosity of the scapula, the lateral head from the posterior and lateral surface of the humerus, and the medial head from the lower posterior surface of the humerus. The muscle inserts on the superoposterior surface of the olecranon and deep fascia of the forearm. The triceps has its maximal force in movements that combine both elbow extension and shoulder extension. Like the biceps, it is a two-joint muscle. The medial head of the triceps is the workhorse of elbow extension, with the lateral and long heads recruited during heavier loads.[50] During strong contractions of the triceps, for example, a push-up, which involves a combination of elbow extension and shoulder flexion, as the triceps strongly contracts to extend the elbow, the shoulder simultaneously flexes by the action of the anterior deltoid, which overpowers the shoulder extension torque of the long head of the triceps.[41]

Anconeus

The anconeus arises from the lateral epicondyle of the humerus and inserts on the lateral aspect of the olecranon and posterior surface of the ulna. The exact function of the anconeus in humans has yet to be determined, although it appears to be a fourth head of the elbow extension mechanism, similar to the quadriceps of the knee.[8] It has been suggested that in addition to assisting with elbow extension, forearm pronation, and supination, the anconeus functions to stabilize the ulnar head in all positions (except radial deviation) and to pull the subanconeus bursa and the joint capsule out of the way during extension, thus avoiding impingement.[5,51] The anconeus has also been found to stabilize the elbow during forearm pronation and supination.[45]

CLINICAL PEARL

Tendonitis of the anconeus can mimic tennis elbow while hypertrophy of the anconeus muscle can compress the ulnar nerve.[52]

CUBITAL TUNNEL

The cubital tunnel, a fibro-osseous canal, was originally described by Feindel and Stratford.[53] The ulnar nerve passes through this tunnel. The floor of the tunnel is formed by the MCL, whereas the roof is formed by an aponeurosis, the arcuate ligament, or Osborne's band, which extends from the medial epicondyle to the olecranon and arises from the origin of the two heads of the FCU.[54–57] The medial head of the triceps constitutes the posterior border of the tunnel, and its anterior and lateral borders are formed by the medial epicondyle and olecranon, respectively.[30]

The volume of the cubital tunnel is greatest with the elbow held in extension.[58] As the elbow is brought into full flexion, there is a 55% decrease in canal volume.[54] Vanderpool et al.[59] reported that with each 45 degrees of flexion of the elbow, there was a concomitant 5-mm increase in distance between the ulnar and humeral attachments of the arcuate ligament. At full elbow flexion, there was a 40% elongation of the ligament and a decrease in canal height of approximately 2.5 mm.

A few other factors have been associated with a decrease in the size of the cubital tunnel. These include space-occupying lesions, osteoarthritis, rheumatoid arthritis, heterotopic bone formation, or trauma to the nerve.[58] Patients with systemic conditions such as diabetes mellitus, hypothyroidism, alcoholism, and renal failure also may have a predisposition.[60]

Bulging of the MCL has also been described as a factor.[59] More than 40% of athletes with valgus instability develop ulnar neuritis secondary to irritation from inflammation of the MCL.[61,62]

O'Driscoll et al.[57] reported that the groove on the inferior aspect of the medial epicondyle was not as deep as the groove posteriorly, and the floor of the canal seems to rise with elbow flexion.[57] These changes lead to an alteration of the cross-sectional area of the cubital tunnel from a rounded surface to a triangular or elliptic surface with elbow flexion.[54,58]

CLINICAL PEARL

The volume of the cubital tunnel is greatest with the elbow held in extension.

CUBITAL FOSSA

The cubital fossa (Fig. 17-8) represents a triangular space, or depression that is located on the anterior surface of the elbow joint, and which serves as an "entry way" to the forearm, or antebrachium. The boundaries of the fossa are as follows:

- Lateral. Brachioradialis and ECRL muscles;
- Medial. Pronator teres muscle;
- Proximal. An imaginary line that passes through the humeral condyles;
- Floor. Brachialis muscle.

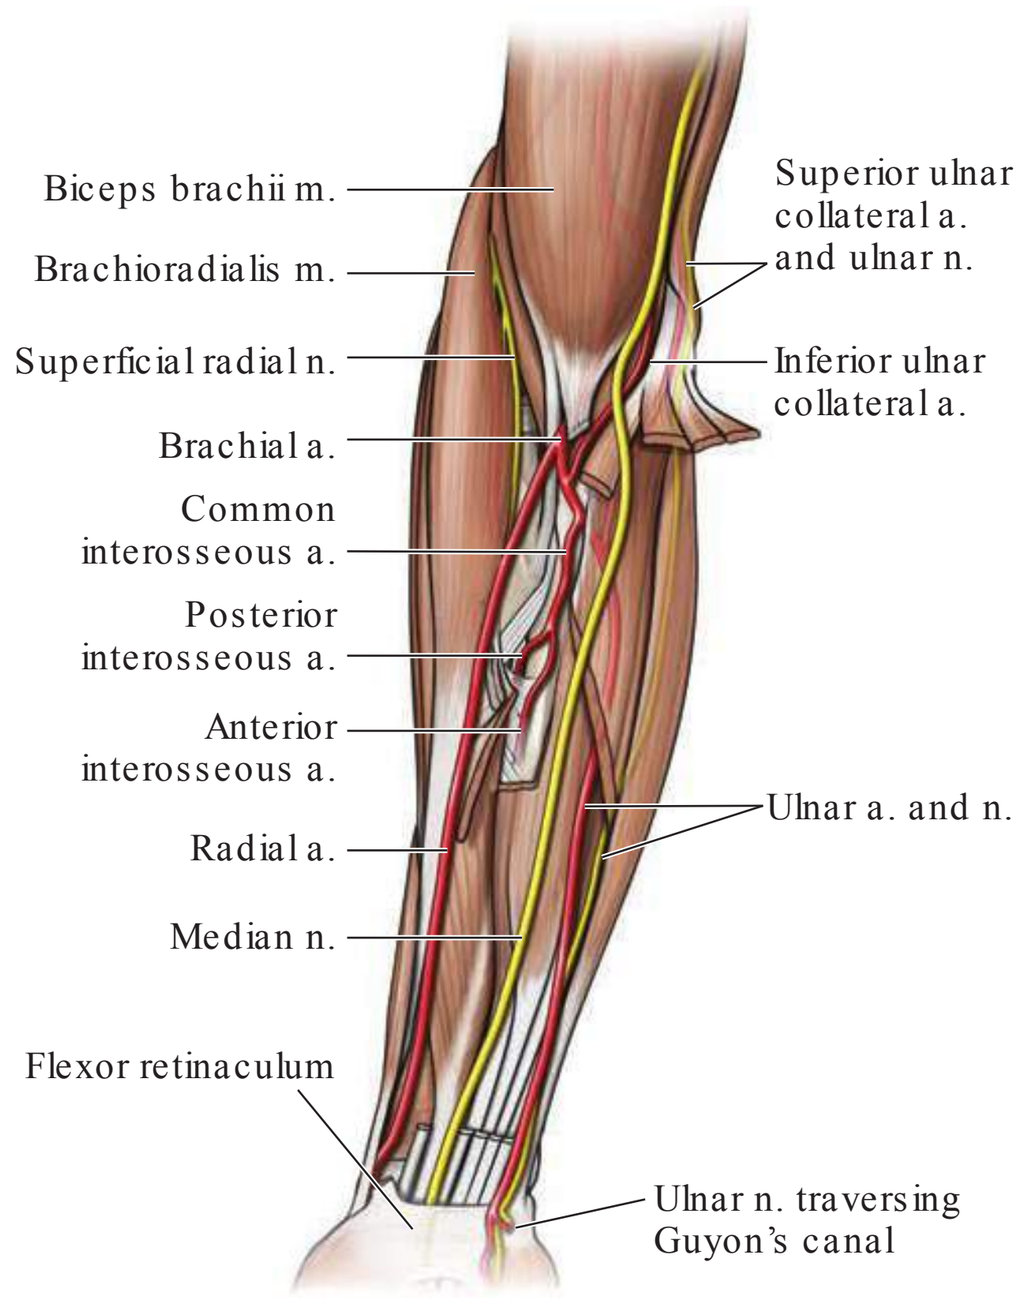

FIGURE 17-8 The cubital fossa. (Reproduced, with permission, from Chapter 32. Forearm. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

The contents of the fossa include (see Fig. 17-8):

- the tendon of the biceps brachii, which lies as the central structure in the fossa;
- the median nerve, which runs along the lateral edge of the pronator teres muscle;
- the brachial artery, which enters the fossa just lateral to the median nerve and just medial to the biceps brachii tendon;
- the radial nerve (not shown), which runs along the medial edge of the brachioradialis and ECRL muscles and is vulnerable to injury here; and
- the median cubital or intermediate cubital cutaneous vein, which crosses the surface of the fossa.

NERVES

The neurologic supply of the bones, joints, muscles, and skin of the elbow and forearm is derived from the C5 through C8 nerve roots, which exit from the intervertebral foramina of C4–5 through C7–T1 (Figs. 17-6 and 17-9).[63]

Ulnar Nerve (C8–T1)

From its origin as the largest branch of the medial cord of the brachial plexus, the ulnar nerve continues along the anterior compartment of the arm, before passing through the medial intermuscular septum at the level of the coracobrachialis insertion.

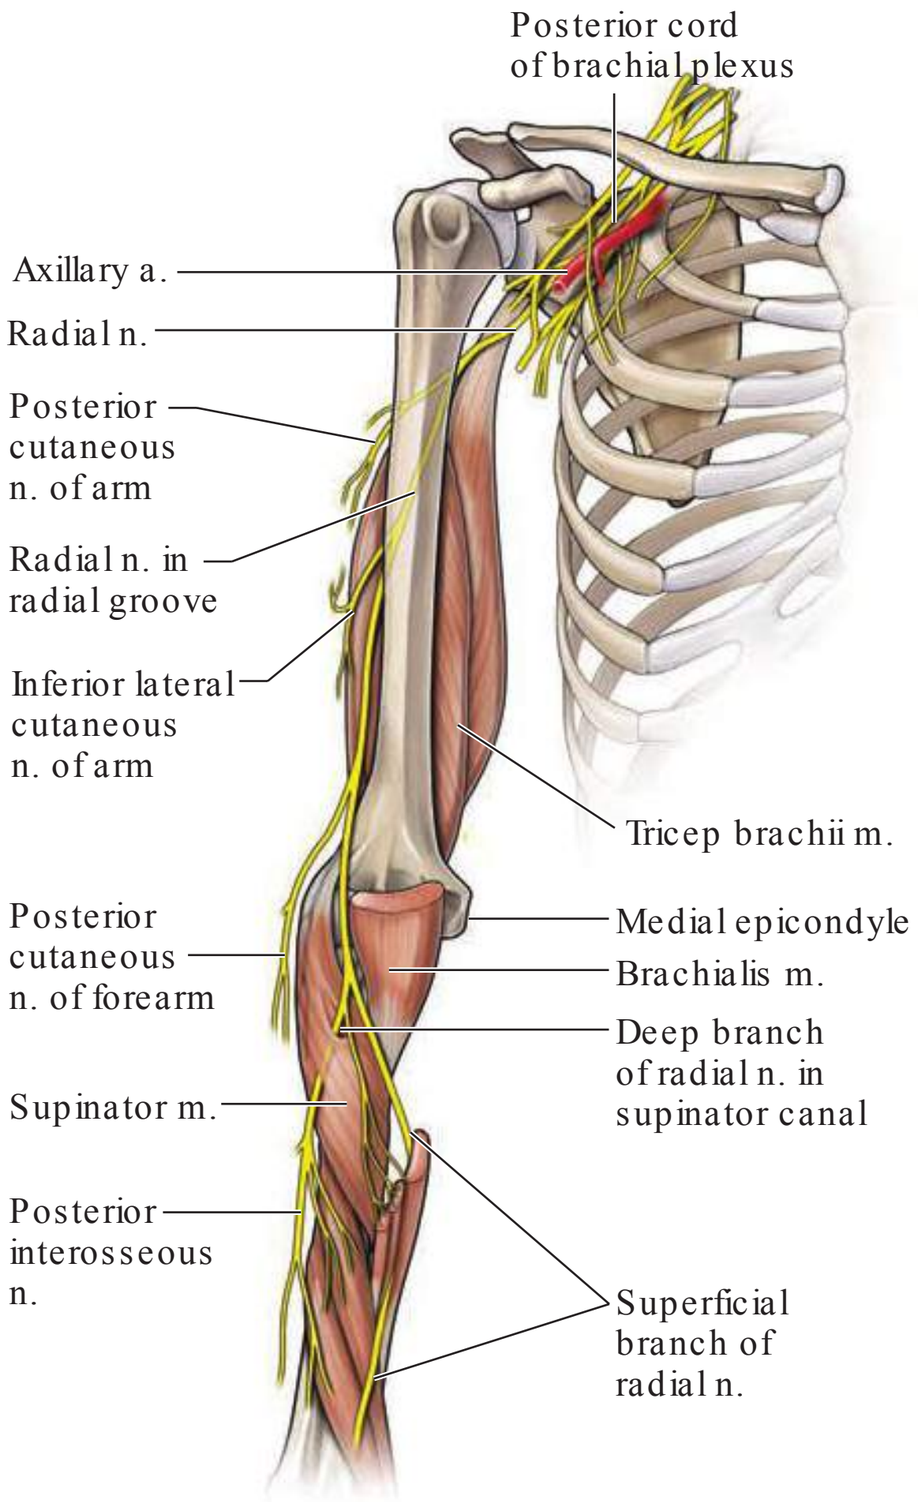

FIGURE 17-9 Nerve supply of the elbow and forearm. (Reproduced, with permission, from Chapter 31. Arm. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

At the level of the elbow, the ulnar nerve passes posterior to the medial epicondyle, where it enters the cubital tunnel. Ulnar nerve compression in the cubital tunnel is a common entrapment neuropathy of the upper extremity, second only to carpal tunnel syndrome (CTS).[64] After leaving the cubital tunnel, the ulnar nerve passes between the two heads of the FCU origin and traverses the deep flexor–pronator aponeurosis.[65,66]

Median Nerve (C5–T1)

The median nerve extends medially down the upper arm across the anterior aspect of elbow joint. The ligament of Struthers arises from an abnormal spur on the shaft of the humerus and runs to the medial supracondylar process.[56] The supracondylar process with its ligamentous extension encloses a foramen, bounded medially by the medial intermuscular septum, and the distal anterior surface of the medial epicondyle, through which the brachial artery and median nerve pass.[67]

As the median nerve passes through the cubital fossa, the anterior interosseous nerve (AIN) branches off it, as it passes through the two heads of the pronator teres muscle. The AIN supplies the motor innervation to the index and middle flexor digitorum profundus (FDP), the flexor pollicis longus (FPL), and the pronator quadratus.

Radial Nerve (C5–T1)

The radial nerve sits superiorly and medially in the upper arm and winds around the humeral shaft. At a point approximately 10–12 cm proximal to the elbow joint, the radial nerve passes from the posterior compartment of the arm by piercing the lateral intermuscular septum.[68] The nerve travels in the anterior forearm between the brachialis muscle and the biceps tendon medially, and the brachioradialis, ECRL, and ECRB muscles laterally.[68] Within an area approximately 3 cm proximal or distal to the elbow joint, the radial nerve branches into a deep mixed nerve, the posterior interosseous nerve (PIN), and a superficial sensory branch.[69,70] After dividing, the two terminal divisions usually follow the same course, sharing a single epineurium for several centimeters, before the superficial radial nerve moves anteriorly to lie on the undersurface of the brachioradialis, and the deep branch travels posteriorly to enter the radial tunnel/supinator canal, distal to the origin of the ECRB, at the level of the radiohumeral joint.[68] Entering the canal, the deep branch supplies the ECRB then passes deep to the superficial head of the supinator, where the arcade of Fröhse[1] can impinge on the nerve.[71,72]

The nerve continues between the two heads of the supinator and innervates this muscle during its passage to the posterolateral aspect of the radius. On emerging from the supinator, a motor division (supplying the abductor pollicis longus, extensor pollicis brevis, extensor indicis proprius, and extensor pollicis longus muscles) and a mixed lateral branch (supplying the extensor carpi ulnaris [ECU], extensor digitorum communis, and extensor digiti minimi muscles) are recognized. The lateral branch continues along the posterior-radial border of the radius to the wrist as the sensory branch of the PIN, which innervates the posterior (dorsal) capsule of the wrist and intercarpal joints (see Chapter 18).[68,72]

The Radial Tunnel/Supinator Canal

The radial tunnel lies on the anterior aspect of the radius and is approximately three to four fingerbreadths long, beginning just proximal to the radiohumeral joint and ending at the site where the PIN passes deep to the superficial part of the supinator muscle.[73] The lateral wall of the tunnel is formed by the brachioradialis, ECRL, and ECRB. These muscles cross over the nerve to form the anterior wall of the radial tunnel as well, while the floor of the tunnel is formed by the capsule of the humeroradial joint, and the medial wall is composed of the brachialis and biceps tendon.[68]

VASCULAR SUPPLY

The vascular supply to the elbow (Fig. 17-10) includes the brachial artery, the radial and ulnar arteries, the middle and radial collateral artery laterally, and the superior and inferior ulnar collateral arteries.[37]

[1]The arcade of Fröhse is an inverted arched structure that lies within 1 cm distal of the fibrous edge of the ECRB and approximately 2–4 cm distal to the radiohumeral joint. It represents the proximal border of the superficial head of the supinator, through which the radial nerve passes.

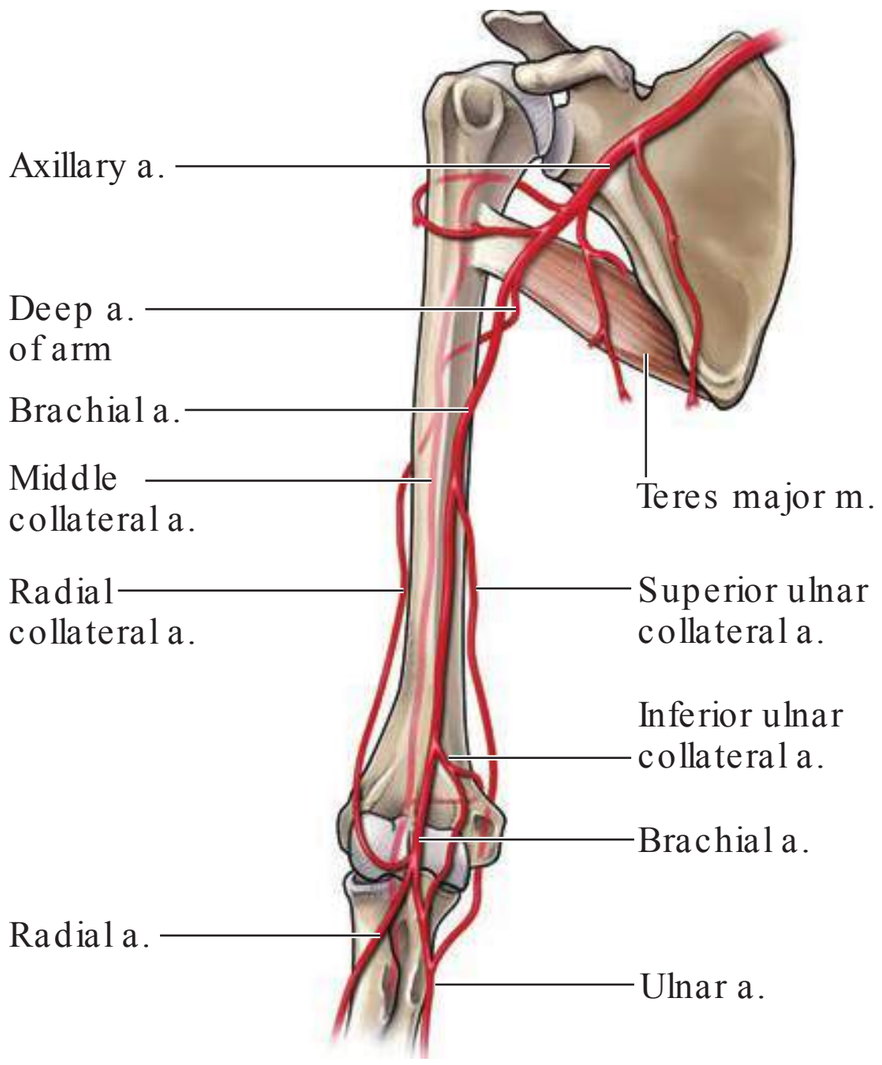

FIGURE 17-10 Vascular supply of the elbow and forearm. (Reproduced, with permission, from Chapter 31. Arm. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

BIOMECHANICS

There is still controversy in the literature as to the precise biomechanics of the elbow,[74] and how the axes of motion relate to the anatomy of the joint. Biomechanically, the elbow predominantly functions as an important central link in the upper extremity kinetic chain, allowing for the generation and transfer of forces that occur in the upper extremity. The common stresses that occur at the elbow include valgus stress, which results in medial tension and lateral compression loading; varus stress, which results in lateral tension loading; extension stress; and multiple combinations of these stresses. These forces produce repetitive tensile loads on the ligamentous and muscular support systems around the elbow, and compressive and shear loads on the bony constraints.[75] Truly impressive loads can be placed on the elbow during activities such as throwing or pitching (see Chapter 30).

It is important that the elbow is able to move freely and painlessly throughout its available motion. These motions include elbow flexion and extension, and forearm pronation and supination.

Flexion–Extension

Flexion–extension of the elbow complex occurs about a relatively fixed axis of rotation passing through the center of arcs formed by the trochlea and the capitellum (Fig. 17-1). The maximal range of passive motion generally available to the elbow is from 5 degrees of hyperextension to 145 degrees of flexion. Full active extension in the normal elbow is some 5–10 degrees short of that obtainable by forced extension, due to passive muscular restraints (biceps, brachialis, and supinator).[76,77] Passive extension is limited by the impact of the olecranon process on the olecranon fossa, tension in the dermis, the fibers of the MCL, and the anterior capsule.[78] Excessive ectopic bone formation around the olecranon fossa can also limit full passive extension. Passive flexion is limited by bony structures (the head of the radius against the radial fossa and the coronoid process against the coronoid fossa), tension of the posterior capsular ligament, soft-tissue approximation, and passive tension in the triceps.[78]

TABLE 17-3 Structures that can Restrict Supination and Pronation

Limit Supination	Limit Pronation
Pronator teres, pronator quadratus	Biceps or supinator muscles
Palmar capsular ligament at the distal radioulnar joint	Posterior (dorsal) capsular ligament at the distal radioulnar joint
Oblique cord, interosseous membrane, and quadrate ligament	
Ulnocarpal complex	Ulnocarpal complex

Data from Bert JM, Linscheid RL, McElfresh EC. Rotatory contracture of the forearm. J Bone Joint Surg Am. 1980;62:1163–1168.

Supination–Pronation

Pronation and supination require simultaneous joint movement at the proximal and distal radioulnar joints (Fig. 17-3).[8] The longitudinal axis of rotation about which supination and pronation occur is considered to pass through the center of the head of the radius to the convex articular surface of the ulnar at the distal radioulnar joint. Supination at the proximal radioulnar joint occurs as a spinning of the radial head within the fibro-osseous ring formed by the AL and radial notch of the ulna.[8] The arthrokinematics of pronation at the proximal radioulnar joint occurs by similar mechanisms.

Restrictions in the passive range of pronation and supination motions can occur from tightness in muscle and/or connective tissues (Table 17-3).[79,80]

HUMEROULNAR JOINT

The motions that occur at the humeroulnar joint involve impure flexion and extension, which are primarily the result of rotation of the concave trochlear notch of the ulna about the convex trochlea of the humerus. At the humeroulnar articulation, flexion involves an anterior roll and a distal/anterior slide at the ulnar joint surface. During extension, there is a posterior roll and a proximal/posterior slide at the ulnar joint surface. From a sagittal section, the firm mechanical link between the trochlear and the trochlear notch, however, limits the motion to essentially a sagittal plane.[8]

HUMERORADIAL JOINT

Any motion at the elbow and forearm complex involves motion at the humeroradial joint. T us, any limitation of motion at the humeroradial joint can disrupt both flexion and extension, and pronation and supination.[8]

During flexion and extension of the elbow, the humeroradial joint follows the pathway dictated by the anatomy of the ulnohumeral joint to which it is firmly attached by the annular and interosseous ligaments.[63] At the humeroradial articulation, flexion involves an anterior roll and an anterior slide at the radial joint surface. During extension, there is a posterior roll and a posterior slide at the radial joint surface. At rest in full extension, little if any physical contact exists at the humeroradial joint.[8,81]

During active flexion, however, muscle contraction pulls the radial fovea against the capitulum.[82,83]

Some supination and pronation also occur at this joint due to a spinning of the radial head.

Although the humeroradial joint provides minimal structural stability to the elbow complex, it does provide an important bony resistance against a valgus force.[8,21]

PROXIMAL RADIOULNAR JOINT

At the proximal radioulnar joint, one degree of freedom exists, permitting pronation and supination (Fig. 17-3). Both the fascia and the musculature of the forearm depend on the integrity of the interosseous radioulnar relationship for their mechanical efficiency.[63]

T e proximal radioulnar joint is structurally an ovoid, with very little swing available to it due to its ligamentous constraints. As a consequence, its movement is confined to accommodating the osteokinematic spin of the radius. As the radial head forms the convex partner, there is a tendency for the radial head to move posterolaterally during pronation and anteromedially during supination, but these movements are strongly curtailed by the annular and interosseous ligaments. At the joint surfaces, pronation involves an anterior roll of the complex rim of the radial head and a posterior slide. During supination, there is a posterior roll of the rim of the radial head and an anterior slide.

COUPLED MOTIONS

Conjunct rotations occur at the elbow complex with all motions. In addition, the elbow motions of flexion and extension are associated with adduction and abduction motions. T e ability to abduct and adduct can easily be observed during pronation and supination. In the fully supinated position, the ulna is much nearer the midline of the body than it is in full pronation. T erefore, abduction occurs with pronation, and adduction occurs with supination.

T e abduction that occurs with extension occurs at the humeroulnar joint and is more apparent than real. An increase in the carrying angle of the forearm during extension must not be confused with the abduction of the ulna, which occurs because of the unequal ranges of extension between the ulna and the humerus, and the radius and the humerus (the capitellum being oriented more anteriorly than the trochlear). T is inequity produces a conjunct humeral adduction with flexion and a conjunct humeroulnar abduction with extension, both of which are controlled by the lateral and MCL.[63]

T us, it is apparent that pronation–supination and flexion–extension are interdependent, and each is a conjunct motion of the other, at least at the extremes of the range. Since pronation and supination involve the proximal and distal radioulnar joints and the humeroulnar, humeroradial, and radiocarpal joints, mechanical dysfunction of any of these joints may become apparent, especially in the extremes of elbow flexion or extension.[63]

FORCE COUPLES OF THE ELBOW

T e role of the elbow musculature as dynamic joint stabilizers is still somewhat unclear. Both varus and valgus forces are produced by muscles during elbow motions. T e valgus forces are produced by the ECU, EDC, ECRL, and brachioradialis, while varus forces are produced by the FCR, FDS, pronator teres, and FCU. Forces transmitted across the articulating surfaces include the forces created by muscles working together to produce the desired activity. T e important force couples of the elbow include:[84]

- the triceps/biceps during elbow extension and flexion;
- pronator teres and pronator quadratus/supinator during forearm pronation and supination;
- FCR, FCU, flexor digitorum communis/ECRL, ECRB, and extensor communis during wrist flexion and extension; and
- triceps/biceps and brachioradialis; pronator teres/supinator; and FCR, FCU/ECRB, and ECRL during activities requiring elbow stabilization.

EXAMINATION

Since the elbow is one of the multiple links of the upper extremity kinetic chain, a thorough static and dynamic examination of the entire upper extremity and cervical spine as well as the trunk should be performed in addition to examination of the elbow proper. T e physical examination must include at least inspection, range-of-motion (ROM) testing, palpation, provocative testing, and neuromuscular testing. T e interventions for the common pathologies of the elbow complex and their interventions are detailed after the examination is described. An understanding of both is obviously necessary. As mention of the various pathologies occurs with reference to the tests and measures and vice versa, the reader is encouraged to switch between the two.

HISTORY

During the history, the clinician must determine the chief complaint and location of symptoms. In addition to the questions listed under history in Chapter 4, answers to the following questions must be obtained:

- What is the patient's chief complaint? The patient's chief complaint can often afford clues as to the underlying pathology. For example, a chief complaint of pain upon leaning on the point of the elbow is usually associated with olecranon bursitis.
- How old is the patient? There are a number of age-related elbow conditions. For example, pain in a young child would be suggestive of nursemaid's elbow (dislocation of the head of the radius), elbow pain between the ages of 15 and 20 could be osteochondritis dissecans, and tennis elbow (lateral epicondylosis) typically occurs in individuals 35 years of age or older.
- Was there a mechanism of injury or any antecedent trauma? Traumatic elbow injuries often occur following a fall on an outstretched hand (FOOSH) injury. This type of fall can result in a number of upper extremity and neck injuries. At the elbow, the FOOSH injury can result in a hyperextension injury of the joint. If the fall was on the tip of the elbow, or there was blunt trauma to the olecranon process, this may indicate an olecranon bursitis, ulnar nerve lesion, or olecranon fracture.[85] If the patient reports an insidious onset of symptoms, especially if the patient has complained of weakness and pain, the clinician should consider performing an examination of the cervical spine, and an upper quarter screening examination as part of the overall examination.
- Is the patient right- or left-hand dominant? This may have an impact on the ability of the elbow to rest or on the functional status of the patient.
- Is there a history of pain following overuse or repetitive activities? Elbow injuries are common in sports as well as from cumulative overuse in the athlete and nonathlete. For example, repetitive hyperextension, accompanied by pronation of the elbow, can stress the distal biceps and lacertus fibrosus in the cubital fossa.[86]
- Are the symptoms related to the patient's occupation? The improper use or unaccustomed use of tools such as hammers, saws, and screwdrivers can cause lateral or medial elbow pain.
- Is there any history of locking or catching of the elbow with movement? Twinges of pain, or locking of the elbow, could indicate a loose body within the joint. An inability to fully extend the elbow may indicate a number of conditions including synovitis of the elbow,[85] especially if it is accompanied by pain and fullness of the paraolecranon grooves.[87]
- Is the patient an athlete? A history of a "pop" followed by pain and swelling on the medial aspect of the elbow in a throwing athlete may indicate an MCL sprain.[88] Individuals involved in racquet sports commonly develop lateral elbow pain suggesting lateral epicondylosis (tennis elbow). In these situations, it is well worth investigating recent changes in equipment (e.g., tennis racquet head size, string tension, grip size).
- How long has the patient had the symptoms and were the symptoms improving or worsening? Such information can give clues as to the stage of healing or seriousness of the condition.

TABLE 17-4 Differential Diagnosis of Elbow Pain According to Symptom Location

Location	Possible Disorders
Anterior	Anterior capsular strain Distal biceps tendon rupture/tendinopathy Dislocation of the elbow Pronator syndrome (throwers)
Medial	Medial epicondylitis Ulnar collateral ligament injury (MCL) Ulna neuritis or ulnar nerve subluxation Flexor–pronator muscle strain Fracture Little league elbow in skeletally immature throwers Valgus extension overload overuse symptoms
Posteromedial	Olecranon tip stress fracture Posterior impingement in throwers Trochlear chondromalacia
Posterior	Olecranon bursitis Olecranon process stress fracture Triceps tendinopathy
Lateral	Capitellum fracture Cervical radiculopathy—referred pain Lateral epicondylitis Lateral collateral injury Osteochondral degenerative changes Osteochondritis dissecans (Panner's disease) Posterior interosseous nerve syndrome Radial head fracture Radial tunnel syndrome Synovitis

MCL, medial collateral ligament.
Data from Conway JE. Clinical evaluation of elbow injuries in the athlete. J Musculoskeletal Med. 1988;10:20–28; Wilk KE, Andrews JR. Elbow injuries. In: Brotzman SB, Wilk KE, eds. Clinical Orthopaedic Rehabilitation. Philadelphia, PA: Mosby; 2003:85–123.

- Where are the symptoms located? Determining the details can help the clinician determine whether the symptoms are from a local source, or whether they are referred, or the result of compromise to a peripheral nerve, or cervical spine nerve root (radiculopathy). With few exceptions, pain in a particular area of the elbow is caused by the surrounding or underlying physical structures (Table 17-4).
- Lateral elbow pain. Epicondylosis should be suspected if there is tenderness over a bony prominence (Fig. 17-11).
- Medial elbow pain. This is usually due to a tendinopathy at the site of the attachment of the superficial forearm flexors and the pronator teres muscle to the medial epicondyle (Fig. 17-12).[88] However, it may also indicate an MCL sprain or an ulnar nerve compression.
- Posterior elbow pain. This suggests olecranon bursitis, triceps tendinosis, or a valgus extension overload.[89]

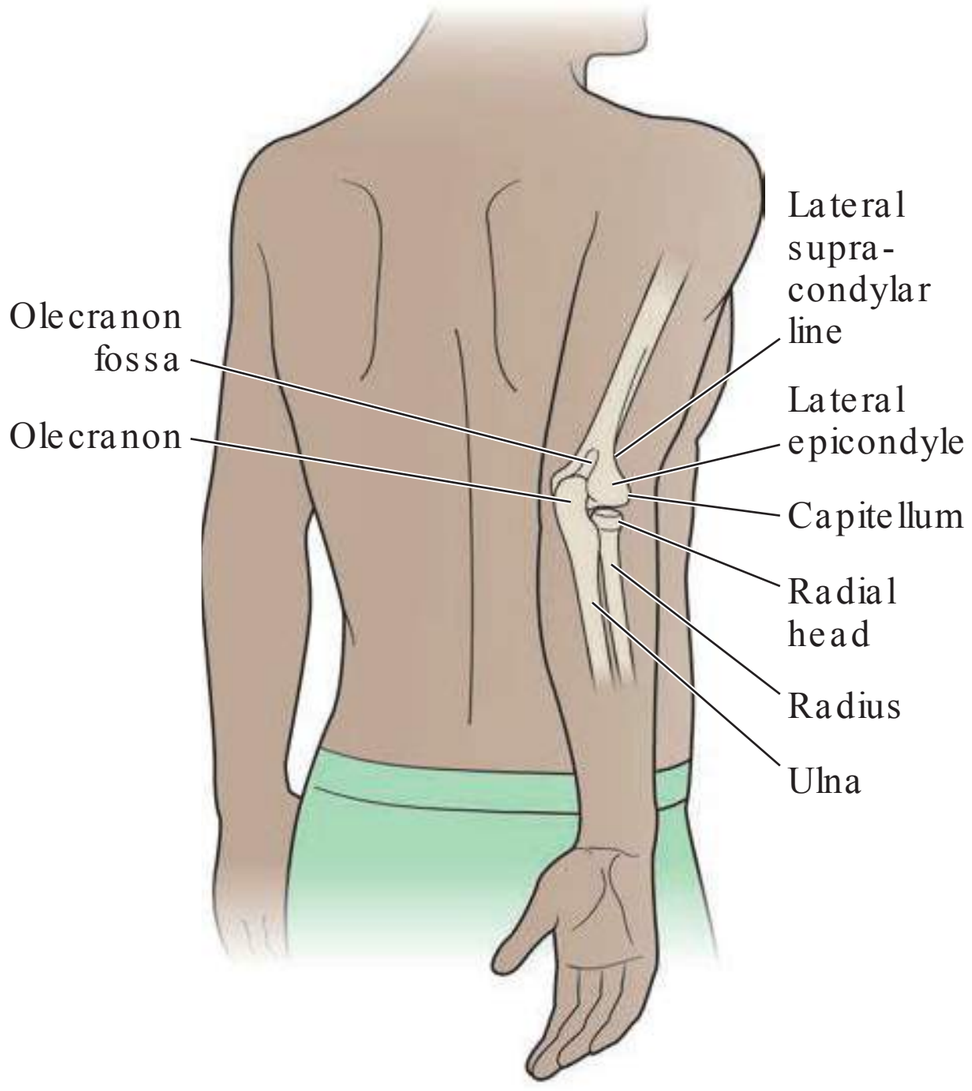

FIGURE 17-11 Lateral view of the elbow.

- Cubital *f*ossa pain. T is is most likely to result from a tear of the brachialis muscle at the musculotendinous junction and is a common injury in rock climbers,[90] or a biceps brachii lesion. Cubital fossa pain may also be associated with a compression of the PIN or a capsular injury.[91]
- Le*ft*-arm and elbow pain. T is, when precipitated by physical exertion and relieved by rest, should suggest angina.[88]
- Are there any associated joint noises or crepitus? A snapping elbow is synonymous with the relatively common recurrent dislocation of the ulnar nerve. However, the medial head of the triceps muscle or tendon may also dislocate over the medial epicondyle and result in snapping either as the elbow is flexed or as it is extended from a flexed position.[85] Dislocation of the medial head of the triceps can occur in combination with dislocation of the ulnar nerve, producing the clinical finding of at least two snaps at the elbow, with or without discomfort on the medial side of the elbow and with or without ulnar neuropathy. Joint crepitus may also indicate the presence of a loose body or synovitis. Catching or locking sensations are suggestive of joint instability or a loose joint body.
- Which activities or arm positions appear to aggravate the condition? Grasping and twisting activities tend to stress the elbow structures.
- Is the pain constant or intermittent? A visual analog scale can be used to record the patient's pain level.
- Is there any associated pain in the neck or shoulder? T e intrinsic pain of the elbow structures is exacerbated by the movement of the elbow joint, whereas referred pain is usually independent of elbow activity (see "Systems Review," later).[85,92]
- Are there any other joints that appear to be painful? T is finding may suggest a systemic or infectious component.
- Are the symptoms better or worse at particular times of day or night?
- Are there any sensory changes, paresthesia, and muscle weakness in the ipsilateral limb? Such neurological findings are suggestive of a spinal nerve root or peripheral nerve lesion.
- Is there any underlying joint disease? Several types of arthritides or osteochondrosis dissecans develop in the elbow region without a known cause.[89]
- How is the condition affecting the patient's function in activities of daily living and recreational pursuits?
- Has the patient had this condition before and, if so, how was it treated and what was the outcome?
- Is the patient taking any medications? What conditions in addition to the present condition are the medications for?
- How is the patient's general health?

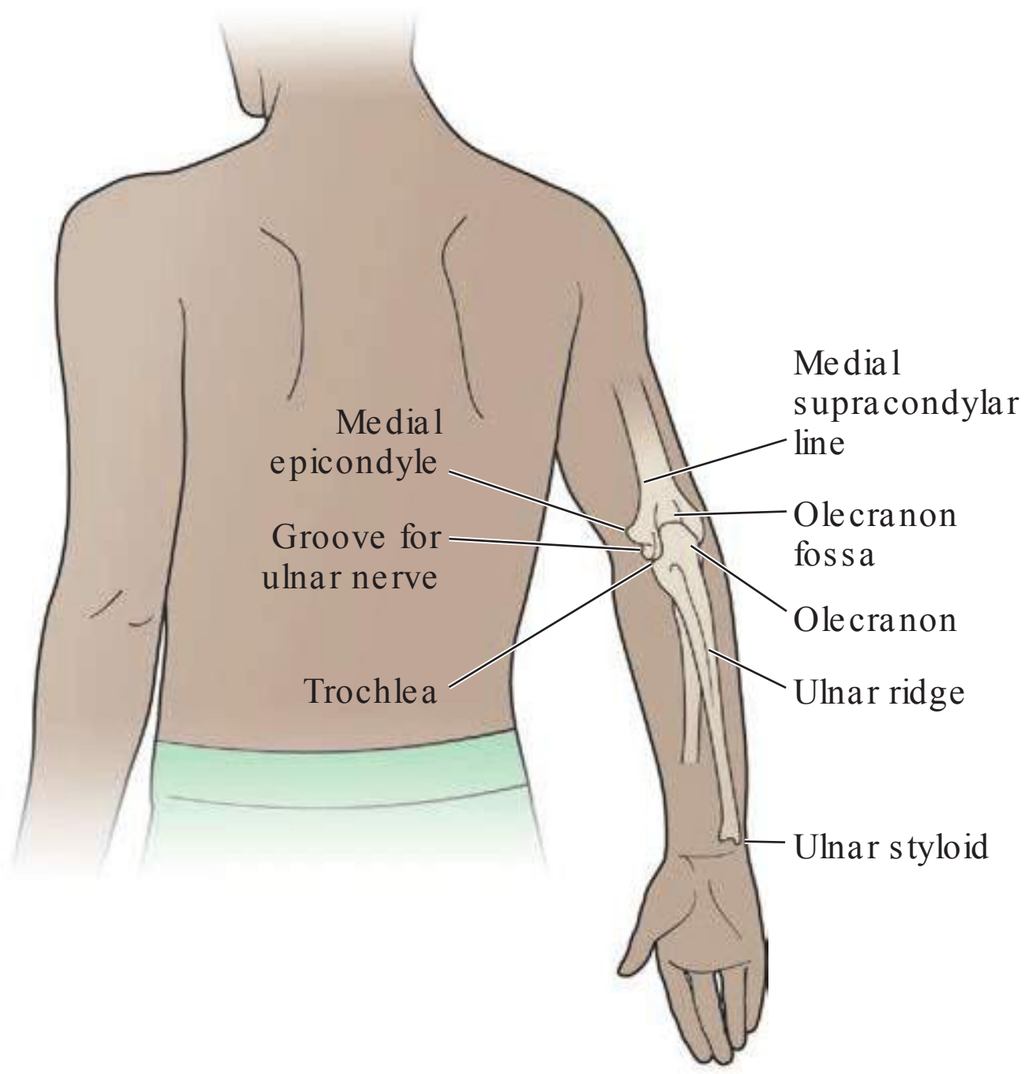

FIGURE 17-12 Medial view of the elbow.

SYSTEMS REVIEW

Signs or symptoms of a visceral, vascular, neurogenic, psychogenic, spondylogenic, or systemic disorder that may be local or referred are described in Chapter 5. Conditions that are out of the scope of physical therapy require that the patient be referred to an appropriate health-care provider. Scenarios related to the elbow that warrant further investigation include an insidious onset of symptoms and complaints of numbness or paresthesia in the upper extremity. T e Cyriax scanning examination (see Chapters 4 and 5) can help highlight the presence or absence of neurological complications including spinal nerve root and peripheral nerve palsies. T e scanning examination includes strength testing of the key muscles (see

"Resistive Testing"), sensation testing, and reflex testing (see "Neurologic Examination").

Reproduction of the patient's elbow or other symptoms with cervical motion, rather than elbow movement, is a strong indicator of a cervical and upper thoracic source (ligaments, muscles, zygapophysial joints, and disks) for the symptoms, with either the segmental roots or the brachial plexus being involved.[19]

In addition to the cervical and upper thoracic spine, the related joints referring symptoms to the elbow require clearing, especially the shoulder.

Systemic causes of insidious elbow pain include gout, infective arthritis, polyarthritis, and vascular disorders, such as Volkmann's ischemia (see Chapter 5). Morning stiffness lasting for more than 1 hour, constitutional signs, and physical signs of joint inflammation are all indicative of an inflammatory disease. Systemic conditions are typically associated with other signs and symptoms that are not related to movement and that are systemic in nature (fever, chills, etc.). Respiratory and cardiovascular conditions must also come into consideration when examining the elbow.[85] The upper arm is very close to the chest and its viscera, so the reference of symptoms to the elbow from these structures can occur.

CLINICAL PEARL

Severe progressive pain not affected by movement, persistent throughout the day and night, and associated with systemic signs may indicate referred pain from malignancy.

Tests and Measures

Following the history and systems review, the clinician should be able to determine the suitability of the patient for physical therapy.

TESTS AND MEASURES

Observation

For an accurate and thorough examination of the elbow, the clinician must be able to visualize both arms. The involved elbow should be inspected for scars, deformities, and swelling. Any asymmetry in size or positioning between the extremities should be noted. The earliest sign of elbow effusion is a loss of the elbow dimples. Most swelling appears beneath the lateral epicondyle. Even minor swelling or effusion prevents full extension of the elbow. Anterior joint effusion is evidence of significant swelling. Gradual swelling over the posterior tip of the elbow, which can be golf ball sized and is often not tender to palpation, is usually olecranon bursitis. The clinician should observe for normal soft-tissue and bony contours. Hypertrophy of the dominant forearm is common in tennis players and pitchers.

CLINICAL PEARL

Sudden swelling in the absence of trauma suggests infection, inflammation, or gout.

The clinician should observe the "carrying angle" of the involved elbow (the angle formed between the arm and the forearm) and compare it to the other side. The carrying angle varies from 13 to 16 degrees for females, and 11 to 14 degrees for males.[5,11] Any difference in the carrying angle of the elbow is obvious when the elbow is in extension. An increased carrying angle (> 15 degrees) is called cubitus valgus. Cubitus varus, or "gunstock deformity," is the term used to describe a decreased carrying angle (< 10 degrees). The most common causes of an altered carrying angle are past trauma or epiphyseal growth disturbances. For example, a cubitus valgus can be caused by a lateral epicondylar fracture, whereas a cubitus varus is frequently the result of a supracondylar fracture.

The triangular relationship of the epicondyles and the olecranon at 90 degrees of elbow flexion and at full extension is often disrupted in the presence of a fracture, dislocation, or degeneration. At 90 degrees of flexion, the three bony landmarks form an isosceles triangle, and when the arm is extended, they form a straight line.[89,93]

Excessive tension at the elbow can be produced in occupations that place the elbows in sustained positions of flexion and adduction (e.g., keyboard operators). The tension increases resistance to movement and joint play at the elbow.[94,95] Elbow flexion also increases tension at the fibrous arch that connects the two heads of the FCU, which can lead to compression of the ulnar nerve.[96]

A combination of sustained flexion and a restriction in joint play decreases the overall volume of the cubital tunnel, which can further increase the potential of ulnar nerve compression.[96,97]

CLINICAL PEARL

The pronated forearm position, combined with elbow flexion, wrist extension, and cyclic finger flexion and extension, creates shearing and compressive forces at several soft-tissue interfaces in the forearm.[98,99] The pronators and extensor digitorum communis adaptively shorten over time because of prolonged contractions in their most shortened positions.[94,98]

Palpation

Since they are superficial, most of the elbow structures are easily palpable (Figs. 17-11 and 17-12), making it easier for the clinician to pinpoint the specific area of pain. However, in cases in which the pain is more diffuse, the diagnosis becomes somewhat more difficult.

Palpation of the elbow complex is best performed with the patient seated or supine, so they are able to relax. A logical sequence based on surface anatomy is outlined below.

Bony Structures

Bony structures feel hard, whereas ligamentous structures feel firm. Bony palpation of the elbow should start with assessment for crepitus during flexion and extension of the elbow. The presence of pain, swelling, or temperature elevation should also be appreciated.

- Medial epicondyle (Fig. 17-12). The medial epicondyle can be palpated on the medial aspect of the distal humerus.

Just anterior and distal to the medial epicondyle one can palpate from proximal to distal the muscle origins of the pronator teres, FCR, palmaris longus, FDS, and FCU.[100] Just posterior to the medial epicondyle, the ulnar groove can be palpated, as can the ulnar nerve traveling within.

- Olecranon process. The olecranon (see Fig. 17-11) should be easy to locate on the posterior aspect of the elbow. The olecranon bursa will not be palpable unless inflamed or thickened. The olecranon ends distally in a point. Just distal to this point, the posterior border of the ulna can be palpated along its entire length (see Fig. 17-11). The clinician should assess for crepitus in the olecranon fossa as well as for any subtle extension blockage suggestive of synovitis, or the presence of intra-articular loose bodies.
- Lateral epicondyle (Fig. 17-11). Midway between the olecranon and the lateral epicondyle is the anconeus muscle. The lateral epicondyle is more difficult to palpate than the medial epicondyle as the former is covered by a large mass of extensor muscle, called the extensor bundle or wad.
- Supracondylar ridge (see Fig. 17-11). The supracondylar ridge is just superior to the lateral epicondyle. A number of tendons/muscles are located in the region between the lateral supracondylar ridge and the lateral epicondyle. The muscles from proximal to distal are the brachioradialis, ECRL, ECRB, and the EDC. By asking the patient to make a fist with the wrist in slight extension, the ECRL can be felt on the supracondylar ridge.[89]
- The joint line. The joint line is located at a point approximately 2 cm down from an imaginary line joining the two epicondyles, which passes medially and inferiorly. The joint lines are firm on palpation and lie between two structures that are harder.[89]
- Head of the radius. The radial head is located in the skin depression immediately distal to the lateral epicondyle. To palpate the radial head (see Fig. 17-11) at the humeroradial joint, the clinician places the index finger on the lateral humeral epicondyle. From here, the index finger slides posteriorly and distally between the humerus and the radial head (see Fig. 17-11). Rotation of the radial head will be noted with pronation and supination.[89] A traumatically dislocated radius will appear out of position and tender to palpation.

After examining the elbow's bony components, attention should be turned to the elbow's soft-tissue structures, which may be divided into four clinical zones: medial, posterior, lateral, and anterior.[89] The elbow's soft-tissue structures are best appreciated in 90 degrees of flexion. Swelling of the elbow can be localized as in a swollen olecranon bursa or diffuse as in a supracondylar fracture.

The medial aspect of the elbow contains the ulnar nerve, the wrist flexor–pronator muscle group (Fig. 17-13), and the MCL. The ulnar nerve can be felt as a soft tubule coursing through the groove between the medial epicondyle and the olecranon process. Secondary damage to the ulnar nerve can occur in supracondylar or epicondylar injuries.[89] The four muscles of the wrist flexor–pronator muscle group, pronator teres, FCR, palmaris longus, and FCU (see Fig. 17-13),

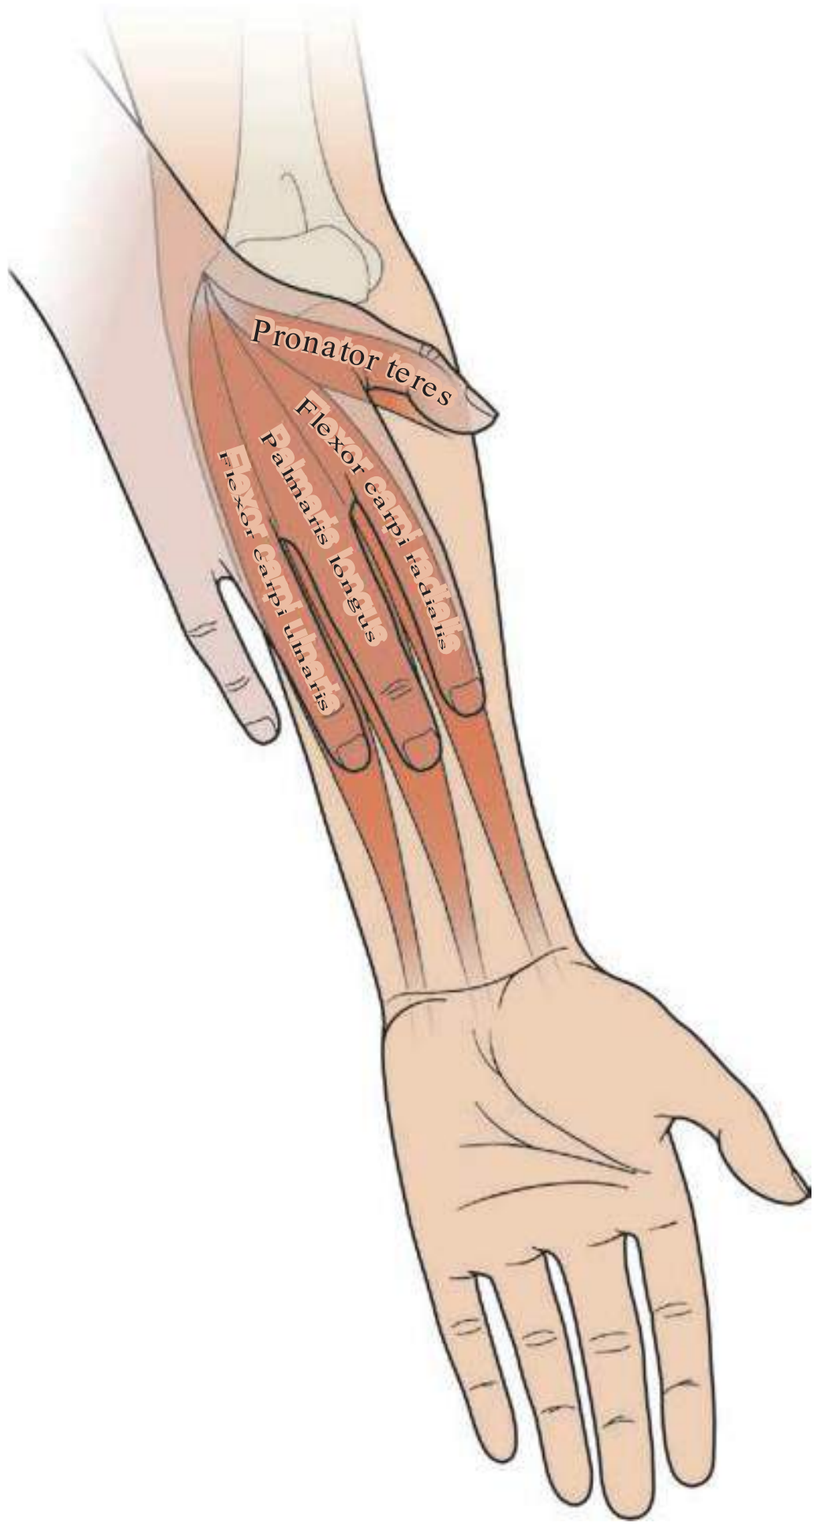

FIGURE 17-13 The wrist flexor–pronator muscle group.

originate from the medial epicondyle before diverging into separate paths down the forearm (see "Muscles," later). Overuse of the flexor mass results in pain and palpable tenderness at the medial epicondyle, extending approximately 1–3 cm distal to the epicondyle. Pain due to medial elbow tendinosis will be intensified with provocative testing, such as resistive wrist flexion and forearm pronation with the elbow extended and, in advanced cases, with the elbow flexed as well. The fan-shaped MCL connects the medial epicondyle to the medial margin of the ulna's trochlear notch. The anterior bundle of the MCL ligament is usually palpable with the elbow flexed from 30 to 60 degrees. Tenderness in this area can be due to MCL sprain. The valgus stress test is performed to assess MCL stability (see later).

Within the lateral aspect of the elbow are the wrist extensors, the LCL, and the AL. The three muscles of the wrist extensor group, brachioradialis, ECRL, and ECRB, are palpated as a unit, with the forearm in a neutral position and the wrist at rest (see "Muscles," later). These three muscles are commonly involved in lateral epicondylosis or "tennis elbow." Palpable tenderness over the ECRB is common in this condition. Pain due to lateral elbow tendinosis is intensified with resisted wrist and finger extension with the elbow extended and, in advanced cases, with the elbow flexed as well.[89] The LCL extends from the lateral epicondyle to the side of the AL, a ring-shaped band located deep to the extensor aponeurosis, cupping the radial head and neck. Although the LCL is difficult to directly

palpate because of the overlying musculature, disruption of either the LCL or the AL can be assessed by palpation of the area and by the varus stress test (see later).

Muscles

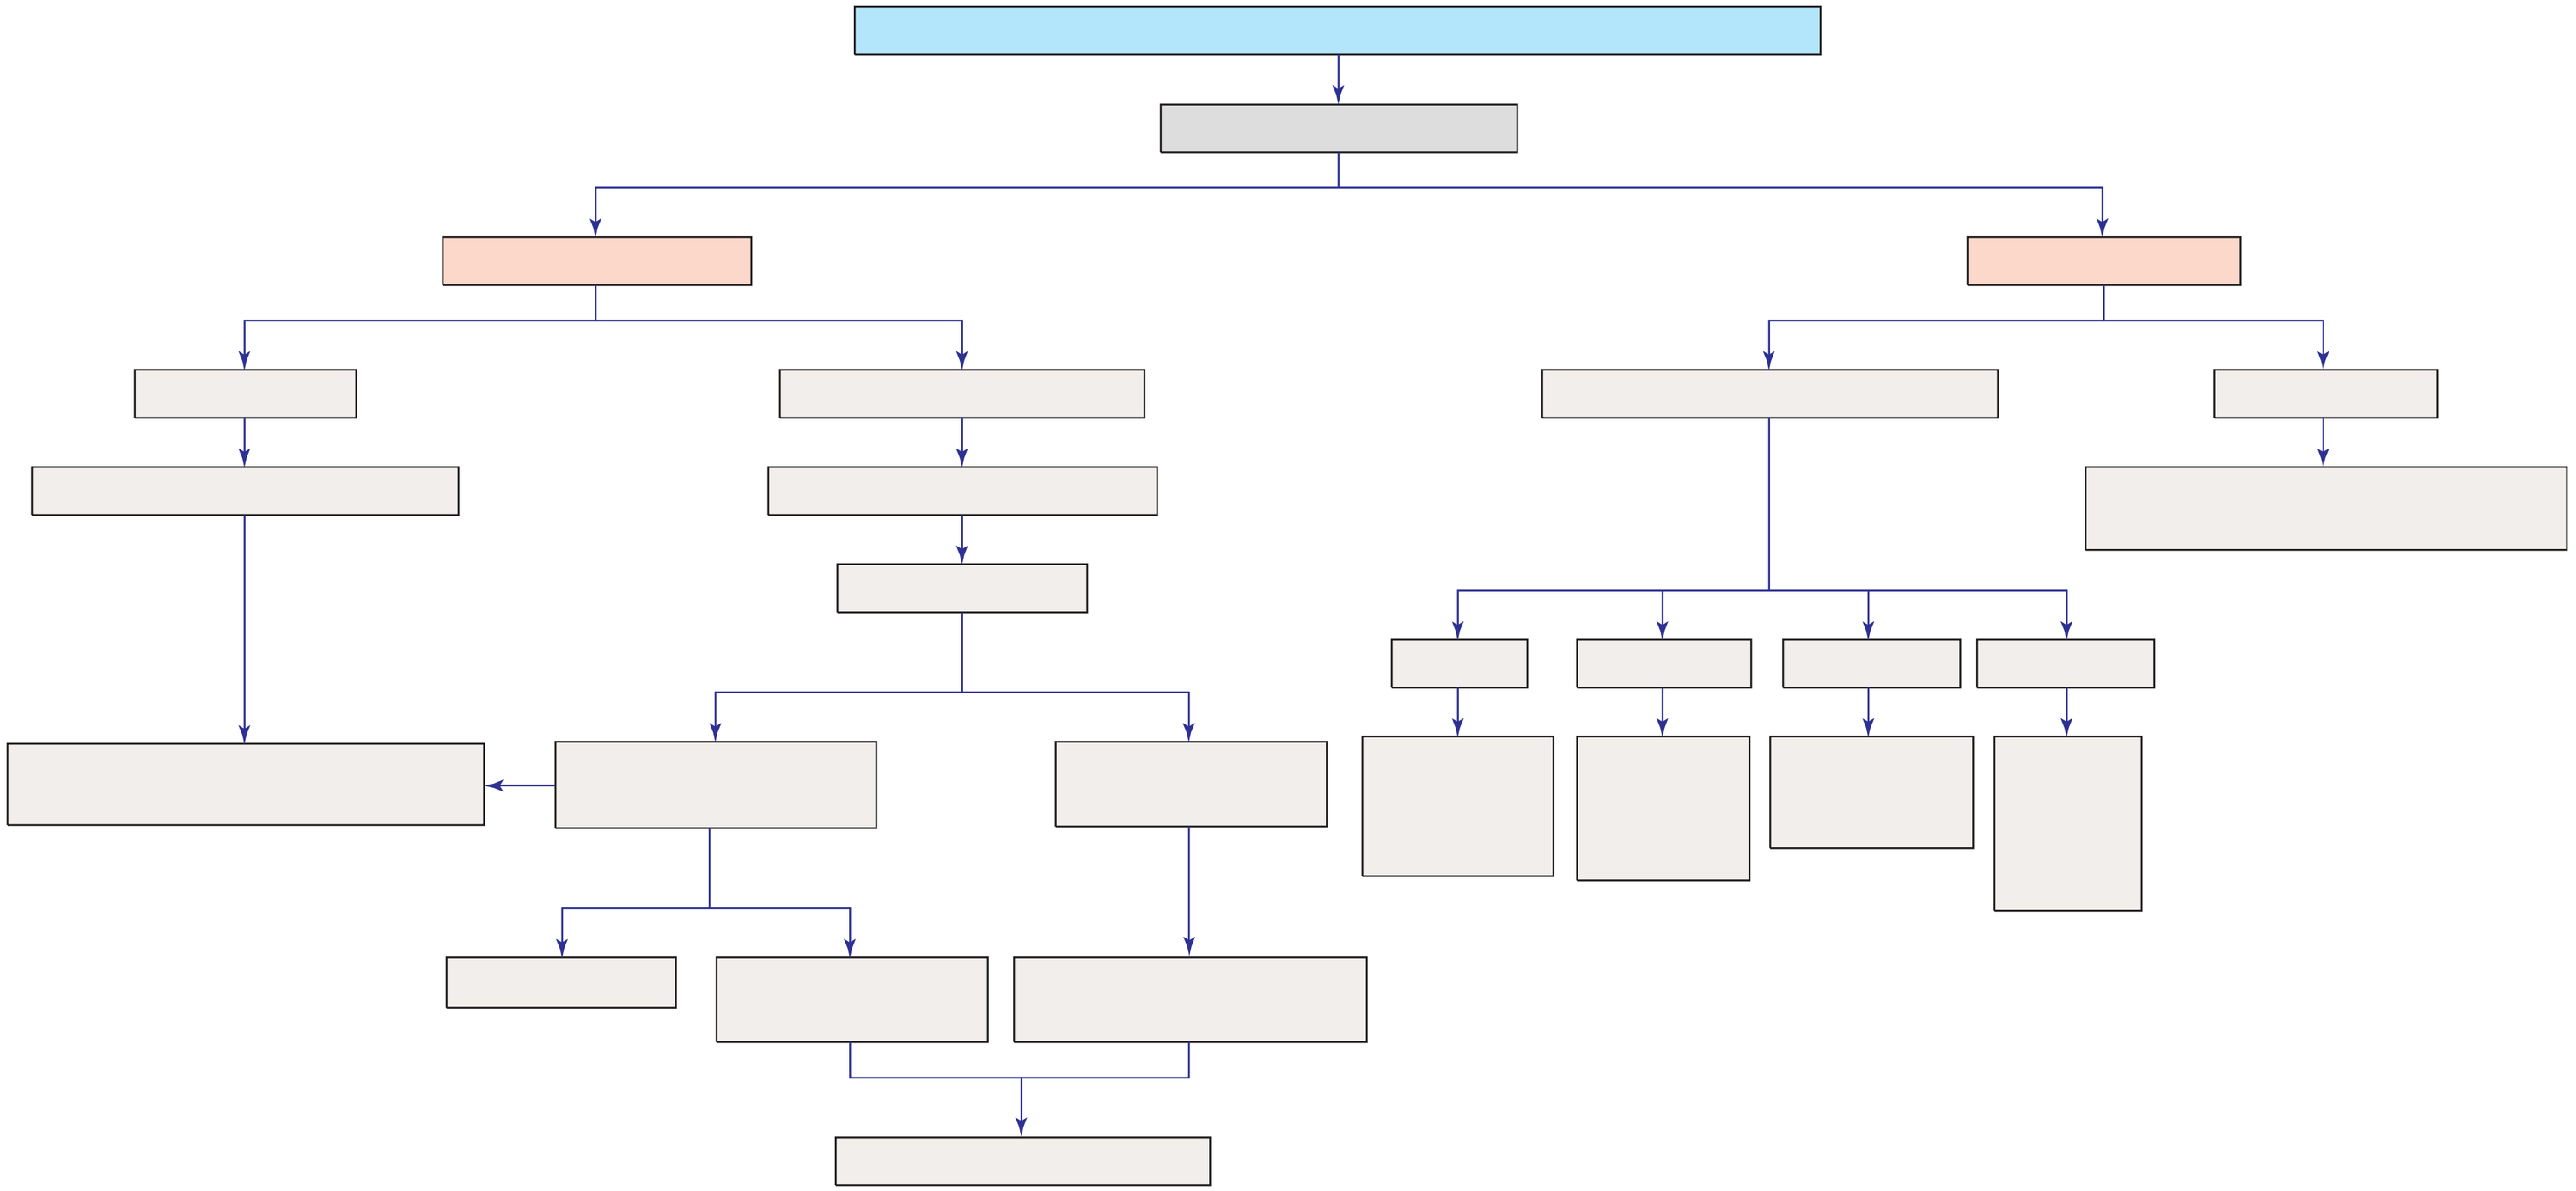
- Biceps. The short head of the biceps is located at the coracoid process (together with the coracobrachialis muscle).[89] The long head of the biceps cannot be palpated at its origin, but it is palpable in the intertubercular groove of the proximal humerus. The muscle belly of the biceps is easily identifiable, especially with resisted elbow flexion and forearm supination.
- Brachialis. The origin of the brachialis can be palpated posterior to the deltoid tuberosity. Its insertion can be palpated at a point medial to the musculotendinous junction of the biceps, at the proximal border of the bicipital aponeurosis.[89]
- Brachioradialis. The brachioradialis can be palpated on the radial border of the cubital fossa distally to the radial styloid process.
- Common flexor origin at the medial epicondyle.
- Common extensor origin at the lateral epicondyle.
- Supinator. The borders of the supinator within the cubital fossa are formed by the brachioradialis (radially), pronator teres (ulnarly), and tendon of the biceps (proximally).[89]
- Triceps. Palpation of the triceps can be simplified by having the patient abduct the arm to 90 degrees. The lateral head of the triceps borders directly on the brachial muscle, whereas the medial head runs underneath both the long and lateral heads of the triceps. These two heads of the triceps can be palpated until their common insertion at the olecranon (Fig. 17-14).[89]
- Anconeus. This is small muscular triangle can be palpated between the olecranon, the posterior border of the ulna, and the lateral epicondyle. If crepitus is felt at full elbow extension, the clinician can manually push the subanconeus bursa superiorly during elbow extension. If the crepitus decreases, a dysfunction of the anconeus should be suspected, which can be treated with electrical stimulation and mobilization of the olecranon in a medial or lateral direction.

FIGURE 17-14 Palpation of the triceps at the elbow.

Active Range of Motion with Passive Overpressure

The patient with elbow pain should have a detailed assessment of his or her motion (Figs. 17-15 and 17-16). The ROM can be assessed with the patient seated, although elbow extension is better evaluated with the patient standing. The patient is asked to perform active flexion and extension of the elbow, pronation, and supination of the forearm, and wrist flexion and extension, with the ranges being recorded using a goniometer (see Chapter 13) VIDEO:

- Flexion: active elbow flexion (Fig. 17-17) is 140–150 degrees.
- Extension: active elbow extension is 0 degrees, although up to a 10-degree hyperextension is not uncommon, especially in women. This is hyperextension is considered normal if it is equal on both sides, and there is no history of trauma.
- Supination: active supination (Fig. 17-18) should be 85 degrees with no substitute motions (adduction) occurring at the shoulder.
- Pronation: active pronation is approximately 75 degrees with no substitute motions (abduction) occurring at the shoulder.



Wrist flexion and extension and forearm supination and pronation should be tested with the elbow flexed to 90 degrees and then fully extended.

In a study by Armstrong et al.,[101] the intratester, intertester, and interdevice (universal standard goniometers, a computerized goniometer, and a mechanical rotation measuring device) reliability of ROM measurements of the elbow and forearm was assessed. Intratester reliability was high for all three measuring devices.[101] Intertester reliability was high for flexion and extension measurements with the computerized goniometer and moderate for flexion and extension measurements with the universal goniometer.[101] Intertester reliability was high for pronation and supination with all three devices.[101] These authors concluded that reliable measurements of elbow and forearm movement are obtainable, regardless of the level of experience, when standardized methods are used.[101]

Capsular or noncapsular patterns should be determined. The capsular pattern at the elbow is characterized by the limitation of more flexion than extension. If motion restrictions are present, the nature and location of the motion barrier, and the relationship of pain to the motion barrier should be noted.[102]

The end-feels of elbow motion should be classified as either compliant, suggesting soft-tissue restriction, or rigid, suggesting a mechanical bony limit. Passive limitation warrants further investigation for the source of the mechanical blockage. Pain that occurs at the limit(s) of motion suggests bony impingement. The clinician should also note the degree of ulnar adduction or abduction that occurs with the elbow motions.

Passive pronation and supination are applied by grasping the proximal aspect of the forearm. Passive overpressure is superimposed at the end of the available ranges of flexion and extension, using the appropriate conjunct rotations. Internal rotation of the forearm (pronation) is the conjunct rotation associated with elbow extension; external rotation of

f f

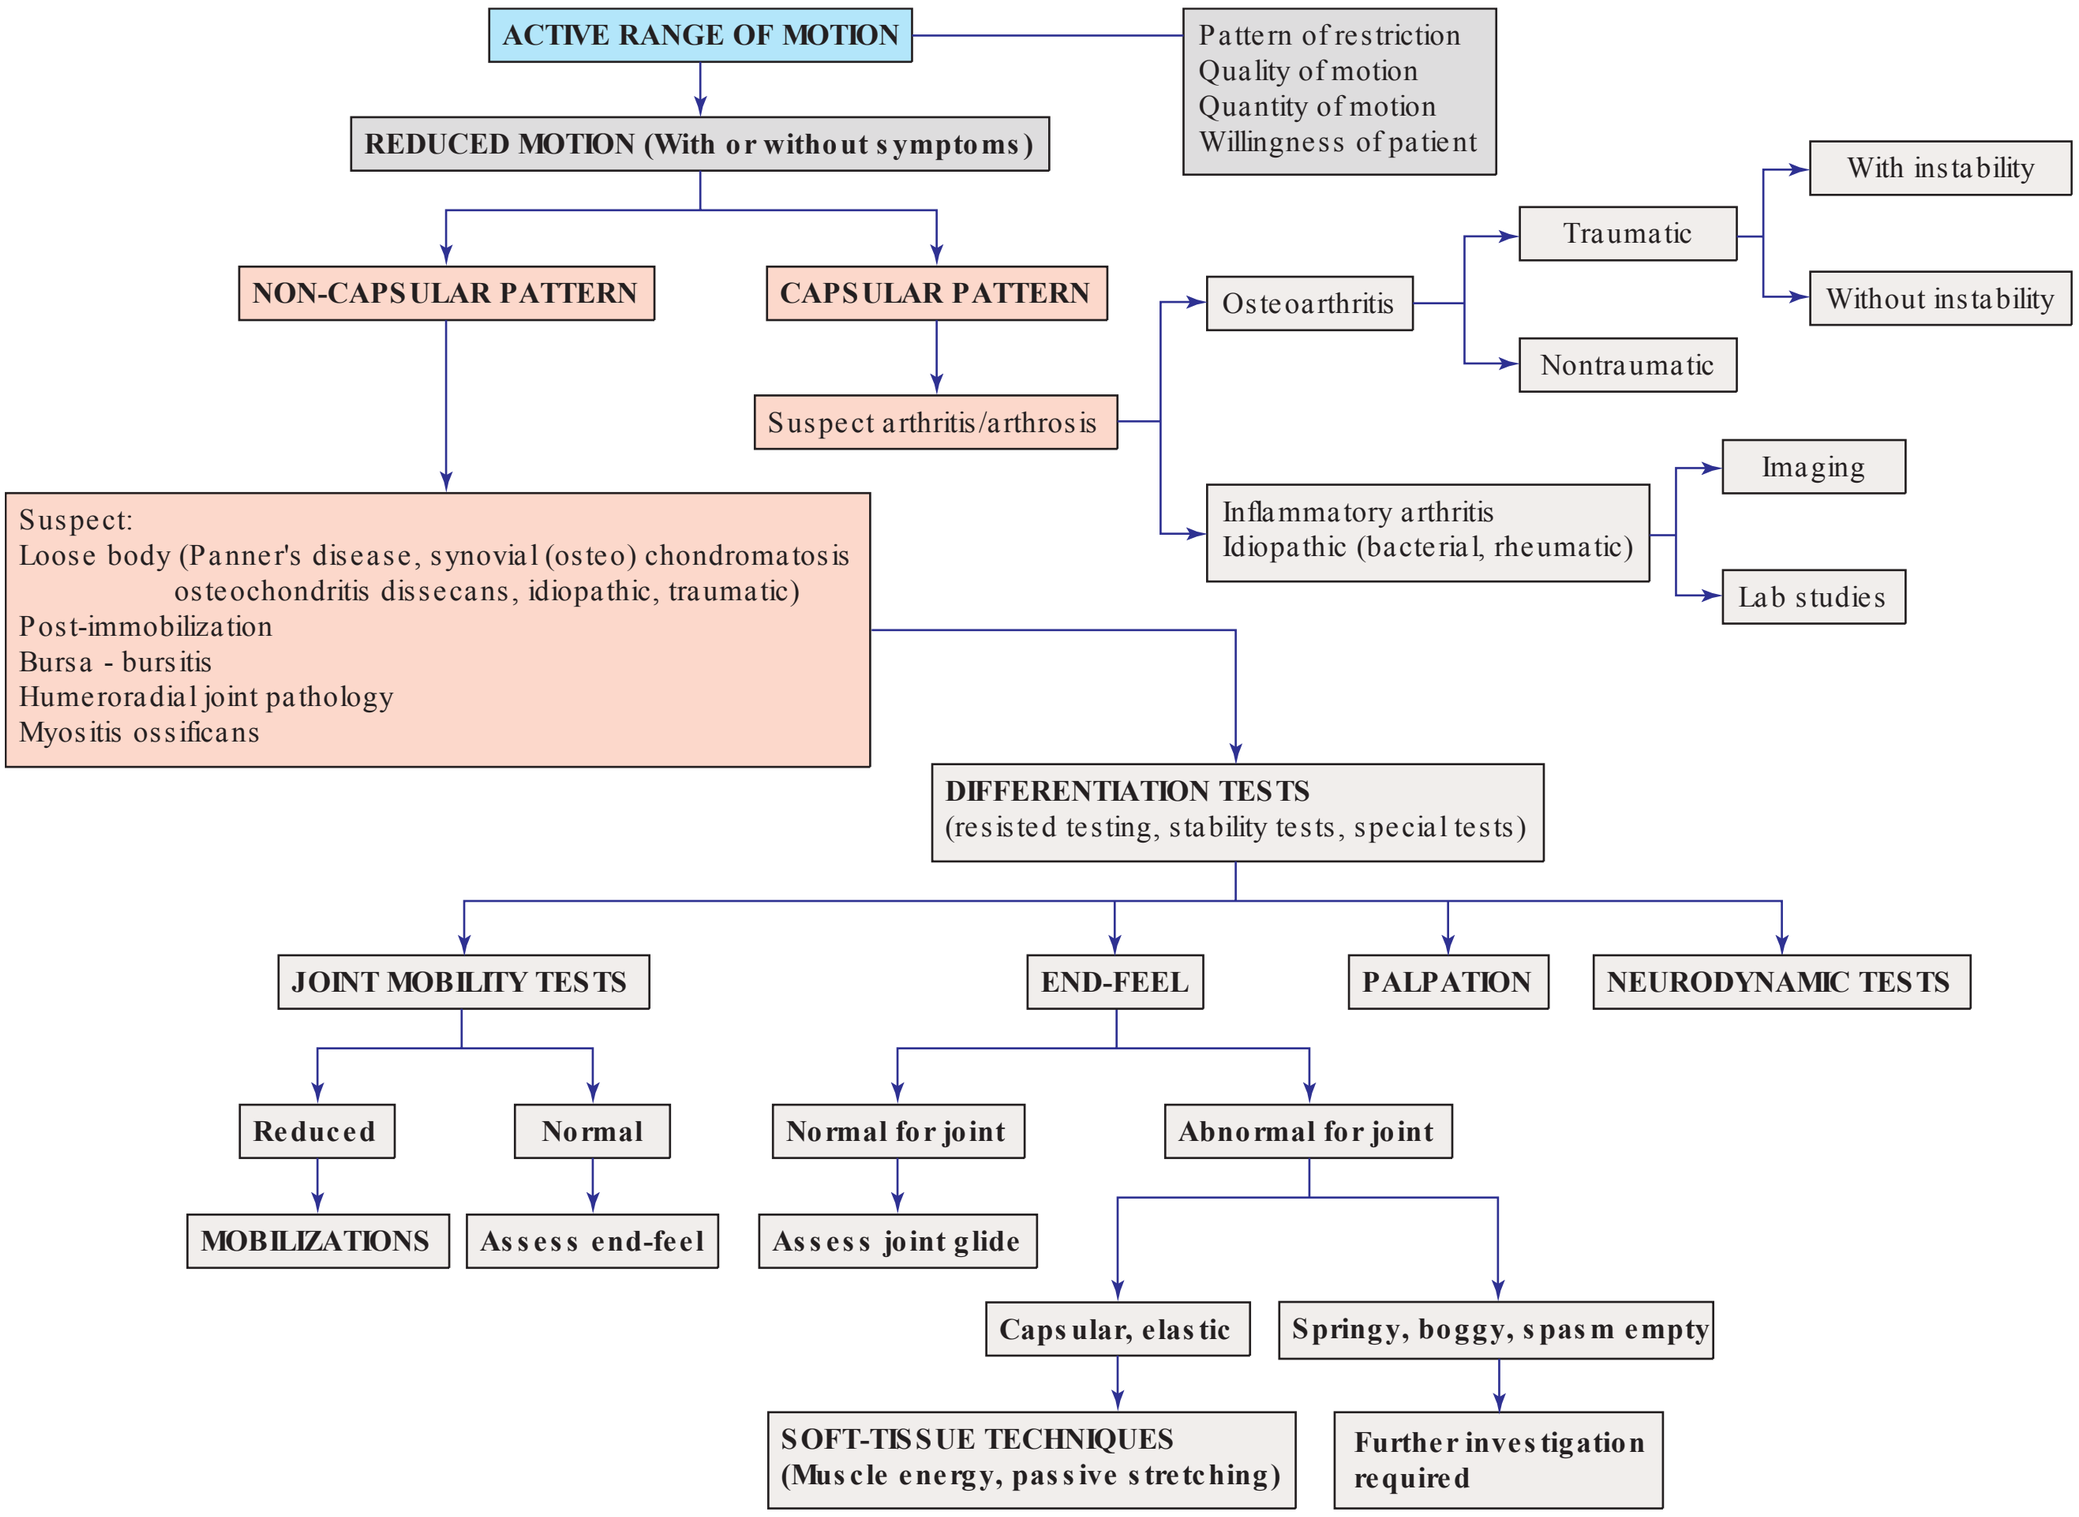


FIGURE 17-16 Examination sequence in the presence of painful flexion and/or extension at the elbow.

the forearm (supination) is the conjunct rotation associated with elbow flexion.[78,86] Normal values for elbow pronation and supination are approximately 75-degree pronation and 85-degree supination.[5]

CLINICAL PEARL

Decreased supination and pronation are frequent sequelae of a Colles' fracture, advanced degenerative changes, dislocations, and fractures of the forearm and elbow.

If there is a gross loss of pronation and supination post-trauma, a fractured radial head is a possibility. Of particular interest is the acute limitation of supination and extension in children, which likely results from a "pulled elbow" (also referred to as "nursemaid's elbow," see "Intervention Strategies" section).

Passive elbow flexion (Fig. 17-19) should have an end-feel of soft-tissue approximation. Elbow flexion combined with supination should have a capsular end-feel whereas elbow flexion combined with pronation should have a bony

FIGURE 17-17 Elbow flexion.

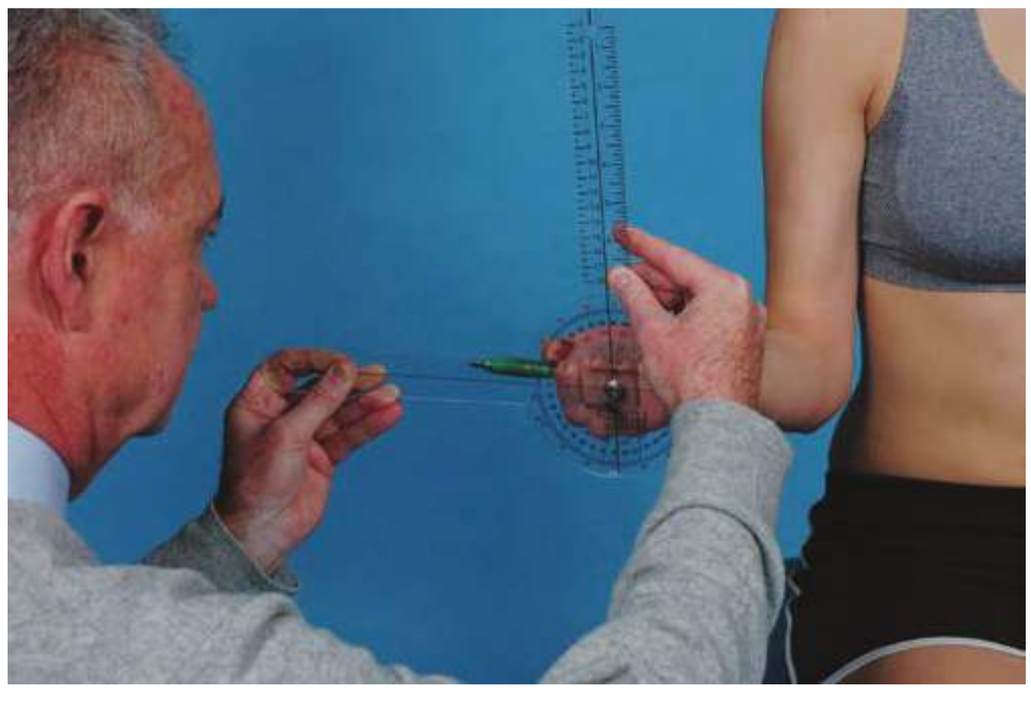

FIGURE 17-18 Forearm supination.

FIGURE 17-19 Passive elbow flexion.

FIGURE 17-21 Combined motion of elbow flexion and pronation.

end-feel. Passive flexion may aggravate an ulnar nerve neuropathy.[78] Loss of normal elbow flexion (□140 degrees) may be caused by osteophytic arthritis, intra-articular loose bodies, posterior capsule tightness, or possibly triceps tendinosis.

Passive elbow extension (Fig. 17-20) should have a bony end-feel. A springy end-feel may indicate a loose body. Elbow extension is usually the first motion to be limited and the last to be restored with intrinsic joint problems.[78,86] The clinician should be particularly careful of an elbow that has lost a gross amount of extension posttrauma, especially if accompanied by a painful weakness of elbow extension, as this may indicate an olecranon fracture. A significant loss of motion, with no accompanying weakness, could indicate myositis ossificans.

FIGURE 17-20 Passive elbow extension.

CLINICAL PEARL

Pain throughout the central arc of flexion and extension, or pronation and supination, implies degeneration of the humeroulnar or proximal radioulnar joints, respectively.

Combined Motions

Combined movement testing is used to assess the patient who has a full ROM but still has complaints of pain. The following combinations are assessed:

- Elbow flexion, adduction, and forearm pronation (Fig. 17-21)
- Elbow flexion, abduction, and forearm supination (see Fig. 17-22)
- Elbow extension, abduction, and forearm pronation (Fig. 17-23)
- Elbow extension, adduction, and forearm supination (see Fig. 17-24)

Resistive Testing

In addition to all of the shoulder muscles that insert at or near the elbow (biceps, brachialis, and triceps), the clinician

FIGURE 17-22 Combined motion of elbow flexion and pronation.

FIGURE 17-23 Combined motion of elbow extension and pronation.

FIGURE 17-24 Combined motion of elbow extension and supination.

must also test the other muscles responsible for elbow flexion (Fig. 17-25) and extension and the muscles involved with forearm supination, pronation, and wrist flexion and extension. Elbow flexion strength is normally 70% greater than extension strength.[103] Muscle flexion power is greatest in the range of 90–110 degrees of flexion with the forearm supinated. In contrast, the flexion power is only 75% of maximum when the elbow is positioned in 45–135 degrees of flexion.[104] Supination strength is normally 15% greater than pronation strength.[103] The use of a dynamometer for testing upper extremity muscle groups has been found to be reliable.[105] Using make or break tests also produce reliable results.[106] The most painful movement or movements should be tested last.

Elbow Flexion (C5–6)

Resisted elbow flexion is tested with the elbow flexed to 90 degrees, with the forearm in pronation VIDEO, then in supination (Fig. 17-26) VIDEO, and then in neutral rotation VIDEO. Pain with resisted elbow flexion most frequently implicates the biceps, especially if resisted supination is also painful. The brachialis is implicated if resisted elbow flexion with the forearm in full pronation is painful. The brachioradialis is rarely involved. Both sides are tested for comparison.

Elbow Extension (C7)

Resisted elbow extension is tested with forearm pronation, supination, and neutral. Both sides are tested for comparison. Pain with resisted elbow extension implicates the triceps muscle, although the anconeus muscle could also be involved.

Forearm Pronation/Supination (C5–7)

The clinician should test the strength of the forearm muscles by grasping the patient's hand in a handshake. The patient should be asked to exert maximum pressure to turn the palm first up (using supinators) and then down (using pronators). Supination is primarily the function of the supinator muscle, with augmentation from the biceps brachii for quickness or to overcome resistance. Supinator function can be effectively isolated during the clinical assessment, by placing the elbow in extension VIDEOor near terminal elbow flexion VIDEO. Both these positions decrease the mechanical advantage of the biceps brachii. A weakness with supination may indicate a rupture, or a subluxation of the biceps tendon at the shoulder. It may also indicate a C5–6 nerve root lesion, radial nerve lesion (supinator), or musculocutaneous nerve lesion (biceps). The supinator muscle is rarely injured.

Pronator weakness is associated with rupture of the pronator teres from the medial epicondyle, fracture of the medial elbow, and lesions of the C6–7 or median nerve roots. Pronator quadratus weakness, which is tested with the elbow held in a flexed position VIDEOto neutralize the humeral head of the pronator teres muscle could indicate a lesion of the

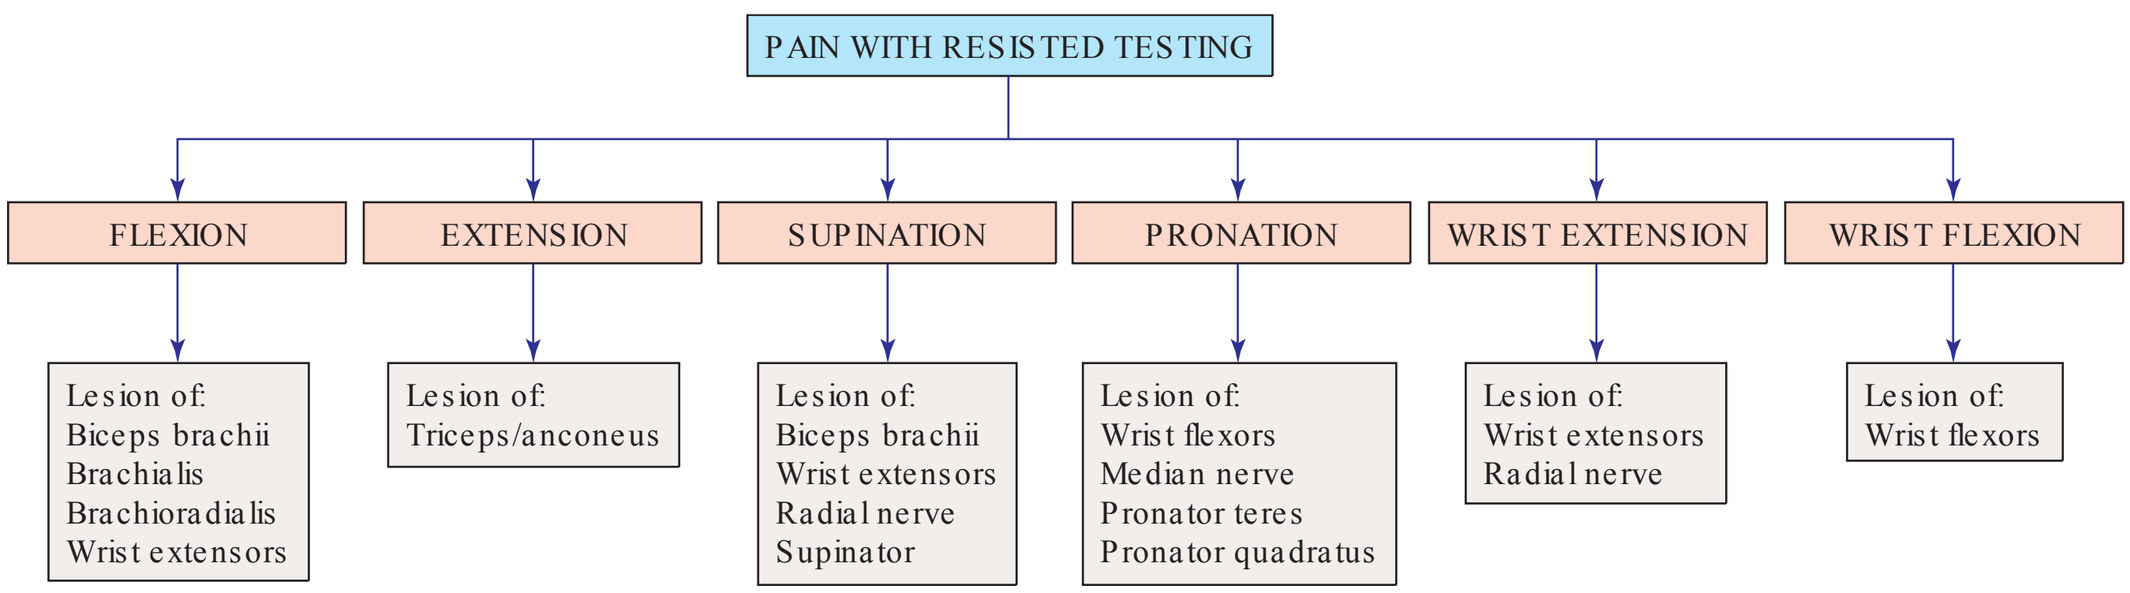

FIGURE 17-25 Symptoms reproduced with resisted testing at the elbow.

FIGURE 17-26 Resisted elbow flexion.

AIN. T e pronator teres or quadratus muscles, which can be tested together VIDEO are rarely injured. Individuals with medial or lateral epicondylosis will also find the aforementioned maneuvers painful, and resisted wrist flexion and extension can be used to help differentiate the former and the latter, respectively.

Wrist Flexion

T e FCU is the strongest wrist flexor. To test the flexors, the clinician stabilizes the patient's mid-forearm with one hand while placing the fingers of the other hand in the patient's palm, with the palm facing the patient (Fig. 17-27). T e patient attempts to flex the wrist, with the elbow flexed and then extended. Weakness is evident in rupture of the muscle origin, lesions involving the ulnar (C8, T1) or median nerve (C6, C7), or tendinopathy at the medial elbow if pain is reported.

Wrist Extension

T e most powerful wrist extensor is the ECU. To test the wrist extensors, the clinician's hands are placed in the same position as in the preceding test, with the patient's palm facing away from the patient. T e patient is asked to extend the wrist, with the elbow flexed (Fig. 17-28) and then extended. Rupture of the extensor origin, lesions of the C6–8 nerve root, or lateral epicondylosis can cause weakness.

FIGURE 17-27 Resisted wrist flexion.

FIGURE 17-28 Resisted wrist extension.

Radial Deviation

Resisted radial deviation is tested with the elbow at 90 degrees of elbow flexion, and at full elbow extension (see Chapter 18). Pain with resisted radial deviation is usually the result of lateral epicondylosis.

Ulnar Deviation

Resisted ulnar deviation, although rarely affected, is tested with the fingers in full flexion, and then in full extension (see Chapter 18).

Extension of Fingers 2–5

For resisted extension of fingers 2–5, the elbow is positioned in full extension, the wrist in neutral, and the metacarpophalangeal (MCP) joints at 90 degrees of flexion. Pain here is usually the result of extensor digitorum tendinopathy or lateral epicondylosis.

Extension of Fingers 2–3

For resisted extension of fingers 2–3, the patient is positioned as above. Pain with resistance implicates lateral epicondylosis.

If the above testing procedures are negative, or if the patient has complained that the combined movements cause the symptoms, resisted testing can be performed using combined movements. For example, testing elbow flexion in supination/pronation in varying degrees of elbow flexion.

Neurologic Examination

Sensation about the elbow is supplied by four different nerves and is evaluated as follows: lateral arm (axillary nerve, C5), lateral forearm (musculocutaneous nerve, C6), medial forearm (antebrachial cutaneous nerve, C8), and the medial arm (brachial cutaneous nerve, T1). Sensory testing may include Semmes–Weinstein sensibility and two-point discrimination (see Chapters 3 and 18). An EMG evaluation can supplement the neuromuscular physical examination as needed. T e three major muscle stretch reflexes of the elbow are the biceps (musculocutaneous nerve, C5), brachioradialis (radial nerve, C6), and the triceps (radial nerve, C7). T e biceps reflex is elicited by placing a thumb over the biceps tendon in the cubital fossa and striking it with a reflex hammer while the patient's arm is relaxed and partially flexed (Fig. 17-29). T e biceps muscle

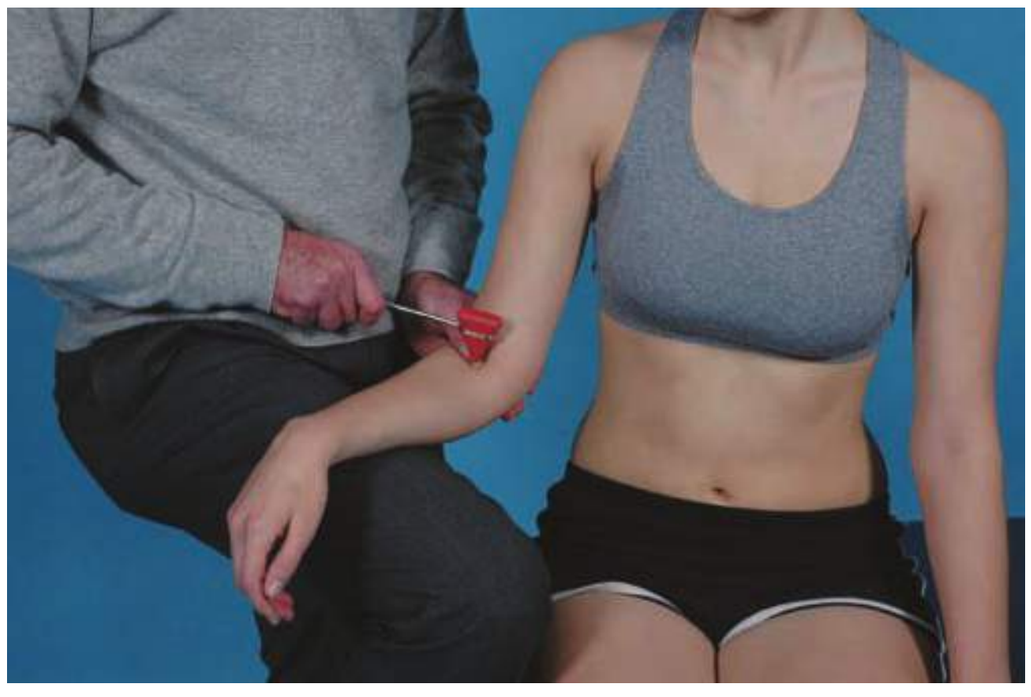

FIGURE 17-29 Biceps DTR.

should be felt or seen to jerk slightly. The brachioradialis reflex is a radial jerk elicited by tapping the brachioradialis tendon at the distal end of the radius (Fig. 17-30). The triceps reflex can be elicited with the arm in the same position of partial, relaxed flexion (Fig. 17-31). The triceps muscle should jerk when the triceps tendon is tapped where it crosses the olecranon fossa. Depressed, exaggerated, or absent upper extremity reflexes are noted and compared with reflex testing at the other elbow.

Functional Assessment

The functional strength of the elbow complex can be assessed using the tests outlined in Table 17-5. Like the shoulder, the elbow serves to position the hand for functional activities. A number of studies have reported the ROM requirements for everyday activities. A total ROM of 60–100 degrees of elbow flexion and 100 degrees of supination–pronation are required for tasks such as eating, dressing, and daily hygiene. The ROM required for athletic activities, such as throwing a baseball, requires at least 10–20% greater ROM.

Passive Articular Motion Testing

The passive articular mobility tests are used to examine the arthrokinematic motions of a joint or the accessory joint glides (see Chapter 4).

FIGURE 17-30 Brachioradialis DTR.

FIGURE 17-31 Triceps DTR.

Ulnohumeral Joint

The patient is positioned in supine, with their head supported. The clinician sits or stands to face the patient.

Distraction/Compression. The clinician wraps the fingers around the proximal third of the forearm (Fig. 17-32). The clinician applies a longitudinal force through the proximal forearm, at an angle that is 45 degrees less flexion than the position of the ulnar shaft, to either distract or compress the ulnohumeral joint. The quality and quantity of motion are noted. The test is repeated on the opposite extremity and the findings compared. An alternative method involves positioning the patient in prone, with the humerus being supported on the table and the arm hanging over the edge of the table (Fig. 17-33). Using one hand to stabilize the humerus, the clinician uses the other hand to apply a distraction force at the ulnohumeral joint. This position can also be used to assess the medial and lateral glides of this joint (Fig. 17-34).

Medial Glide. The clinician glides the ulna medially on the fixed humerus along the mediolateral plane of the joint line. The quality and quantity of motion are noted. The test is repeated on the opposite extremity and the findings compared.

Lateral Glide. The clinician glides the ulna laterally on the fixed humerus along the mediolateral plane of the joint line. The quality and quantity of motion are noted. The test is repeated on the opposite extremity and the findings compared.

Radiohumeral Joint

The patient is positioned in sitting or supine, with their arm resting on the table. The following tests are performed[107,108]:

Anterior Glide. The clinician stabilizes the humerus and applies an anterior glide of the radius (Fig. 17-35), to assess the accessory glide that accompanies flexion.

Posterior Glide. The clinician stabilizes the humerus and applies a posterior glide of the radius (see Fig. 17-35) to assess the accessory glide that accompanies extension.

Distraction. The clinician stabilizes the radial head and the lateral epicondyle with one hand. With the other hand, the clinician grasps the radius and applies a longitudinal distraction force along the length of the radius (Fig. 17-36). A

TABLE 17-5 Functional Testing of the Elbow

Starting Position	Action	Functional Test
Sitting, cuff weight attached to wrist	Elbow flexion	5-lb weight: functional 3–4-lb weight: functionally fair Active flexion (0 lb): functionally poor Cannot flex elbow: nonfunctional
Standing	Elbow extension with wall push-up	5 reps: functional 3–4 reps: functionally fair 1–2 reps: functionally poor 0 reps: nonfunctional
Standing facing door	Turning door knob into supination	5 reps: functional 3–4 reps: functionally fair 1–2 reps: functionally poor 0 reps: nonfunctional
Standing facing door	Turning door knob into pronation	5 reps: functional 3–4 reps: functionally fair 1–2 reps: functionally poor 0 reps: nonfunctional

Data from Palmer ML, Epler M. Clinical Assessment Procedures in Physical Therapy. Philadelphia, PA: JB Lippincott; 1990.

longitudinal compression force can be applied using the same patient–clinician position.

Motion Testing of the Radial Head. The patient is positioned in sitting or supine, with the clinician facing the patient. The radial head is located by flexing and extending the elbow. Once located, the radial head is grasped by the clinician between the thumb and the index finger (see Fig. 17-36). The radial head is moved in an anterior and posterior direction, and any restriction of motion is noted. The posterior glide of the radius is coupled with pronation/extension, and anterior glide is coupled with supination/flexion. The most common dysfunction of the radial head is a posterior-radial head, which is accompanied by a loss of the anterior glide.

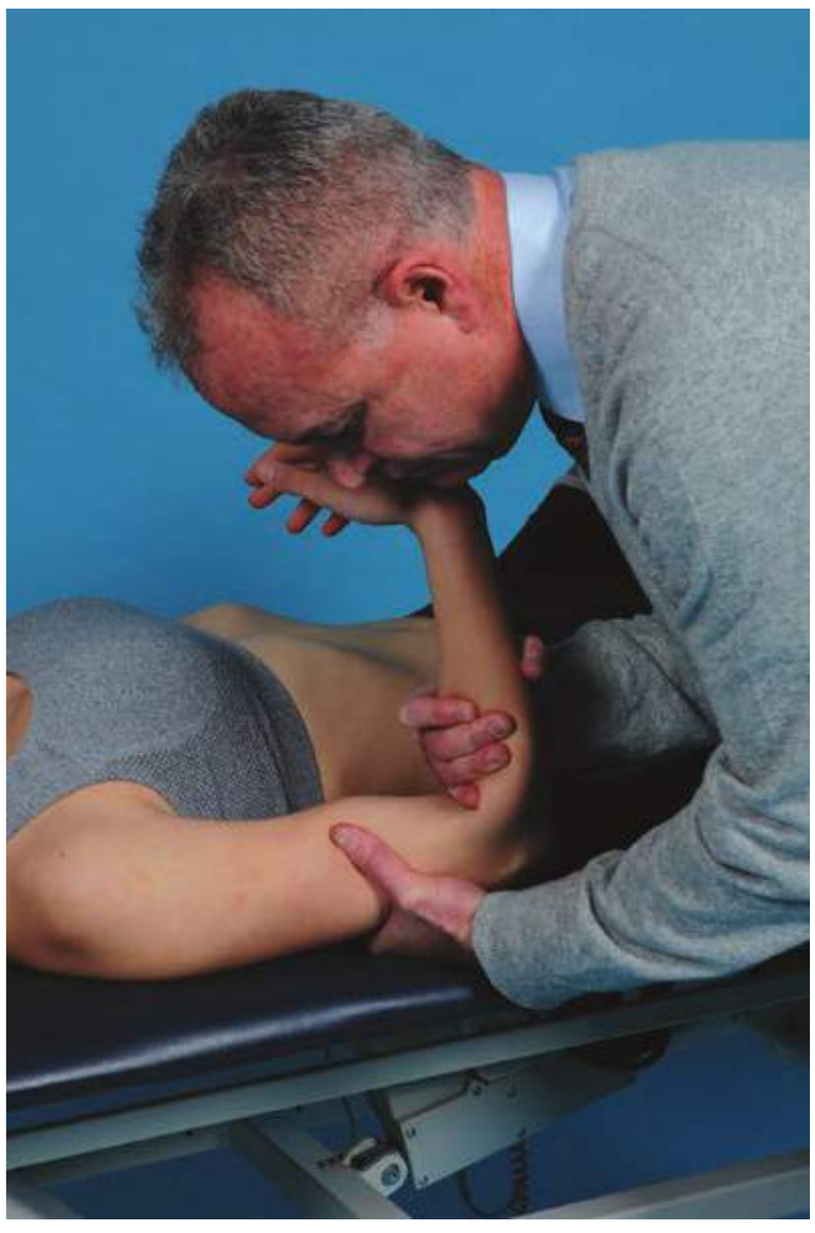

FIGURE 17-32 Ulnohumeral distraction/compression.

FIGURE 17-33 Ulnohumeral distraction.

FIGURE 17-34 Medial and lateral glides of the ulnohumeral joint.

Stress Tests

Medial (Ulnar) Collateral Ligament (Valgus Test)

The patient is positioned in supine, with their head supported. The clinician stabilizes the distal humerus with one hand and palpates the distal forearm with the other. The anterior band of the MCL tightens in the range of 20–120 degrees of flexion, becoming lax in full extension, before tightening again in hyperextension. The posterior bundle is taut in flexion beyond 55 degrees.[3,14,23,86]

The anterior band is tested by flexing the elbow to between 20 and 30 degrees to unlock the olecranon from its fossa, as a valgus stress is applied continuously (Fig. 17-37).[25,61]

The posterior band is best tested using a "milking" maneuver. The patient is seated, and the arm is positioned in shoulder flexion, elbow flexion beyond 55 degrees, and forearm supination. The clinician pulls downward on the patient's thumb (Fig. 17-38).[25] This maneuver generates a valgus stress on the flexed elbow. A positive sign is indicated by the reproduction of pain.

FIGURE 17-35 Radiohumeral joint glides.

FIGURE 17-36 Distraction of the radius.

FIGURE 17-37 Ulnar collateral ligament stress test.

FIGURE 17-38 Milking maneuver.

T e tests are repeated on the opposite extremity and the findings compared. No diagnostic accuracy studies have been performed to determine the sensitivity or specificity of this test.

Lateral Pivot Shift Apprehension Test

T e lateral pivot shift test is used in the diagnosis of posterolateral rotatory instability.[36] T e patient is positioned in supine, with the involved extremity overhead. T e clinician grasps the patient's wrist and elbow. T e elbow is supinated with a mild force at the wrist, and a valgus moment and compressive force is applied to the elbow during flexion (Fig. 17-39).[36] T is results in a typical apprehension response with reproduction of the patient's symptoms and a sense that the elbow is about to dislocate. Reproducing the actual subluxation, and the clunk that occurs with reduction usually can only be accomplished with the patient under general anesthesia or occasionally after injecting a local anesthetic into the elbow.

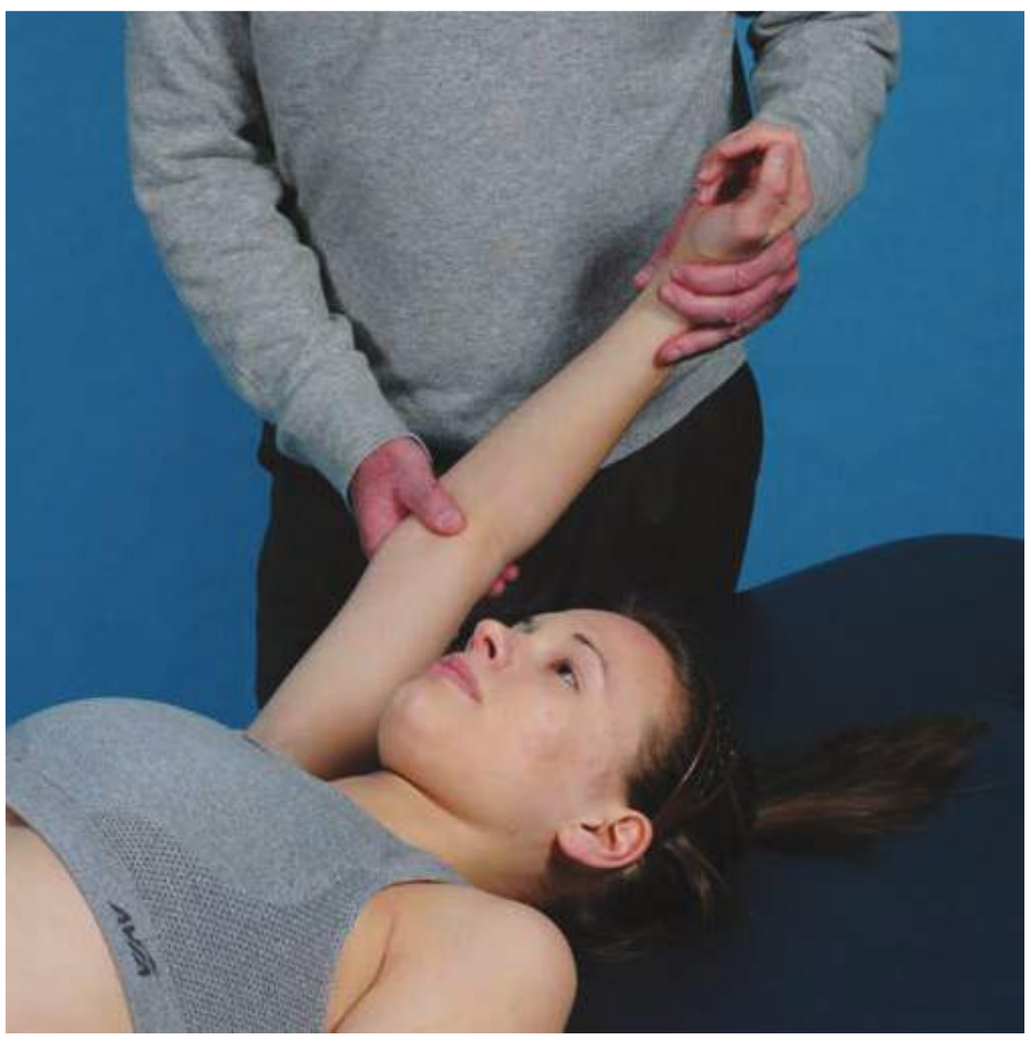

FIGURE 17-39 Lateral pivot shift apprehension test.

FIGURE 17-40 Radial collateral ligament stress test.

Lateral (Radial) Collateral Ligament (Varus Test)

T e LCL is tested with the elbow positioned in 5–30 degrees short of full extension. T e clinician stabilizes the humerus and adducts the ulna, producing a varus force at the elbow (Fig. 17-40). T e end-feel is noted. No diagnostic accuracy studies have been performed to determine the sensitivity or specificity of this test.

Special Tests

A number of special tests for the elbow exist. T e diagnostic usefulness for some of these tests is outlined in Table 17-6.

Tennis Elbow

A number of tests exist for tennis elbow (lateral epicondylosis). T ree are described here.

Chair Test. T e patient is positioned in front of a chair and is asked to lift the chair while maintaining the shoulders in adduction, the elbows extended, and the forearms pronated.[109] A positive test is the reproduction of lateral elbow pain.

Cozen's Test. T e clinician stabilizes the patient's elbow with one hand, and the patient is asked to pronate the forearm and extend and radially deviate the wrist against the manual resistance of the clinician (Fig. 17-41). A reproduction of pain in the area of the lateral epicondyle indicates a positive test. No diagnostic accuracy studies have been performed to determine the sensitivity or specificity of this test.

Mills' Test. T e clinician palpates the patient's lateral epicondyle with one hand while pronating the patient's forearm, fully flexing the wrist, and extending the elbow (Fig. 17-42). A reproduction of pain in the area of the lateral epicondyle

TABLE 17-6 Diagnostic Usefulness of Some Special Tests for the Elbow

Test and Related Diagnosis	Study Description	Reliability	Sensitivity	Specif city	LR+	LR–	DOR	QUADAS Score
Elbow flexion (cubital tunnel syndrome)	Evaluated the clinical usefulness of provocative testing in 32 subjects with electrodiagnostically proven cubital tunnel syndrome using Tinel's sign, elbow flexion (without wrist extension and with forearm supination held for 60 seconds), pressure provocation, and combined elbow flexion and pressure provocation.[a]	NT	75	99	75	0.25	297	7
Pressure provocation (cubital tunnel syndrome)		NT	89	98	45	0.11	396	7
Percussion test/Tinel's sign (cubital tunnel syndrome		NT	70	98	35	0.31	114	7
Elbow extension (elbow fracture)	110 of 114 patients with acute elbow injury underwent radiographic evaluation. Inability to extend the elbow was found in 37 of 38 patients with bone injury.[b]	NT	97	69	3.1	0.04	72	10
Moving valgus stress (chronic medial collateral ligament tear of the elbow)	21 patients, who underwent surgical intervention for medial elbow pain due to medial collateral ligament insuf ciency or other abnormality of chronic valgus overload, were assessed preoperatively with this test.[c]	NT	100	75	4	0	NA	10
Biceps squeeze test (distal biceps tendon rupture)	25 consecutive patients with presumptive distal biceps tendon ruptures were evaluated using this test. The test was positive in 24 patients. 21 of 22 patients had operative confirmation of a complete distal biceps tendon rupture.[d]	NT	96	100	N/A	0.04	N/A	9

FIGURE 17-41 Cozen's test.

indicates a positive test. No diagnostic accuracy studies have been performed to determine the sensitivity or specificity of this test.

Maudsley Test. The patient is seated facing the clinician. Using one hand, the clinician grasps the patient's wrist, and using the other hand, resists third digit (middle finger) extension, stressing the extensor digitorum muscle (Fig. 17-43). A positive test is a reproduction of pain along the lateral epicondyle. No diagnostic accuracy studies have been performed to determine the sensitivity or specificity of this test.

Golfer's Elbow (Medial Epicondylosis)

The clinician palpates the medial epicondyle with one hand while supinating the forearm and extending the wrist and elbow with the other hand. A reproduction of pain in the area of the medial epicondyle indicates a positive test.

FIGURE 17-42 Mills' test.

FIGURE 17-43 Maudsley test.

Elbow Flexion Test for Cubital Tunnel Syndrome

The patient is positioned in sitting or standing with both arms and shoulders in the anatomic position. The patient is asked to depress both shoulders, flex both elbows maximally, and supinate the forearms (Fig. 17-44). The patient is then asked to extend the wrists.[110] This position is maintained for 3–5 minutes and then the patient is asked to describe any symptoms. Tingling or paresthesia in the ulnar distribution of the forearm and hand indicates a positive test.

Pressure-Provocative Test for Cubital Tunnel Syndrome

Pressure is applied by the clinician, proximal to the cubital tunnel, with the elbow held in 20 degrees of flexion and the forearm in supination (Fig. 17-45).[111]

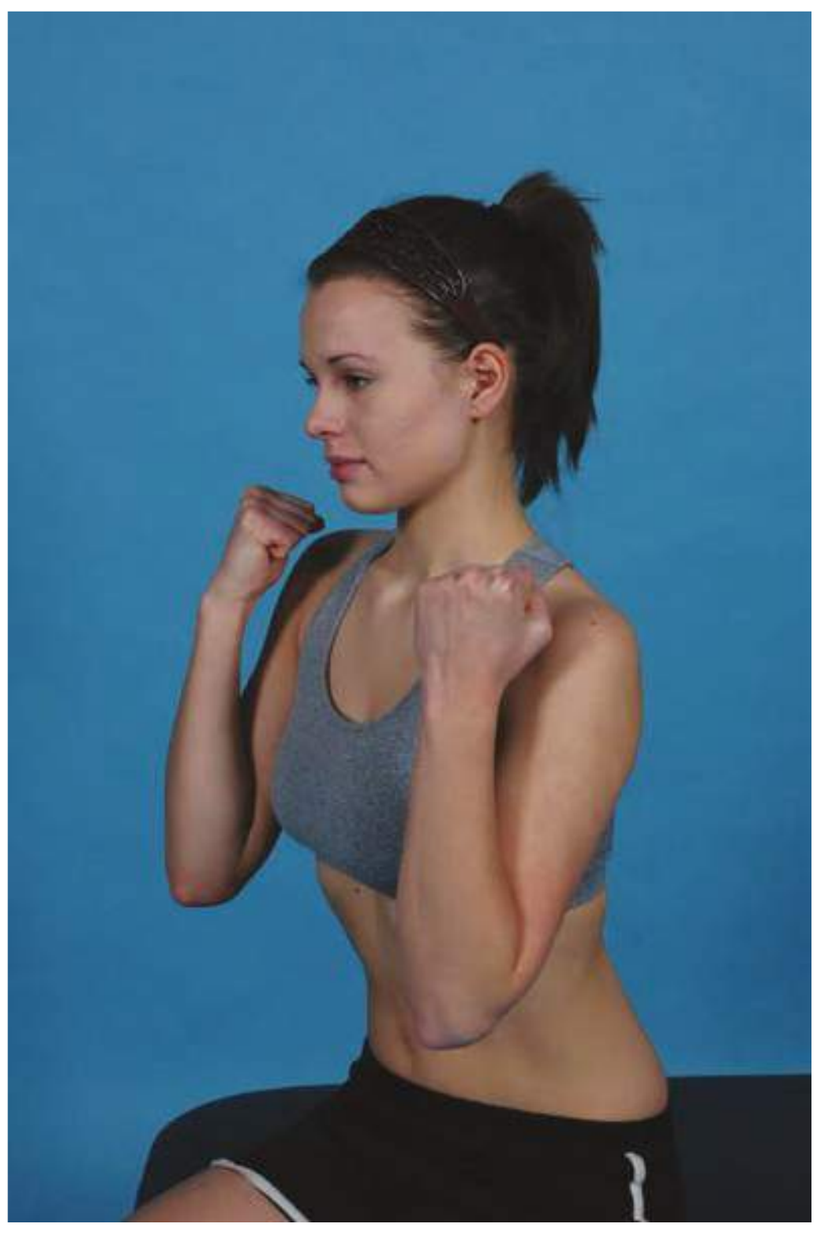

FIGURE 17-44 Elbow flexion test.

FIGURE 17-45 Pressure-provocative test for cubital tunnel syndrome.

FIGURE 17-46 Percussion test/Tinel's sign (at the elbow).

Percussion Test/Tinel's Sign (at the Elbow) for Cubital Tunnel Syndrome

The clinician locates the groove between the olecranon process and the medial epicondyle through which the ulnar nerve passes. This groove is tapped four to six times by the index finger of the clinician (Fig. 17-46). A positive sign is indicated by a tingling sensation in the ulnar distribution of the forearm and hand distally to the tapping point.

Elbow Extension Test

The patient is positioned in supine and is asked to fully extend the elbow. A positive test for elbow fracture is indicated by the patient's inability to fully extend the elbow.

Moving Valgus Stress Test

The patient is positioned in sitting, and the clinician stands behind the patient. The clinician positions the patient's shoulder in 80–90 degrees of abduction and 100–120 degrees of elbow flexion (Fig. 17-47). The clinician applies a modest valgus torque to the elbow until the shoulder reaches full external rotation. While applying a constant valgus torque, the elbow is quickly extended to 30 degrees. A positive test for a chronic MCL tear of the elbow is the reproduction of medial elbow pain when forcibly extending the elbow from a flexed position between 120 and 70 degrees.

Biceps Squeeze Test

The patient is seated with the forearm resting comfortably in the patient's lap with the elbow flexed to approximately 60–80 degrees and the forearm in slight pronation. Standing on the involved side, the clinician squeezes the biceps firmly with one hand stablizing the upper extremity and the other hand around the belly of the biceps brachii (Fig. 17-48). A positive test for a distal biceps tendon rupture is a loss of forearm supination as the biceps brachii is squeezed.

Radiographic Evaluation

The standard x-ray series of the elbow includes anteroposterior (A-P) and lateral views (see Chapter 7).

THE EVALUATION

Following the examination, and once the clinical findings have been recorded, the clinician must determine a specific diagnosis or a working hypothesis, based on a summary of all of the findings. This diagnosis can be structure related (medical diagnosis) (Tables 17-7 and 17-8), or a diagnosis based on the

FIGURE 17-47 Moving valgus stress test.

FIGURE 17-48 Biceps squeeze test.

preferred practice patterns as described in the Guide to Physical T erapist Practice.

INTERVENTION STRATEGIES

T e intervention following elbow injury or elbow surgery follows a sequential and progressive multiphase approach. However, due to the unique orientation of the elbow complex, the clinician is faced with multiple clinical challenges to successfully rehabilitate the injured elbow and should always consider the functional expectations of the individual patient when determining the most appropriate intervention.[7]

T e techniques to increase joint mobility and the techniques to increase soft-tissue extensibility are described in the "T erapeutic Techniques" section.

ACUTE PHASE

T e goals of the acute phase of elbow rehabilitation include:

- protection of the injury site;
- restoration of pain-free ROM in the entire kinetic chain;

TABLE 17-7 Differential Diagnosis for Common Causes of Elbow Pain

Condition	Patient Age (years)	Mechanism of Injury	Area of Symptoms	Symptoms Aggravated by	Observation
Bicipital tendinopathy	20–50	Repetitive hyperextension of the elbow with pronation or repetitive stressful pronation–supination	Anterior aspect of the distal part of the arm	Elbow extension and shoulder extension	Unremarkable
Triceps tendinopathy	20–50	Overuse of the upper arm and elbow, especially in activities like throwing and hammering	Posterior aspect of elbow	Activities involving elbow extension or full elbow flexion	Possible swelling near the point of the elbow
Lateral epicondylosis	35–55	Gradual overuse	Lateral aspect of elbow	Activities involving wrist extension/grasping	Possible swelling (over lateral elbow)
Medial epicondylosis	35–55	Gradual overuse	Anteromedial aspect of elbow	Activities involving wrist flexion	Possible swelling (over medial elbow)
Olecranon bursitis	20–50	Trauma	Posterior aspect of elbow	Contact with posterior elbow	Swelling over posterior elbow
Medial collateral ligament injury	20–45	Excessive valgus force to medial compartment of the elbow	Ulnar aspect of the elbow	Valgus stress of the elbow, throwing, and pitching	May have ecchymosis over ulnar aspect
Ulnar nerve entrapment	20–40	Gradual overuse Trauma	Medial elbow, forearm, and hand Medial 11/2 fingers	Activities involving elbow and wrist extension	Atrophy of hand muscles if chronic
Radial nerve entrapment	Varies	Can be overuse, direct trauma	Lateral elbow	Varies	Usually unremarkable
Median nerve entrapment	20–40	Gradual overuse	Anterior forearm Lateral 31/2 fingers	Activities involving full elbow extension or pronation of the forearm	Atrophy of anterior forearm and hand muscles if chronic

AROM	PROM	End-Feel	Resisted	Special Tests	Tenderness with Palpation
Possible pain with elbow flexion	Pain with passive shoulder and elbow extension		Pain on elbow flexion and supination		Distal biceps belly The musculotendinous portion of the biceps Bicipital insertion of the radial tuberosity
Elbow extension Possible pain with extreme elbow flexion	Pain with passive shoulder and elbow flexion		Pain on elbow extension		Posterior aspect of elbow
Possible pain on wrist flexion with elbow extension	Pain on wrist flexion with the forearm pronated and the elbow extended		Pain on resisted wrist extension and radial deviation, with the elbow extended Pain on finger extension	Cozen Mills'	Lateral elbow (over the ECRB and ECRL)
Pain on wrist extension	Pain on combined wrist extension and forearm supination		Pain on pronation with wrist flexion	Passive supination of the forearm and extension of the wrist and elbow	Anteromedial elbow
Possible pain with extreme elbow flexion	Pain on full elbow flexion		Strong and pain free	Valgus stress with elbow flexed at □25 degrees and humerus in external rotation	Posterior elbow
Pain with full extension possible	Passive extension of the elbow, valgus stress	Depends on severity	Usually unremarkable		Ulnar aspect of elbow
Inability to fully close hand	Full and pain free		Weakness of grip	Elbow flexion and pressure-provocative test Tinel's at elbow Wartenberg's sign Froment's sign	Anteromedial elbow
Usually unremarkable	Usually unremarkable		Pain with resisted forearm supination, resisted extension of middle finger		Maximal tenderness is usually elicited over the radial tunnel if radial tunnel syndrome
Pain on forearm pronation	Full and pain free		Weakness on pronation, wrist flexion, and thumb opposition	Benediction sign Inability to perform "OK" sign (anterior interosseous syndrome) Resisted supination (compression of the lacertus fibrosus)	Over the pronator teres 4 cm distal to the cubital crease, with concurrent resistance against pronation, elbow flexion, and wrist flexion—pronator syndrome

AROM, active range of motion; PROM, passive range of motion; ECRB, extensor carpi radialis brevis; ECRL, extensor carpi radialis longus.

TABLE 17-8 Findings in Common Conditions of the Elbow and Forearm

Condition	Findings
Valgus extension overload syndrome	Tenderness around the tip of the olecranon Pain with forced passive elbow extension Increased valgus laxity (variable)
Cubital tunnel syndrome	Tenderness over the course of the ulnar nerve Abnormal Tinel's sign over the ulnar nerve, as it passes through the cubital tunnel (medial elbow) Ulnar nerve compression test abnormal Elbow flexion test abnormal (variable) Abnormal sensation (two-point discrimination or light touch), in the ulnar distribution: little finger; ulnar aspect of ring finger; ulnar aspect of hand Possible weakness and atrophy of the ulnar-innervated intrinsic muscles of the hand Possible weakness of flexor digitorum profundus to the little finger Possible signs of concomitant ulnar nerve instability, elbow instability, or elbow deformity
Radial tunnel syndrome	Tenderness in the extensor muscle mass of the forearm (distal to lateral epicondyle) at the arcade of Fröhse Long finger extension test reproduces pain Weakness of finger and thumb extensors and extensor carpi ulnaris
Pronator teres syndrome	Tenderness over the pronator teres in the proximal forearm Possible abnormal sensation (two-point discrimination or light touch) in the median nerve distribution: thumb, index finger, long finger, and radial side of ring finger On occasion, prolonged resisted pronation reproduces symptoms of weakness of median-innervated muscle Rare, but often incorrectly diagnosed as carpal tunnel Resisted elbow flexion and forearm supination reproduce symptoms due to compression at the lacertus fibrosus Resisted long finger proximal interphalangeal joint flexion reproduces symptoms due to compression by the flexor digitorum superficialis Possible weakness of median-innervated muscles
Anterior interosseous nerve syndrome	Weakness of flexor pollicis longus and flexor digitorum profundus to index finger Weakness of pronator quadratus
Distal biceps tendon rupture	Swelling Ecchymosis Palpable gap in the biceps tendon Weak or absent elbow flexion and supination
MCL strain or tear	Medial elbow joint pain in a thrower Complete tears open on valgus stress testing with the elbow flexed at 25 degrees compared to the uninvolved side, whereas incomplete tears are tender on palpation of the MCL but do not open on valgus stressing
Nursemaid's elbow (pulled elbow syndrome)	Mean age is 2–3 years History is critical to making diagnosis: reports of longitudinal traction on an extended elbow, resulting in a partial slippage of the annular ligament over the head of the radius and into the radiocapitellar joint Child typically holds the arm at the side, with the hand pronated (palm down) Closed reduction with manipulation is highly successful
Little league elbow	Covers a spectrum of pathologies about the elbow joint in young developing (pediatric) throwers Four distinct vulnerable areas to throwing stress: (1) medial elbow tension overload; (2) lateral articular surface compression overload; (3) posterior-medial shear forces; and (4) extension overload of the lateral restraints May present as Panner's disease (necrosis of the capitellum), OCD, medial epicondylar fracture, medial apophysitis, medial ligament rupture, and posterior osteophyte formation at the tip of the olecranon

MCL, medial collateral ligament.

Data from Birnie R, Reider B. Elbow and forearm. In: Reider B, ed. Orthopaedic Physical Examination. Philadelphia, PA: WB Saunders; 1999:67–98. With permission from WB Saunders.

- improvement of patient comfort by decreasing pain and inflammation;
- retardation of muscle atrophy;
- minimization of the detrimental effects of immobilization and activity restriction[112–117];
- maintenance of general cardiovascular fitness; and
- ensuring that the patient is independent with a home exercise program.

During the early stages of the acute phase, the principles of PRICEMEM (protection, rest, ice, compression, elevation, manual therapy, early motion, and medication) are applied as appropriate. Icing for 20–30 minutes, three to four times a day, concurrent with nonsteroidal anti-inflammatory drugs (NSAIDs) or aspirin, can aid in reducing pain and swelling.

CLINICAL PEARL

Corticosteroid injections have been advocated for elbow injuries to promote and progress healing. Although the use of local injections increases the risks of disrupting tissue planes, fenestration of the area of tendonosis may be beneficial because of the bleeding that occurs in the new channels, which has the potential for transforming a failed intrinsic healing process into an extrinsic response.[118,119]

FIGURE 17-50 Passive elbow extension using weight in the hand.

Early active-assisted and passive exercises are performed in all planes of the shoulder, elbow (Fig. 17-49) VIDEO, and wrist motions VIDEO, to nourish the articular cartilage and assist in collagen tissue synthesis and organization.[7,120–123] As the available range at the elbow occurs at the humeroulnar, humeroradial, and proximal and distal radioulnar joints, restrictions or laxities at any of these joints can affect the eventual outcome of the rehabilitative process.

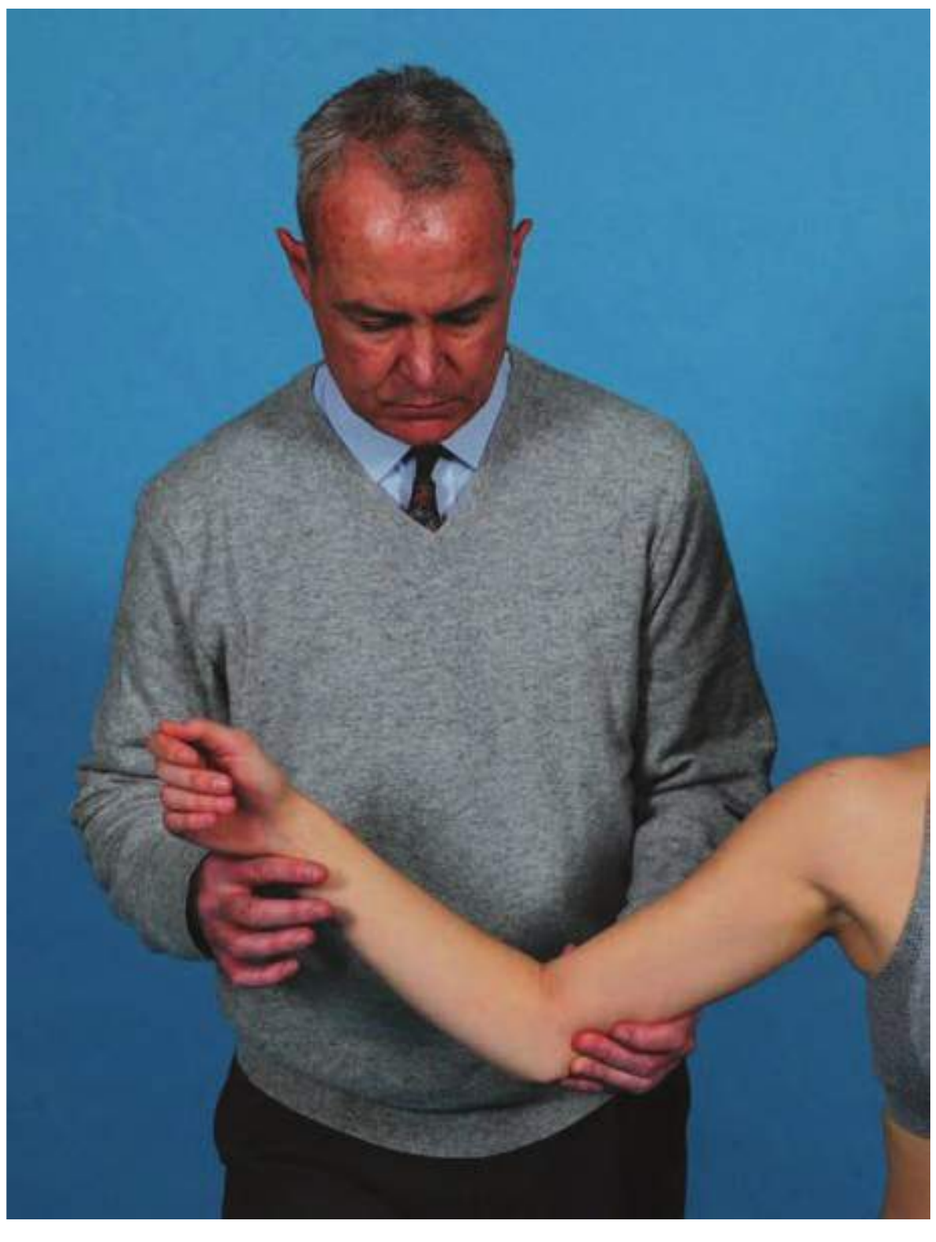

FIGURE 17-49 PROM/AAROM of elbow flexion.

The formation of an elbow flexion contracture must be avoided, as this contracture can place abnormal stresses on the elbow complex, especially during athletic activities.[124] One of the most common causes of joint contracture at the elbow is scarring of the anterior capsule, and at the insertion site of the brachialis.[7] This scarring can be minimized by performing joint mobilizations to the humeroulnar and humeroradial joints. A posterior glide of the ulna on the humerus is used to help restore elbow extension. The anterior capsule can be stretched using long-duration, low-intensity stretching to produce a plastic response from the collagen tissue.[7,125,126] Such a stretch can be accomplished by positioning the patient in supine, with a towel roll placed under the elbow joint, and the forearm hanging over the edge of the bed (Fig. 17-50). A light weight (2–4 lb) is placed in the hand, and the elbow is extended as far as is comfortable. The passive stretch is maintained for 5–7 minutes, avoiding excessive pain manifested by a protective muscle response. This exercise becomes an important component of the patient's home exercise program. The elbow flexors (Fig. 17-51) and wrist flexors (Fig. 17-52) can also be stretched manually by the patient as part of the home exercise program.

Initially, the patient is advised to decrease the level of activity with the level of pain as the limiting factor, but without immobilizing the injured part completely.

Patients are initially instructed to perform submaximal isometric exercises at multiple angles for the elbow flexors and extensors, the forearm supinators and pronators, and the wrist flexors and extensors. Once the full pain-free ROM has been achieved, the patient's strengthening program is progressed from the multiple angle isometrics to concentric

FIGURE 17-51 Elbow and wrist flexor stretch.

progressive resistance exercises (PREs) using dumbbells or surgical tubing. Low resistance is used initially with one to two sets of 10 repetitions, progressing as tolerated to five sets of 10 repetitions. Once five sets of 10 repetitions can be performed without pain and in a slow and controlled manner, additional resistance is added in 1–3-lb increments.[7] The resistance-based exercise program is the mainstay of nonoperative intervention for the elbow and serves to retard muscle atrophy of the elbow and wrist musculature. Patients are advanced in concordance with their ability to participate in the program. Patients should be taught how to perform these exercises independently at the earliest opportunity.

Specific exercises to increase strength should include the following:

- Concentric exercises to the wrist flexors VIDEO and extensors VIDEO, elbow flexors VIDEO and extensors VIDEO, and radial VIDEO and ulnar deviators VIDEO, performed at varying speeds and resistance. These include wrist curls (Fig. 17-53), reverse wrist curls (Fig. 17-54) VIDEO, neutral wrist curls VIDEO, biceps curl (Fig. 17-55), and triceps strengthening (Fig. 17-56) resisted pronation (Fig. 17-57), resisted supination (Fig. 17-58) VIDEO. The exercises are initially performed using low speeds and resistance; the speed and the intensity of resistance are then gradually increased.
- The broom-handle exercise, which is a recommended exercise for the wrist flexors and extensors. A weight is tied to a rope or piece of string approximately 3 ft in length, which is then tied to a broom handle or dowel. The broom handle is held out in front of the patient with the palms down (for wrist extensors, see Fig. 17-59) or palms up (for wrist flexors). The patient then rolls the string onto the handle/dowel to raise and then lower the weight.
- Tennis ball squeezes (Fig. 17-60) to improve grip strength (once symptoms have subsided).
- Exercises to increase the strength of opposing muscles, such as the flexors of the wrist and digits, in order to balance the force couple.

Shoulder exercises should also be introduced as early as possible, although caution should be used with shoulder external rotation exercises because of the potential for valgus

FIGURE 17-52 Wrist flexor and elbow flexor stretch.

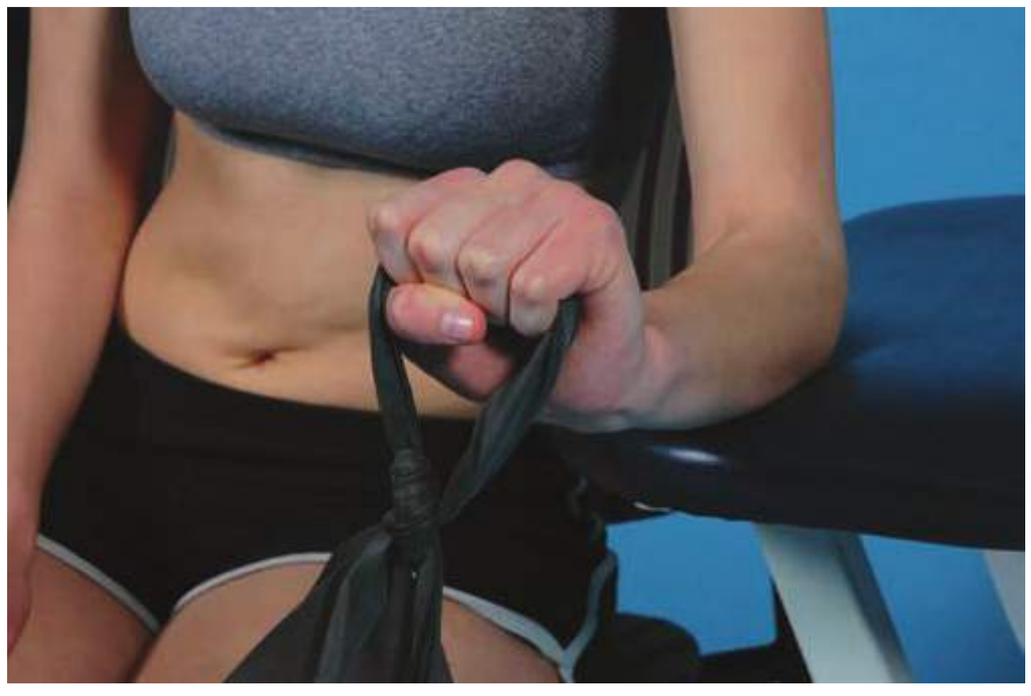

FIGURE 17-54 Wrist extensor PREs.

FIGURE 17-55 Elbow flexion PREs.

stress to the elbow.[7,119,127,128] In the earlier phases of pain, modification of activity may involve alternating between low- and high-intensity workouts.[129,130] Endurance is developed over time, as the patient becomes able to tolerate more repetitions and sustained activities. If endurance is not developed and the muscle–tendon unit becomes fatigued, the muscular

FIGURE 17-59 Broom-handle exercise.

FIGURE 17-60 Tennis ball squeezes.

portion can no longer absorb the stresses, and greater stresses are absorbed by the tendon.[131] T roughout all phases of rehabilitation and exercise, training, should be within physiologic limits for cellular response and homeostasis.[132] T erefore, relative rest is sometimes advised during painful periods.

Stability at the shoulder and the elbow is extremely important for those patients returning to overhead sports and can be addressed using proprioceptive neuromuscular facilitation (PNF) patterns with increasing resistance.

In the presence of joint laxity that is not controllable with adequate exercise or ergonomic modifications, bracing can be effective.

Progression to the next phase occurs when the patient has full, pain-free ROM, and strength at least 70% of the contralateral limb.

FUNCTIONAL PHASE

T e functional phase addresses any tissue overload problems and functional biomechanical deficits. T e goals of the functional phase include:

- restoring normal joint kinematics;
- improving muscle strength to within normal limits;
- improving neuromuscular control;
- restoring the normal strength and relationships of the muscle force couples.

If the feet and trunk are stabilized during an activity, the upper quarter kinetic chain involves the cervical spine, thoracic outlet, thoracic spine, shoulder, elbow, wrist, and hand. T e upper quarter operates as a mechanical unit whose links are functionally interdependent on one another.

T e clinician must be aware of any substitutions as individuals will instinctively modify their exercises to avoid motions involving painful, injured tissues, and to prevent further abuse of the overused tissues.[130,132] In such cases, the exercises must be corrected or discontinued.

Cocontraction of the muscles around the elbow can be produced with closed-chain exercises such as the push-up, quadruped exercises, and dips, incorporating a wide range of equipment such as gymnastic balls, BAPS boards, minitramp, and slide board (see Chapter 16).

Training can also involve dynamic muscle cocontractions in an open kinetic chain by using ballistic movement patterns, with elastic tubing incorporating PNF diagonals. T ese ballistic movements, which can be increased in terms of speed based on tolerance, result in synchronous activation of agonists and antagonists.[133–135]

T e function of the biceps is integral to the stability of the elbow complex and must be exercised, emphasizing slow and fast muscular contractions in both concentric and eccentric modes.[7]

Wilk et al.[7] advocate the following drill to enhance the dynamic stability of the elbow:

- T e patient flexes the elbow against resistance provided by elastic tubing.
- T e patient holds a position isometrically while the clinician employs rhythmic stabilization resistance anteriorly and posteriorly.
- T e procedure is repeated for the wrist flexors–extensors and the forearm pronators–supinators.

Plyometric exercises are introduced as tolerated and as appropriate:[136]

- T e patient grasps a length of elastic tubing and fully flexes the elbow, with the shoulder flexed to about 60 degrees (Fig. 17-61). T is position is maintained briefly. T e patient then releases the isometric hold, allowing the elbow to extend rapidly. As the full extension is reached, the movement is quickly reversed back into full elbow flexion.[136] T e forearm pronators–supinators can all be exercised in a similar fashion.
- For overhead athletes, ER exercises can be performed with elastic tubing at 0 degrees of shoulder abduction and 90 degrees of elbow flexion (Fig. 17-62), before progressing to more abduction.

FIGURE 17-61 Plyometric exercise with elastic tubing.

FIGURE 17-62 ER exercises performed at 0 degrees of shoulder abduction and 90 degrees of elbow flexion.

- Plyometric-weighted ball throws into IR at 0 degrees of shoulder abduction (Fig. 17-63), and at 90 degrees of shoulder abduction (Fig. 17-64).
- Prone plyometric–weighted ball throws with the patient's arm positioned at 90 degrees of shoulder abduction and 90 degrees of elbow flexion (Fig. 17-65).
- Plyometric wrist flips and snaps (Figs. 17-66 and 17-67)

T e shoulder stabilizers, triceps, and the wrist flexors–extensors can be trained as a unit using Swiss ball push-ups (Fig. 17-68), PNF patterns using T-band (Figs. 17-69 and 17-70), and medicine ball throws (Fig. 17-71).

Sports-specific training is essential before an athlete returns to play. T ere should be a gradual transition back to sports activities and other strenuous activities of daily living, depending on the recovery of the involved tissues and the restoration of the athletic skills required to perform the activity. Too often, patients return to full activity prematurely, with resulting reinjury. T is is both frustrating and discouraging for the patient.

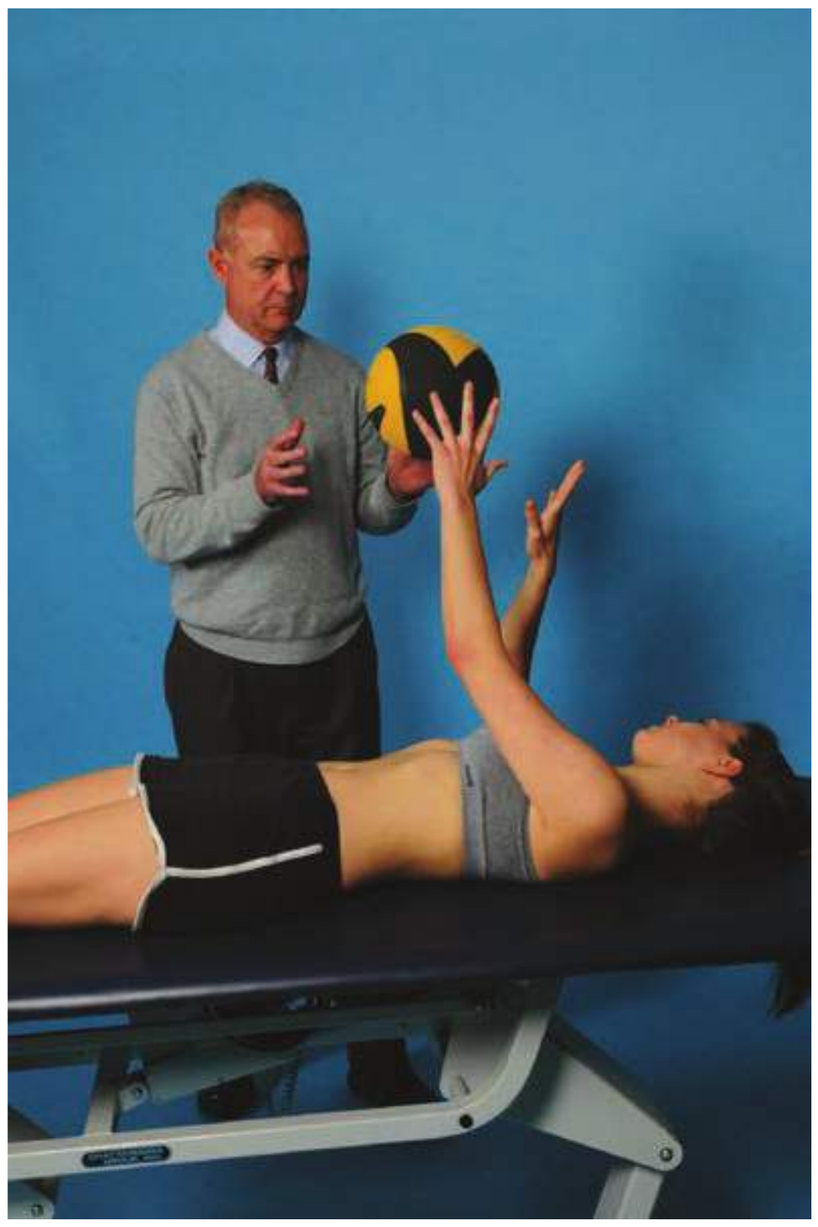

FIGURE 17-71 Medicine ball throws.

In order for the athlete to begin the return to sporting activities, the elbow must have full, pain-free ROM; no pain or tenderness on physical examination; and adequate muscle strength, power, and endurance that is 90% of the uninvolved side.[7]

T ose athletes who are returning to throwing can undergo a strength comparison through isokinetic testing. T is can be achieved with the patient in the seated position. Speeds of 180 degrees per second and 300 degrees per second are used. A bilateral comparison should indicate that the overhead athlete's elbow flexors are 10–20% stronger, the elbow extensors are 5–15% stronger when compared to the uninvolved side, and that the flexor–extensor ratio should be 70–80% at 180 degrees per second, and 63–69% at 300 degrees per second.[7]

Advanced strengthening exercises specific for the patient's activity/position are emphasized during the latter part of this phase. T ese include high-speed/high-energy strengthening and eccentric muscular contractions performed in functional positions.[7]

PRACTICE PATTERN 4D: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, AND RANGE OF MOTION ASSOCIATED WITH CONNECTIVE TISSUE DYSFUNCTION

Impairments involving capsular restriction include every form of arthritis. It is important that the clinician establish the cause of arthritis using the history, the tests and measures, results from any imaging studies, and findings from any laboratory tests before initiating treatment.

Traumatic Arthritis

Trauma at the elbow has the potential to produce traumatic arthritis. T e most common mechanism is the hyperextension injury, resulting in a sprain of the anterior capsule and the anterior band of the medial (ulnar) collateral ligament. T e patient typically complains of diffuse elbow pain, especially on the medial aspect. Upon examination, a capsular pattern of passive flexion more limited than extension is present, whereas the motions of pronation and supination are unaffected. Traumatic arthritis of the elbow is usually treated with a corticosteroid injection in adults, whereas in children a brief period of immobilization in a sling, followed by gentle passive and active range of motion (PROM and AROM), is recommended.

Arthrosis

See Chapter 5.

Osteochondritis Dissecans Capitellum

Osteochondritis dissecans occurs in many areas of the adolescent skeleton, and patients usually present with an insidious onset of diffuse lateral elbow pain accompanied by a decrease in the ROM, including locking.[137] T e etiology of this condition is not completely understood, but its occurrence in the elbows of adolescents probably relates to a focal arterial injury and subsequent bone necrosis resulting from increased radiohumeral lateral compression forces.[138]

Pain is usually felt at the humeroradial joint and is increased with activities that involve pronation and supination. Physical examination usually demonstrates a loss of full active and passive elbow extension. Resistive testing can produce crepitus, in addition to pain at the humeroradial joint.[138] X-rays may reveal a flattening or focal distortion of the capitellum and perhaps even loose bodies.

Intervention for this condition depends on the findings from the radiographic, clinical, and, on occasion, arthroscopic examination but usually focuses on the control of pain.[138] Usually 3–4 months of nonabusive activity with exercises directed toward minimizing the strength loss during the rest period often proves effective. T e exercises prescribed are similar to those for lateral epicondylosis with an emphasis on biceps and triceps strength and muscular balance to control elbow extension forces. A motion-limiting brace can be used to reduce stress.

Surgical intervention is reserved for patients who do not respond to conservative measures, or those with loose bodies or separation of the cartilage cap.[138]

Radiocapitellar Chondromalacia

Radiocapitellar chondromalacia of the elbow occurs because of repetitive valgus forces, such as those encountered in throwing sports. Such activities can result in lateral elbow joint compression of the humeroradial articulation, and sometimes subsequent damage to the radial head, the capitellum, or both. Frank osteochondral fracture and loose bodies may also occur (osteochondritis dissecans).

The typical presenting symptoms are crepitus, catching, locking, and lateral elbow pain with active flexion and extension and pronation–supination of the elbow. Swelling and localized tenderness are noted at the involved site.

An axial load applied with passive supination, and pronation often provokes pain and can be helpful in differentiating this condition from lateral epicondylosis. Radiographs may show a loss of joint space, marginal osteophytes, and, possibly, loose bodies.

Mild cases of this condition respond to NSAIDs and those exercises prescribed for lateral epicondylosis. However, care must be taken to perform exercises within pain-free ranges only to ensure joint safety.

Posterior Elbow Impingement

Posterior elbow impingement results from mechanical abutment of bone and soft tissues in the posterior compartment of the elbow. Pathologic processes such as fibrous tissue deposits in the olecranon fossa, chondral injury, osteophytes, and loose bodies are sometimes responsible.[139] MCL insufficiency may also be present.

Radiography may show posterior or posteromedial osteophytes and loose bodies.

Surgical removal of the osteophytes and loose bodies is indicated if symptoms do not resolve with a conservative treatment consisting of ROM and strengthening exercises.

Malpositioning of the Elbow

Abducted Ulna Lesion

This lesion usually results from a FOOSH injury, forcing the ulna medially into full extension and abduction. Clinical findings include the following[140]:

- An increased carrying angle and apparent longer radius that is forced to glide distally. Initially, the hand is held in slight ulnar deviation due to a relative distal shift of the radius. However, this usually adapts, producing an ulnar carpal shift due to the pull of the radial deviators and wrist extensors.
- The elbow flexion may be decreased, but usually only an abnormal hard end-feel is detected.
- The forearm supination may be decreased, but usually only an abnormal hard end-feel is detected.
- The lateral glide at the elbow is decreased with an abnormally hard end-feel (the ulna is unable to adduct).
- decreased wrist extension.

There are potentially many and varied consequences of this lesion, including:[140]

- the development of tennis-elbow symptoms as the radial deviators overwork to correct the ulnar deviation;
- an ulnar nerve traction injury, MCL sprain, and medial epicondylosis due to the increased carrying angle;
- carpal dysfunction due to the abnormal wrist biomechanics because of the distally displaced radius;
- MCL laxity due to the adaptation occurring to correct the ulnar deviation; and
- hypertonicity and overuse of the radial deviators and extensors as the hand attempts to adopt a neutral position by attempting to radially deviate or extend.

The intervention for these conditions includes a correction of the malposition with either joint mobilizations or a high-velocity thrust.

Adducted Ulna Lesions

In the adducted ulna lesion, there is no involvement of the wrist. In fact, the head of the radius impacts the capitellum, resulting in decreased elbow extension and forearm pronation, and clinical findings that are exactly the opposite of those described above. The consequences of this lesion are less severe than with the abducted ulna, as the shift of the wrist is less due to the accommodation by the ulnar meniscus, but they include:[140]

- the development of tennis-elbow symptoms due to the prolonged stretch on the common extensor tendon;
- LCL laxity;
- minor carpal dysfunction; and
- ulnar meniscus tearing due to continuous compression.

Posterior-Radial Head (External Rotation of the Ulna) Lesion

With this lesion, the radial head shifts posteriorly into extension on the humerus and the ulna. There is typically a history involving forced or excessive supination. ROM testing demonstrates decreased elbow extension and forearm pronation. Passive accessory motion testing reveals a decreased medial radial glide and a decreased gapping space between the ulna and the radius.

Anterior-Radial Head (Internal Rotation of the Ulna) Lesion

With this lesion, the radial head shifts anteriorly into flexion on the humerus and the ulna. There is typically a history involving forced or excessive pronation. ROM testing demonstrates decreased elbow flexion and forearm supination. Passive accessory motion testing reveals a decreased lateral-radial glide.

Medial (Ulnar) Collateral Ligament Sprain

The most common mechanisms associated with MCL sprains are a chronic attenuation of valgus and external rotation forces,[22,31,61,141,142] as seen with a tennis serve or during a baseball throwing pitch,[143,144] and posttraumatic, usually following a FOOSH injury.[19] Related injuries after trauma may include fractures of the radial head, olecranon, or medial humeral epicondyle.[22,31] An MCL injury can also be iatrogenic, secondary to an excessive medial epicondylectomy for cubital tunnel syndrome,[145,146] or irritation of the ulnar nerve, secondary to inflammation of the ligamentous complex.[61,147,148]

The most common patient complaint is medial elbow pain at the site of the ligament's origin,[138] or at the insertion site in cases of an acute avulsion.[19] As the primary restraint to valgus stress is the anterior bundle of the MCL,[14,20–24,28] the physical examination of an individual with presumed medial joint

insufficiency should focus on palpation of the course of the MCL.[19] Valgus stress testing of the elbow must also be performed.

An important secondary stabilizer of the elbow is the articular geometry of the joint complex.[3,21] Repetitive stress to the joint can lead to osteophyte formation and degenerative changes, which can produce medial elbow pain.

T e intervention for an MCL injury includes rest and activity modification or restriction for about 2–4 weeks, ROM exercises, modalities, and NSAIDs.[30] During the acute phase, the goals are as follows:

- To increase ROM
- To promote healing of MCL
- To retard muscular atrophy
- To decrease pain and inflammation (ice and compression)

Methods to increase ROM during this period include:

- brace (optional) nonpainful ROM (20–90 degrees); and
- active-assisted ROM, passive ROM elbow and wrist (nonpainful range).

Strengthening and stretching of the FCU, pronator teres, and FDS are initiated once the acute inflammatory stage has subsided. T ese exercises are performed in the pain-free mid-ROM.[49,143,149,150] Emphasis is placed on isometric exercises of the forearm flexors, ulnar deviators, and pronators, in order to enhance their role as secondary stabilizers of the medial joint. In addition, strengthening of the shoulder and elbow muscles are incorporated to prevent or minimize injury and to facilitate rehabilitation of the upper extremity.[49,138]During the subacute phase, the goal is to gradually increase motion 0–135 degrees (increase 10 degrees/week). Concentric exercises are initiated, which should include:

- wrist curls;
- wrist extension PREs;
- pronation–supination PREs; and
- biceps–triceps PREs.

Criteria to advance to the chronic phase include:

- full ROM;
- no pain or tenderness;
- no increase in laxity;
- the strength at 4/5 of elbow flexors–extensors.

T e goals during the chronic phase include:

- improve strength, power, and endurance; and
- improve neuromuscular control.

T ese goals can be achieved using the following exercises:

- initiating exercise tubing and shoulder program;
- biceps–triceps program;
- supination–pronation PREs; and
- wrist extension–flexion PREs.

As appropriate, a well-supervised throwing and conditioning program is initiated at approximately 3 months.[30] Criteria for progression to return to throwing include:

- full, nonpainful ROM;
- no increase in laxity; and
- isokinetic testing fulfills criteria.

Operative repair of the MCL typically is required only in competitive throwing athletes or those involved in heavy manual labor,[19] as valgus laxity has been shown to cause minimal functional impairment with normal activities of daily living.[31] T e surgical repair or reconstruction can be performed with or without ulnar nerve transposition.[151] T e Tommy John technique is a surgical procedure in which the UCL is replaced by a tendon from elsewhere in the body. T e palmaris longus tendon, which has been found to have a tensile strength of 357 N, is the most frequently used graft,[152] although the plantaris and toe extensor tendons can also be used.[141]

Lateral (Radial) Collateral Ligament Sprain

Posterolateral rotatory instability results from insufficiency of the lateral soft-tissue support of the elbow, especially the LCL complex.[34,36,153] T e mechanism of injury typically involves a combination of axial compression, external rotation, and valgus force applied to the elbow.[154,155] It may also have an iatrogenic origin and has been reported after overly aggressive debridement of the lateral soft tissues of patients with recalcitrant tennis elbow.[153,156]

Elbow Instability

Both the humeroulnar and the humeroradial articulation provide approximately 50% of the overall stability of the elbow.[21,24,25] Additional support is supplied by ligaments and muscles.

Although elbow instability has been documented for decades, the clinical tests for making the diagnosis of elbow instability are relatively recent.[36,154]

T e following five-item classification system for elbow instability is useful for correct diagnosing and treatment decision-making:[157–159]

1. T e timing (acute, chronic, or recurrent).
2. T e articulation(s) involved. Since the elbow is a complex joint, there are two categories of elbow instability, according to the articulation(s) involved, although the instability can involve both joints in a combined fashion:[157]
   a. T e ulnohumeral joint. T e instability of this hinge joint, which is most commonly predisposed to recurrent instability, can be congenital or acquired although the former is rare.
   b. T e proximal radioulnar joint. T is involves a subluxation or dislocation of the radial head from the ulna, which can be congenital or acquired. Dislocation of the radial head from the ulna is usually traumatic and often part of a Monteggia fracture–subluxation.
3. T e direction of displacement (valgus, varus, anterior, or posterolateral rotatory).
   a. Valgus displacement. T e medial stabilizers of the elbow are the strongest. T e mechanism of injury

for a valgus displacement is usually a FOOSH injury and occurs in individuals who perform overhead movements such as sledgehammer users and baseball pitchers and javelin throwers.[142] T e instability is characterized by pain in the anteromedial aspect of the arm, a moderate-to-severe flexion limitation (acute), and a positive valgus test at 20 degrees of flexion. Valgus instability is seen in one of two varieties: posttraumatic or chronic overload.[157]

Posttraumatic Valgus Instability. T is type is often associated with disruption of the soft tissues on the medial side of the elbow, including the MCL, and the common flexor and pronator origin.[160] Valgus instability is usually found in patients with radial head fractures associated with tears of the MCL, or in patients with severe elbow instability following a dislocation that has disrupted the lateral ligament complex.

Chronic. T is type typically occurs from repetitive microtrauma or overload, resulting in attenuation or rupture of the anterior band of the MCL.

b. Varus displacement. Because of the anatomic design of the elbow, any force across the elbow principally distorts the elbow in a valgus direction, usually in combination with external rotation rotatory force as occurs from a FOOSH injury. T us, a pure varus mechanism of injury is uncommon.[139] Lateral instability can occur acutely in patients with elbow dislocations and in many patients with recurrent or chronic instability when the LCL fails to heal.[157] Patients with a varus instability are unlikely to complain of symptoms except when using their arms as weight-bearing extremities (using crutches).[157]

c. Anterior displacements. T ese injuries, which are rare, usually occur from a blow to the flexed elbow, which drives the olecranon anteriorly.[161] Associated injuries include fractures of the olecranon, with varying degrees of the sprain to the collateral ligaments and damage to the vessels and nerves around the joint. On examination, the arm appears shorter, while paradoxically the forearm appears elongated and held in supination. T e elbow is usually held in extension.

d. Posterior displacements. Posterior elbow displacements, which are much more common than anterior or lateral displacements, involve a posteriorly displaced ulna in relation to the distal humerus. T e patient's arm is held in 45 degrees of flexion. Posterior displacements can be further subdivided into three types: posterior, posterior-medial, and posterior-lateral.[153,159] T e most common is usually posterior-lateral rather than direct posterior, so that the coronoid passes inferior to the trochlea, and the ulnar displacement on the humerus is three dimensional (the radius moves with the ulna), such that the ulna supinates (externally rotates) away from the trochlea.[157] T e most common mechanism for a posterolateral instability involves proximal attenuation or avulsion of the ligamentous and muscular origins from the lateral epicondyle during a traumatic event. T e LCL is the primary static restraint against posterolateral rotatory instability.[33,34,160,162–164] T e lateral pivot shift test, also called the posterolateral rotatory instability test, is commonly used to assist in the diagnosis.[139] T e surgical intervention for posterolateral rotatory instability involves a repair of the common tendon and ligament origins to the lateral epicondyle.[19]

4. T e degree of displacement (subluxation or dislocation). Posterolateral rotatory instabilities typically consist of three stages, each of which has specific clinical, radiographic, and pathologic features that are predictable and have implications for treatment:[157]
   a. Stage 1. T e elbow subluxates in a posterolateral rotatory direction, and the patient has an associated positive lateral pivot shift test.
   b. Stage 2. T e elbow dislocates incompletely so that the coronoid is perched under the trochlea.
   c. Stage 3. T e elbow dislocates fully so that the coronoid rests behind the humerus.
5. T e presence or absence of associated fractures. Elbow subluxations and dislocations can be associated with elbow fractures. Fracture–dislocations most commonly involve the coronoid and/or radial head, an injury so difficult to treat and prone to unsatisfactory results that it has been termed the "terrible triad" of the elbow.[165]

T e diagnosis of elbow instability is made by the history and a careful physical examination. Patients typically present with a history of recurrent painful clicking, snapping, clunking, or locking of the elbow, that occurs in the extension portion of the arc of motion with the forearm in supination.[157] An examination of the peripheral nerves and distal pulses is necessary to help determine the severity of the instability. Swelling may make the diagnosis of elbow instability difficult. However, if the clinician palpates the two epicondyles and the tip of the olecranon, the following findings help determine the diagnosis:

- If the three points are on the same plane, a supracondylar fracture is suspected.
- If the olecranon is displaced from the plane of the epicondyles, a posterior dislocation is suspected.

T e diagnosis of a dislocation can be confirmed by a radiograph.

With patients presenting with a history of dislocation, the diagnosis of recurrent elbow instability is to be suspected. T is diagnosis should also be considered when there has been trauma without dislocation. Recurrent instability may also be caused by surgeries such as tennis-elbow surgery or surgery on the radial head.[36,153,156,157]

Conservative intervention for elbow instability should focus on the entire kinetic chain, including the lower extremities and trunk. Posterior capsular tightness in the shoulder must be addressed.[166–168]

During the inflammatory phase, the intervention includes:

- immobilization of the elbow positioned at 90 degrees of flexion in a well-padded posterior splint for 3–4 days;
- initiation of light gripping exercises (putty or tennis ball);
- avoidance of any passive ROM (patient to perform active ROM when the posterior splint is removed and replaced

with a hinged elbow brace or sling), and any valgus stresses to the elbow; and

- use of cryotherapy and high-voltage galvanic stimulation (HVGS).

At days 4–14 the posterior splint is replaced with a hinged elbow brace initially set at 15–90 degrees. Exercises during this phase should include:

- wrist- and finger-active ROM in all planes;
- active elbow ROM (while avoiding valgus stress)—flexion–extension–supination–pronation;
- multiangle flexion isometrics;
- multiangle extension isometrics (while avoiding valgus stress);
- wrist curls/reverse wrist curls;
- light biceps curls; and
- shoulder exercises (avoidance of external rotation of the shoulder, because this places valgus stress at the elbow). T e elbow should be stabilized during shoulder exercises.

At around 2–6 weeks, the hinged brace is set from 0 degrees to full flexion. Exercises include:

- PRE progression of elbow and wrist exercises;
- gentle low-load, long-duration stretching is initiated around 5–6 weeks to enhance extension;
- gradual progression of weight with curls, elbow extension, and so on;
- initiation of sports-specific exercises and drills; and
- External rotation and internal rotation exercises of the shoulder may be incorporated at 6–8 weeks.

An interval throwing program can be initiated at around 8 weeks. However, there should be no return to play until strength is 85–90% of the uninvolved limb. PNF, rhythmic stabilization, and plyometric exercises are used to improve functional stabilization of the joint, beginning with two-handed exercises in the nonprovocative ranges with the elbow close to the body, and progressing to one-handed activities with the involved arm in functional or sports-related positions.[37]

Surgical intervention is reserved for those patients in whom conservative measures fail.

PRACTICE PATTERN 4E: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, AND RANGE OF MOTION ASSOCIATED WITH LOCALIZED INFLAMMATION

Overuse injuries at the elbow, which are relatively common, result from repetitive trauma that leads to local tissue damage in the form of cellular and extracellular degeneration, which can be cumulative and result in tendinopathy or tendinosis, stress fractures, ligament sprains, or muscle myositis. Both intrinsic and extrinsic factors contribute to overuse injuries. Intrinsic factors include biomechanical abnormalities; extrinsic factors are primarily training errors (incorrect technique, improper equipment, and changes in the duration or frequency of activity).

Olecranon Bursitis

Because of its superficial location, the olecranon bursa is easily injured through direct trauma or can be irritated through repetitive grazing and weight bearing, resulting in bursitis. Olecranon bursitis is common in individuals who spend long periods weightbearing through the elbows, such as students, or where the potential for falling and striking an elbow on hard playing surfaces is high.[169]

Acute bursitis presents as a swelling over the olecranon process that can vary in size from a slight distension to a large mass several centimeters in diameter.[170] In chronic cases, the pain and swelling can be gradual, or sudden as in acute injury or an infection. An inflamed bursa can occasionally become infected, requiring differentiation between septic and nonseptic bursitis.[171]

Redness and heat suggest infection, whereas exquisite tenderness indicates trauma or infection as the underlying cause. Patients often note a decreased ROM or an inability to don a long-sleeved shirt.[172] Whilst a simple posttraumatic bursitis can be treated with the principles of PRICEMEM, the infected bursa needs prompt medical attention.[172]

Included in the differential diagnoses of olecranon bursitis are acute fractures, rheumatoid arthritis, gout, and synovial cysts.[170] If the patient is experiencing significant pain or discomfort with the movement of the elbow, a sling helps to reduce these symptoms and calm the joint.[170] In those cases of marked swelling, or to distinguish between a septic and nonseptic bursitis, aspiration is the appropriate management. Aspiration also helps to reduce the level of discomfort and restriction of movement. T e aspirated fluid is cultured and evaluated for crystals to rule out infection or gout. After aspiration, the elbow should be maintained in a splint and sling and reevaluated after 1 week. Bursitis that recurs despite three or more repeated aspirations, or an infection that does not respond to antibiotics, requires evaluation for surgical excision.[170,172]

Injection of corticosteroids is used to manage chronic bursitis once the diagnosis of infection has been excluded.[170]

Olecranon Impingement Syndrome

Repetitive impingement of the olecranon in the olecranon fossa may occur with valgus stresses in throwing sports. Stress to both articular surfaces of the joint may result in the formation of loose bodies, osteophytes, chondromalacia, and synovitis.[173]

T e patient may report catching, clicking, and crepitus, which are worsened by elbow extension. Full elbow extension may be limited by a mechanical block. X-rays confirm loose bodies, olecranon osteophytes, and commonly associated anterior elbow changes.

Mild cases respond to a rehabilitation program focusing on restoration of normal motion, strength, and endurance. Continued pain, loose bodies, or mechanical blockage are indications for surgery.

Tendon Injuries of the Elbow

Tendon injuries of this region can be divided into several categories on the basis of the nature of their onset and the tissues involved. While acute tendon injuries are traumatic in nature, chronic overuse injuries are the result of multiple microtraumatic events that cause disruption of the internal structure of the tendon and produce tendinopathy or tendinosis.

Bicipital Tendinosis

Bicipital tendinosis typically results from repetitive hyperextension of the elbow with pronation, or repetitive flexion combined with stressful pronation–supination.[86] Typically the patient complains of pain located at the anterior aspect of the distal part of the arm, with tenderness to palpation of the distal biceps belly, the musculotendinous portion of the biceps, or the bicipital insertion of the radial tuberosity.[78,86] Other findings include a reproduction of pain with resisted elbow flexion and supination, and with passive shoulder and elbow extension.

The conservative intervention focuses on regaining the strength, endurance, and flexibility of the flexor/supinator mechanism, and on strengthening the shoulder stabilizers. Other approaches involve electrotherapeutic and thermal modalities, transverse friction massage, trigger point assessment, and specific elbow joint mobilizations.

Biceps Tendon Rupture

The distal biceps tendon can be avulsed partially or completely either at the musculotendinous junction or at the radial tuberosity, the latter of which is more common.[42] Avulsions of the biceps tendon at the elbow occur almost exclusively in males, and the most common scenario is a rupture of the dominant elbow of a muscular male in his fifth decade of life.[174] Biceps ruptures typically involve a sudden contracture of the biceps against a significant load with the elbow in 90 degrees of flexion.[42]

Clinical findings vary depending on the extent of the rupture; whether it is partial or complete. The typical history includes a report of a sharp, tearing pain concurrent with an acute injury in the antecubital fossa.[139] The sharp pain typically dissipates within hours to days and is followed by a dull ache.[42] The patient may also describe noticing a loss of strength in activities involving elbow flexion and supination (e.g., turning a door knob, or lifting objects).[42] The objective findings may include ecchymosis in the antecubital fossa, visible deformity (complete rupture), a palpable defect of the distal biceps (partial rupture), loss of strength of elbow flexion and grip, but especially a loss of forearm supination strength.[175]

Although, in low functioning or medically complicated patients, nonoperative measures may be pursued, in active individuals, the normal recommendation is primary repair of the acute tendon avulsion.[42] If not repaired, an 88% loss of elbow flexion and a 74% loss of supination strength can be expected.[176] Postoperatively, the elbow is protected for 6–8 weeks, after which unrestricted ROM and gentle strengthening exercises are initiated. Return to unrestricted activity is usually not allowed until nearly 6 months of healing has passed.[139]

Triceps Tendinosis

Triceps tendinosis is a chronic condition stemming from overuse, repetitive extension, and repetitive, heavy lifting which can occur in such activities as competitive weightlifting, boxing, gymnastics, throwing, and racquet sports.

Subjectively, the patient reports localized tenderness of the triceps insertion at the olecranon with palpation that is aggravated with resisted elbow extension. Strength testing typically shows a weakness of elbow extension.

X-rays are indicated to rule out olecranon apophysitis in adolescence and an avulsion fracture in adults.

The initial stages of the intervention emphasize the principles of PRICEMEM. Therapeutic exercises emphasize strength of the elbow extensor mechanism, with a focus on closed-chain exercises for the involved upper extremity.[173] In addition, shoulder strengthening and scapular stabilization exercises are introduced.

Triceps Tendon Rupture

A distal triceps tendon rupture, which is relatively uncommon, usually occurs when a deceleration force occurs during elbow extension or with an uncoordinated contraction of the triceps muscle against the flexing elbow.[177] As with the biceps tendon rupture, the physical findings depend on whether the avulsion is partial or complete, but the most common findings include a loss of elbow extension strength, and an inability to extend overhead against gravity. A tendon defect may be present if the tear is complete.[139]

Primary repair is the treatment of choice in acute complete ruptures. The partial injury may be treated conservatively with immobilization for about 3 weeks, followed by a gradual progression of ROM and strengthening exercises.

Brachialis Strain

A brachialis strain is relatively rare, but the brachialis is prone to myositis ossificans, a pathologic bone formation, due to the fact that it is likely to hemorrhage when injured (see later).

Typically, the patient reports pain that is felt on the anterior aspect of the distal part of the arm, and there is palpable tenderness in the muscle belly of the brachialis. Resisted supination is not painful, although resisted elbow flexion combined with forearm pronation is.

The conservative intervention involves electrotherapeutic and thermal modalities, transverse friction massage, trigger point assessment, correction of muscle imbalances, and specific elbow joint mobilizations.

Epicondylosis

While the terms epicondylitis and tendinitis have been commonly used to describe tennis elbow and golfer's elbow, histopathologic studies have demonstrated that these conditions are often not inflammatory conditions; rather, they are degenerative conditions. Therefore, epicondylosis, or angioblastic tendinosis, better describe the condition. Epicondylosis is common in persons who frequently overuse the upper arm, particularly with activities that involve rotation of the arm with flexion and extension. Tendon changes due to epicondylosis include dense populations of fibroblasts, vascular hyperplasia, and disorganize collagen.[178] Two types of epicondylosis are commonly described: lateral epicondylosis (tennis elbow) and medial epicondylosis (golfer's elbow). Lateral

epicondylosis is far more common than medial epicondylosis with an annual prevalence of 1–2% in the general public,[179] and 40–50% in recreational tennis players during their lifetime.[180]

Lateral Epicondylosis (Tennis Elbow)

Lateral epicondylosis is a costly musculoskeletal disorder, characterized by degeneration of the tendon and frequently reported pain at the lateral aspect of the elbow.[181] MRI findings demonstrate that the common extensor tendon origin is involved and shows increased signal intensity, with the region of greatest signal abnormality being at the origin of the ECRB tendon from the lateral epicondyle of the humerus. The tendons of the common extensor bundle connect to the muscles that control wrist extension and radial deviation.[138]

As mentioned, tennis players are commonly affected, but it also affects those with professions that require repetitive and/or forceful/heavy manual tasks, nonneutral wrist postures, and repetitive gripping.[182,183]

Lateral epicondylosis usually results from overuse although it can be traumatic in origin. The overuse injuries tend to involve abusive tissue trauma secondary to repetitive activity, which promotes microtraumatic tissue failure. Those tendons that wrap around a convex surface or the apex of a concavity, and those that cross two joints, are particularly vulnerable to overuse injuries, as are those with areas of scant vascular supply, or those subjected to repetitive tension.[184] One possible etiology for overuse at the elbow is the fact that the hand does not have a supportive function but functions predominantly to grasp some object. Repetitive grasping, with the wrist positioned in extension, places the elbow at risk. Participants of tennis, baseball, javelin, golf, squash, racquetball, swimming, and weight lifting are all predisposed to this risk.[139]

Clinical Presentation. A thorough but focused history and physical examination are critical to a timely and accurate diagnosis. Pain is the primary symptom of lateral epicondylosis.[181] Historical factors should be solicited, such as tobacco use, occupation, hand dominance, recreational activities, duration of symptoms, and prior episodes and attempted treatments.[42] The pain is often related to activities that involve wrist extension/grasp, as it is the wrist extensors that must contract during grasping activities to stabilize the wrist. For example, pouring a gallon of milk may reproduce the symptoms. Diffuse achiness and morning stiffness are also common complaints.[138] Occasionally the pain is experienced at night, and the patient may report dropping objects frequently, especially if they are carried with the palm facing down. The pain can be assessed using a self-reported measure such as the patient-rated tennis elbow evaluation (PRTEE),[185] a valid, reliable, and sensitive clinical instrument for individuals with chronic lateral epicondylosis (Table 17-9).[186]

Palpable tenderness is usually found over the ECRB and ECRL, especially at the lateral epicondyle, with the site of maximum tenderness most commonly being over the anterior aspect of the lateral epicondyle.[138]

The ROM tests typically reveal the following:

- Active motions are usually painless, although there may be a pain with wrist flexion when combined with elbow extension.
- Passive motion can produce pain, especially with passive wrist flexion with the forearm pronated and the elbow extended.

The resisted tests typically reproduce symptoms with resisted wrist extension and radial deviation with the elbow extended. Pain-free grip strength is the most commonly affected motor impairment.[187] Rate of force development is considered to be a measure of the ability to rapidly generate strength and is associated with higher functional performance.[188] A 2007 cohort study by Dorf et al.[189] found that with the elbow in extension, the affected side had 50% grip strength when compared to the unaffected side. Pain on resisted middle finger extension has also been reported (Maudsley test—see Special Tests). The chair test (see Special Tests), and Cozen's or Mills' special tests are typically positive.

The cervical spine, shoulder, and wrist must also be examined. As a large number of tennis elbows appear to be secondary to a dysfunction of either the cervical spine or the shoulder,[182] testing isometric wrist extension in varying positions of the cervical spine or shoulder will help differentiate the cause. If the primary cause is remote, the amount of discomfort on testing will vary with changes in the head or shoulder girdle position. If the pain disappears entirely during these maneuvers, there can be no symptomatic pathologic changes at the elbow, and no local treatment is required. However, usually the pain is reduced rather than being eliminated, indicating that the cause may be remote and local pathologic changes have since supervened. If the diagnosis of lateral epicondylosis is clear following the history and physical examination, diagnostic imaging is not indicated.[42] However, if uncertainty exists, imaging and diagnostic test can be useful for exploring the differential diagnosis, including radiocapitellar chondromalacia, posterolateral elbow instability, plica, loose bodies, malignancy, cervical radiculopathy (C6 or C7), or compression of the PIN at the arcade of Frosche (supinator syndrome).[42]

Intervention. To date, there is no consensus on the optimal treatment approach for lateral epicondylosis, which is in large part due to its unclear underlying etiology.[182] Thus, there are numerous interventions cited for this condition, both medical and surgical.[190] In fact, more than 40 treatments have been suggested, indicating that the ideal remedy has yet to be found, although there is agreement that the initial management should be conservative. Many studies of the use of physical therapy in the management of tennis elbow are poorly designed and statistically weak.[191,192]

The goals during the acute phase are to decrease inflammation/pain, promote tissue healing, increase flexibility, and retard muscle atrophy. Methods to accomplish this include:[193]

- cryotherapy;
- whirlpool;
- HVGS;
- phonophoresis;
- iontophoresis;
- stretches for
  - wrist extension–flexion;
  - elbow extension–flexion;
  - forearm supination–pronation; and
- avoidance of painful movements (such as gripping).

TABLE 17-9 Tennis Elbow Questionnaire

Patient Name: _____ Date: _____

The questions below will help us understand the amount of difficulty you have had with your arm in the past week. You will be describing your average arm symptoms over the past week on a scale 0–10. Please provide an answer for all questions. If you did not perform an activity because of pain or because you were unable, then you should circle a "10." If you are unsure please estimate to the best of your ability. Only leave items blank if you never perform that activity. Please indicate this by drawing a line completely through the question.

1. PAIN in your affected arm

Rate the average amount of pain in your arm over the past week by circling the number that best describes your pain on a scale from 0–10. A zero (0) means that you did not have any pain and a ten (10) means that you had the worst pain imaginable.

RATE YOUR PAIN:	No pain										Worst Imaginable
When you are at rest	0	1	2	3	4	5	6	7	8	9	10
When doing a task with repeated movement	0	1	2	3	4	5	6	7	8	9	10
When carrying a plastic bag of groceries	0	1	2	3	4	5	6	7	8	9	10
When your pain was at its least	0	1	2	3	4	5	6	7	8	9	10
When your pain was at its worst	0	1	2	3	4	5	6	7	8	9	10

2. FUNCTIONAL DISABILITY

SPECIFIC ACTIVITIES

Rate the average amount of difficulty you experienced performing each of the tasks listed below, over the past week, by circling the number that best describes your difficulty on a scale of 0–10. A zero (0) means you did not experience any difficulty and a ten (10) means it was so difficult you were unable to do it at all.

	No difficulty										Unable to do
Turn a doorknob or key	0	1	2	3	4	5	6	7	8	9	10
Carry a grocery bag or briefcase by the handle	0	1	2	3	4	5	6	7	8	9	10
Lift a full coffee cup or glass of milk to your mouth	0	1	2	3	4	5	6	7	8	9	10
Open a jar	0	1	2	3	4	5	6	7	8	9	10
Pull up pants	0	1	2	3	4	5	6	7	8	9	10
Wring out a washcloth or wet towel	0	1	2	3	4	5	6	7	8	9	10

3. USUAL ACTIVITIES

Rate the amount of difficulty you experienced performing your usual activities in each of the areas listed below, over the past week, by circling the number that best describes your difficulty on a scale of 0–10. By "usual activities," we mean the activities that you performed before you started having a problem with your arm. A zero (0) means you did not experience any difficulty and a ten (10) means it was so difficult that you were unable to do any of your usual activities.

	No difficulty										Unable to do
1. Personal activities (dressing, washing)	0	1	2	3	4	5	6	7	8	9	10
2. Household work (cleaning, maintenance)	0	1	2	3	4	5	6	7	8	9	10
3. Work (your job or everyday work)	0	1	2	3	4	5	6	7	8	9	10
4. Recreational or sporting activities	0	1	2	3	4	5	6	7	8	9	10

Comments:

PRTEE Scoring Instructions

Minimize non-response by checking forms when the patient completes them. Make sure that the patient left an item blank because they could not do it, that they understand that should have recorded this item as a "10." If the patient is unsure because they have rarely performed an activity in the past week, then they should be encouraged to estimate their average difficulty. This will be more accurate than leaving it blank. If they never perform an activity they will not be able to estimate and should leave it blank. If items from a subscale are left blank, then you can substitute the average score from that subscale.

Pain Subscale—Add up 5 items. Best score = 0; Worst score = 50

Specific Activities—Add up 6 items. Best Score = 0; Worst Score = 60

Usual Activities—Add up 4 items. Best Score = 0; Worst Score = 40

Function Subscale—(Specific Activities + Usual Activities)/2 – Best score = 0; Worst score = 50

Total Score = Pain Subscale + Function Subscale (pain and disability contribute equally to score). Best Score = 0 Worst Score = 100

Reliability of subscales and total score are sufficiently high that both subscales and total are reportable.

Data from Overend TJ, Wuori-Fearn JL, Kramer JF, MacDermid JC. Reliability of a patient-rated forearm evaluation questionnaire for patients with lateral epicondylitis. J Hand Ther. 1999;12:31–37.

During the subacute phase, the goals should be to[193]

- improve flexibility;
- increase muscular strength and endurance;
- increase functional activities and return to function;
- emphasize concentric–eccentric strengthening with a focus on
  - wrist extension–flexion;
  - forearm pronation–supination;
  - elbow flexion—extension;
- initiate shoulder strengthening (if deficiencies are noted);
- continue flexibility exercises;
- use counterforce brace;
- continue use of cryotherapy after exercise or function;
- initiate gradual return to stressful activities; and
- gradually reinitiate previously painful movements.

During the chronic phase, the goal should be to[193]

- improve muscular strength and endurance;
- maintain/enhance flexibility;
- gradually return to high-level sports activities;
- continue strengthening exercises (emphasize eccentric–concentric);
- continue to emphasize deficiencies in shoulder and elbow strength;
- continue flexibility exercises;
- gradually diminish the use of the counterforce brace;
- continue to use cryotherapy as needed post-exercise;
- initiate gradual return to sports activity;
- equipment modifications (grip size, string tension, and playing surface); and
- emphasize maintenance.

T e effectiveness of ultrasound for tennis elbow is undetermined. One study[194] found ultrasound to be effective in a placebo-controlled, double-blind trial,[195] but another study,[196] found no difference. A recent randomized pilot study by Struijs et al.[197] of 31 patients diagnosed with tennis elbow found that manipulation of the wrist was more effective at a follow-up of 3–6 weeks than ultrasound, friction massage, and muscle stretching and strengthening exercises. T e wrist manipulation used was an anterior (ventral) manipulation of the scaphoid (refer to Chapter 18), which was repeated 15 times, two times a week, with a maximum of nine intervention sessions. In a randomized study of 18 subjects,[198] joint mobilization to the radial head combined with neurodynamic techniques to the radial nerve was compared with a program consisting of ultrasound, transverse friction massage, and strengthening and stretching exercises. At 3-month follow-up, only the group receiving joint mobilizations and neurodynamic interventions had improved.

More recently, there has been a trend toward treatment of the cervical and thoracic spines with this disorder. Vincenzino et al.[199] demonstrated that cervical lateral glides resulted in an immediate improvement in pain at the lateral elbow, in pain-free grip strength, and in increased ROM during upper limb neurodynamic testing in patients with lateral epicondylosis. A retrospective study by Cleland et al.[200] demonstrated that patients receiving manual therapy techniques directed at the cervical spine achieved similar success rates as a group who received treatment solely directed at the elbow, but that they achieved this success in significantly fewer visits ($p = 0.01$). Another clinical trial by Cleland et al.[201] which compared the outcomes of 10 patients with lateral epicondylosis who were randomly assigned to receive localized treatment or localized treatment plus manual therapy to the cervicothoracic spine, found that the latter group demonstrated greater improvement in all outcome measures as compared to the treatment group receiving the localized management. Replication of these results is needed in a large-scale randomized clinical trial with a control group and a longer-term follow-up before any meaningful conclusions can be drawn.

In a randomized trial by Bisset et al.[202] that investigated the efficacy of physical therapy for tennis elbow (combining mobilizations with movement [MWM] techniques and exercise) compared with a wait-and-see approach or corticosteroid injections over a 52-week period concluded that the physical therapy intervention had a superior benefit to a wait-and-see approach in the first 6 weeks and to cortisone injections after 6 weeks.

Other forms of physical therapy including electrotherapy and thermotherapy have not been proven to be effective.[194]

T e patient may be prescribed an orthotic device as a treatment strategy, and many different types of braces and other orthotic devices are available. T e main type is a band or strap around the muscle belly of the wrist extensors. T eoretically, binding the muscle with a clasp, band, or brace should limit expansion and thereby decrease the contribution to force production by muscle fibers proximal to the band.[203] However, the benefits of tennis-elbow braces remain unproven. Snyder-Mackler and Epler reported on a comparison of a "standard" tennis-elbow brace and one with an air-filled bladder,[204] but it is not possible to extrapolate from their findings to the efficacy of tennis-elbow braces in the management of tennis elbow. Counterforce bracing[205] (such as the Count-R-Force brace from Medical Sports, Arlington, VA) has been shown to;

- beneficially impact force couple imbalances and altered movements,[127,206,207]
- decrease angular acceleration; at the elbow;[208] and
- decrease EMG activity.[208]

However, tennis-elbow braces have been shown to have little effect in vibrational dampening.[209] As an alternative to bracing, Gellman[210] recommends a protective 20-degree wrist extension splint for tennis elbow to help offload the ECRB.[138] In a study by Struijs et al.,[203] a total of 180 patients were randomized into three groups: brace-only treatment, physical therapy, and a combination of these. Main outcome measures were success rate, the severity of complaints, pain, disability, and satisfaction. Physical therapy was superior to brace only at 6 weeks for pain, disability, and satisfaction. Contrarily, brace-only treatment was superior in the ability of daily activities. Combination treatment was superior to brace on the

severity of complaints, disability, and satisfaction. At 26 and 52 weeks, no significant differences were identified.[203] The results from the study would tend to indicate that the brace treatment might be useful as an initial therapy.

The Mills' manipulation (see Intervention section), a thrust technique that is intended to maximally stretch the ECRB tendon in order to try to pull apart the two surfaces of the painful scar, has been recommended to treat true tennis elbow.[211] Manipulation of this kind has also been advocated in other studies.[212–214]

Nirschl and Sobel[119] have attempted to determine whether the presenting symptoms are helpful in both diagnosing and directing the intervention. This information was previously published in the form of a table.[119]

- *Types 1 and 2.* Benign (nonharmful) pain: Type 1 pain is characterized by stiffness or mild soreness after activity and resolves within 24 hours. Type 2 pain is marked by stiffness or mild soreness after exercise, lasts more than 48 hours, is relieved with warm-up exercises, is not present during activity, and resolves within 72 hours after the cessation of activity. The pain associated with types 1 and 2 may be due to peritendinous inflammation.
- *Type 3.* Semibenign (likely nonharmful) pain: Type 3 pain is characterized by stiffness or mild soreness before activity and is partially relieved by warm-up exercises. The pain does not prevent participation in the activity and is only mild during activity. However, minor adjustments in the technique, intensity, and duration of activity are needed to control the pain. Type 3 pain may necessitate the use of nonsteroidal anti-inflammatory medications.
- *Type 4.* Semiharmful pain: Type 4 pain is more intense than type 3 pain and produces changes in the performance of a specific sports- or work-related activity. Mild pain accompanies the activities of daily living. Type 4 pain may reflect tendon damage.
- *Types 5–7.* Harmful pain: Type 5 pain, which is characterized as moderate or severe before, during, and after exercise, greatly alters or prevents the performance of the activity. Pain accompanies but does not prevent the performance of activities of daily living. Complete rest controls the pain. Type 5 pain reflects permanent tendon damage. Type 6 pain, which is similar to type 5 pain, prevents the performance of activities of daily living and persists despite complete rest. Type 7 pain is a consistent, aching pain that intensifies with activity, and that regularly interrupts sleep.

The pain of types 1 and 2 is usually self-limiting when proper precautions are taken. Types 3 and 4 usually respond to nonoperative medical therapy. The pain types of 5–7 are more likely to necessitate operative treatment.[119]

Johnson[215] recommends an exercise regimen consisting of PREs to the wrist extensors, with the elbow flexed to 90 degrees and also with the elbow straight. The exercises are performed on a 10-repetition maximum, morning and night. Gradually, the weight is increased so that the 10-repetition maximum is always maintained. The pain may increase for the first week or two or three, but by the fifth or sixth weeks, the elbow pain will be better. An ice pack or heating pad can be used during the painful period.[215]

FIGURE 17-72 Start position for twisting exercise.

Since eccentric exercises are typically advocated for tendon injuries, one study[216] randomly assigned 38 patients to a contract-relax stretching or eccentric exercise treatment group. Seventy-one percent reported full recovery in the eccentric exercise group, with 39% in the contract-relax stretching group.[216] The elastic FlexBar (Thera-band, Hygienic Corp, Akron, Ohio) produces an eccentric overload to wrist and forearm musculature by preloading the wrist and finger musculature followed by a slower eccentric contraction. A twisting exercise using the FlexBar can be designed to eccentrically load the wrist extensors. To eccentrically strengthen the wrist extensors of the right upper extremity, the patient grasps one end of the FlexBar with the right hand (Fig. 17-72). The FlexBar is then grasped by the left hand (Fig. 17-73) and both elbows are extended with the forearms supinated (Fig. 17-74). Once in this position, the patient twists the FlexBar into wrist flexion using the right hand (Fig. 17-75).

Incorrect technique, particularly with racquet sports, is the cause of many elbow problems. Emphasis should be placed on recruiting the whole of the shoulder and trunk when hitting

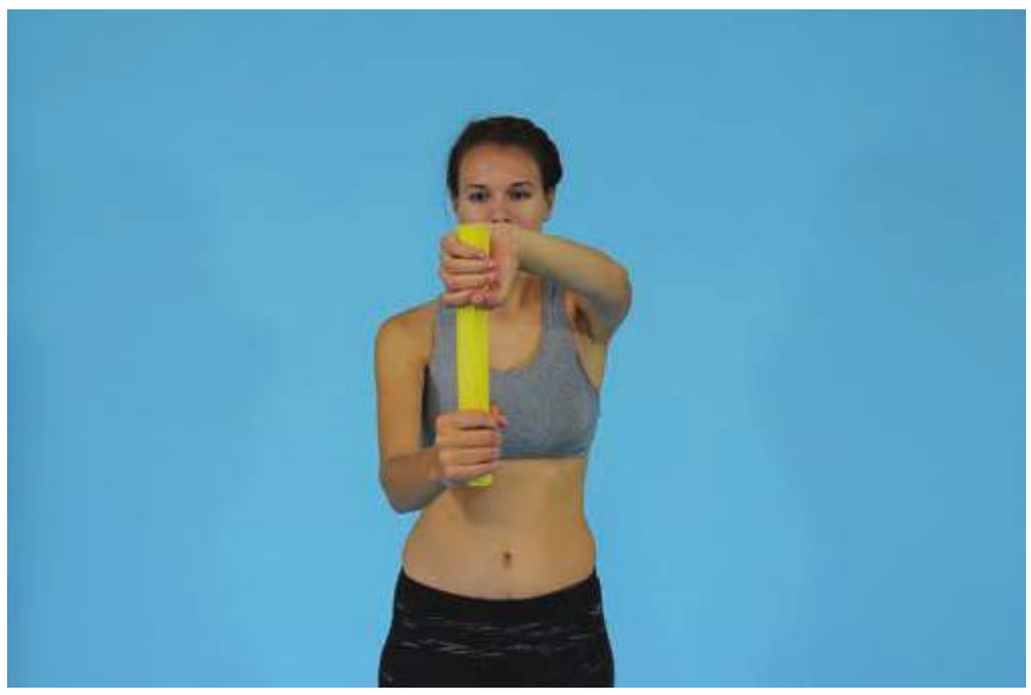

FIGURE 17-73 Patient grasps FlexBar using left hand.

FIGURE 17-74 Both hands holding FlexBar with elbows extended, forearms pronated.

the ball, so as to dissipate the forces as widely as possible. It is important to hit strokes with a firm wrist and not by means of wrist movements to return the ball. A late backhand in tennis should be corrected as this stroke is the most common cause of stress to the elbow if performed incorrectly.[130,217,218] Whereas the forehand demonstrates good weight transfer; the faulty backhand has no forward weight transfer, and the front shoulder is usually elevated.[172] T e trunk leans away from the net at the time of impact, and the racquet head is down.[172] T e elbow and wrist extend before impact, and the power source is forearm extension in the pronated position, resulting in a stroke that is nonrhythmic and jerky and with sharp pronation at follow-through.[172] Sometimes the use of a two-handed backhand may be helpful. One theory to support this is that the one-handed backhand links five body parts prior to impact (hips to trunk to shoulder to elbow to wrist), while the two-handed backhand only links two body parts (hips to trunk) prior to impact with the ball.[138]

T e ball should be hit with the center point of the strings, or "sweet spot." When the ball is hit incorrectly, the forces are transmitted as an acute strain up and along the muscle mass to the extensor origin at the elbow.[217]

FIGURE 17-75 Patient twists the FlexBar into wrist flexion using right hand.

In addition to correcting poor technique, patient education should address racquet size, grip size, and string tension. A fiberglass, graphite, or wood racquet is more forgiving than a metal one. Tennis racquets with larger head sizes reduce arm vibration.[219] Tennis racquets should be strung with gut, as it is more resilient than nylon strings, to 52–55 lb to allow the impact to be spread over slightly more time and decrease the forces transmitted to the forearm muscles.[220,221] Currently, the use of a mid-sized medium-flex, graphite tennis racquet with loosely strung nylon monofilament is recommended. T e grip size should not be too large or too small,[222] and an increased racquet handle diameter is helpful for players with relatively weak wrist extensors.

If the symptoms are not controlled with the above measures, local injection of a corticosteroid may be helpful. It was not until the 1950s that the injection of corticosteroids was first reported.[223–225] Freeland and Gribble found that hydrocortisone was neither more nor less effective than procaine and concluded that the short-term relief of pain was a nonspecific response that may be due to the volume of fluid injected or to the trauma of introducing the needle.[224] Subsequently a number of studies have shown steroids to be beneficial, and this has remained one of the mainstays of conservative treatment.[226–228]

Operative Intervention. Surgery is indicated if the symptoms do not resolve despite a properly performed conservative intervention lasting 6 months.[139] A simple handshake test can help to determine whether surgical intervention is required.[229] T e patient is asked to perform a firm handshake with the elbow extended, and then supinate the forearm against resistance. T e clinician notes whether the patient reports having pain at the origin of the extensors of the wrist. T e elbow is then flexed to 90 degrees, and the same maneuver is performed. If the pain is decreased in the flexed position, operative treatment is less likely to be needed. If the pain is equally severe with the elbow flexed and extended, then operative intervention is more likely to be needed.[229]

T e goals of operative treatment of tendinosis of the elbow are to resect the pathologic material to stimulate neovascularization by producing focused local bleeding, and to create a healthy scar while doing the least possible structural damage to the surrounding tissues. Postoperatively, a carefully guided resistance-based rehabilitation program is recommended.

Medial Epicondylosis (Golfer's Elbow)

Medial epicondylosis is only one-third as common as lateral epicondylosis.[100] It primarily involves a tendinopathy of the common flexor origin, specifically the FCR and the humeral head of the pronator teres.[49,100,230] To a lesser extent, the palmaris longus, FCU, and FDS may also be involved.[217]

As with "tennis" elbow, "golfer's" elbow is not only found in athletes that play golf but can also be found in throwing athletes, and workers in occupations that demand repetitive wrist flexion activities. Although the mechanism for medial epicondylosis can involve direct trauma, it is more likely to be caused by overuse or repetitive stress. T is commonly occurs for three reasons:

FIGURE 17-76 Start position for twisting exercise.

- Fatigue of the flexor–pronator tissues in response to repeated stress.
- A predisposition for medial ligamentous injury due to a sudden change in the levels of stress.[231]
- The MCL fails to sufficiently stabilize against the valgus forces.[232]

Medial epicondylosis usually begins as a microtear at the interface between the pronator teres and FCR origins with subsequent development of fibrotic and inflammatory granulation tissue.[30] An inflammation develops in an attempt to speed up tissue production to compensate for the increased rate of microdamage caused by increased use and decreased recovery time.[233] Chronic symptoms result from a loss of extensibility of the tissues, leaving the tendon unable to cope effectively with tensile loads.

Clinical Presentation. The typical clinical presentation for medial epicondylosis is pain and tenderness over the flexor–pronator origin, slightly distal and anterior to the medial epicondyle. The symptoms are typically reported to be exacerbated with either resisted wrist flexion and pronation or passive wrist extension and supination.[30,100]

Differential diagnosis for medial elbow symptoms includes:[234]

- MCL injury or insufficiency;[22,235,236]
- ulnar nerve entrapment (ulnar neuritis, which also commonly occurs along with medial epicondylosis); and
- medial elbow intra-articular pathology.[237]

Intervention. Conservative intervention for medial epicondylosis has been shown to have success rates as high as 90%.[100] The conservative intervention for this condition initially involves rest, activity modification, and local modalities. Complete immobilization is usually not recommended as it eliminates the stresses necessary for maturation of new collagen tissue. Once the acute phase has passed, the focus switches to restoring ROM and correcting any imbalances of flexibility and strength. The strengthening program initially includes multiangle isometrics, and then concentric and eccentric exercises of the flexor–pronator muscles. Similar to the treatment of lateral epicondylosis, a twisting exercise using the FlexBar can be designed to eccentrically load the wrist flexors. To eccentrically strengthen the wrist flexors of the right upper extremity, the patient grasps one end of the FlexBar with the right hand (Fig. 17-76). The FlexBar is then grasped by the left hand (Fig. 17-77), and both elbows are extended with the right forearm supinated and the left forearm pronated (Fig. 17-78). Once in this position, the patient twists the FlexBar into wrist extension using the right hand (Fig. 17-79)

Splinting or the use of a counterforce brace may be a useful adjunct.[30]

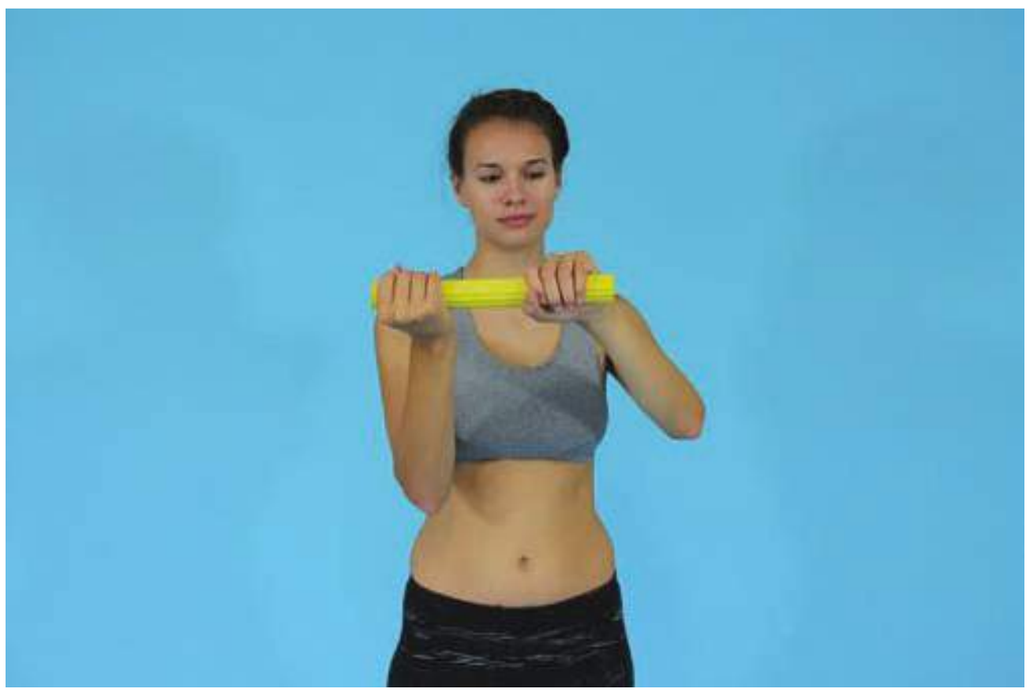

FIGURE 17-77 Patient grasps FlexBar using right hand.

INTEGRATION OF PRACTICE PATTERNS 4F AND 5F: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, AND RANGE OF MOTION, OR REFLEX INTEGRITY SECONDARY TO SPINAL DISORDERS, PERIPHERAL NERVE ENTRAPMENTS, COMPARTMENT SYNDROME, AND MYOFASCIAL PAIN DYSFUNCTION

Compressive Neuropathies

In the region of the elbow, there are a multitude of sites where the peripheral nerves can be entrapped or compressed (Table 17-10), with involvement of the ulnar and median and radial nerves and their branches being by far the most common.[68] Table 17-11 outlines a summary of conservative management strategies for the various nerve entrapments.

Ulnar Nerve Entrapment (Cubital Tunnel Syndrome)

Although the ulnar nerve is well protected above the elbow, the nerve can be compressed or entrapped at a number of locations. Nirschl has divided the medial epicondylar groove into three zones:[238,239]

- zone I: proximal to the medial epicondyle;
- zone II: the level of the medial epicondyle (retrocondylar groove); and
- zone III: distal to the medial epicondyle (cubital tunnel).

TABLE 17-10 Nerve Injuries about the Elbow

Nerve	Motor Loss	Sensory Loss	Functional Loss
Median nerve (C6–8, T1)	Pronator teres Flexor carpi radialis Palmaris longus Palmaris longus Flexor digitorum superficialis Flexor pollicis longus Lateral half of flexor digitorum profundus Pronator quadratus Thenar eminence Lateral two lumbricals	Palmar aspect of hand with thumb, index, middle, and lateral half of ring finger Posterior (dorsal) aspect of distal third of index, middle, and lateral half of ring finger	Pronation weakness Wrist flexion and abduction weakness Loss of radial deviation at wrist Inability to oppose or flex thumb Thumb abduction weakness Weak grip Weak or no pinch (ape hand deformity)
Anterior interosseous nerve (branch of median nerve)	Flexor pollicis longus Lateral half of flexor digitorum profundus Pronator quadratus Thenar eminence muscles Lateral two lumbricals	None	Pronation weakness, especially at 90-degree elbow flexion Weakness of opposition and thumb flexion Weak finger flexion Weak pinch (no tip to tip)
Ulnar nerve (C7–8, T1)	Flexor carpi ulnaris Medial half of flexor digitorum profundus Palmaris brevis Hypothenar eminence Adductor pollicis Medial two lumbricals All interossei	Posterior (dorsal) and palmar aspect of little and medial half of ring finger	Weak wrist flexion Loss of ulnar deviation at wrist Loss of distal flexion of little finger Loss of abduction and adduction of fingers Inability to extend second and third phalanges of little and ring fingers (benediction hand deformity) Loss of thumb adduction
Radial nerve (C5–8, T1)	Anconeus Brachioradialis Extensor carpi radialis longus and brevis Extensor digitorum Extensor pollicis longus and brevis Abductor pollicis longus Extensor carpi ulnaris Extensor indicis Extensor digiti minimi	Posterior aspect of hand (lateral two-thirds) Posterior aspect and lateral aspect of thumb Proximal two-thirds of posterior aspect of index, middle, and half of ring finger	Loss of supination Loss of wrist extension (wrist drop) Inability to grasp Inability to stabilize wrist Loss of finger extension Inability to abduct thumbs

TABLE 17-10 Nerve Injuries about the Elbow (Continued)

Nerve	Motor Loss	Sensory Loss	Functional Loss
Posterior interosseous nerve (branch of radial nerve)	Extensor carpi radialis and brevis Extensor digitorum Extensor pollicis longus and brevis Abductor pollicis longus Extensor carpi ulnaris Extensor indicis Extensor digiti minimi	None	Weak wrist extension Weak finger extension Difficulty stabilizing wrist Difficulty with grasping Inability to abduct thumb

Data from Magee DJ. Orthopaedic Physical Assessment. 2nd eds. Philadelphia, PA: WB Saunders; 2008.

Repetitive overuse can result in compression of the ulnar nerve in zone III by a tight FCU muscle.[173] Entrapment can also be precipitated in zones II and III by a subluxating ulnar nerve, in zone II by elbow synovitis, in zone I or II by a cubitus valgus deformity, or in zone I by the medial intermuscular septum, which slopes from a thick wide base at the medial epicondyle, to a weak and thin edge more proximal on the humeral shaft.[60,66,173]

It has been suggested that because of the superficial location of the ulnar nerve, any repetitive motion may initiate a cycle of inflammation and edema that inhibits the normal gliding of the nerve.[55,240] Additional injury occurs when traction forces caused by elbow flexion produce an additional compressive force on the internal architecture of the nerve.[58,241] The severity of nerve injury will be dependent on the magnitude, duration, and character of the applied forces.[55,240]

The anconeus has also been reported as a cause of cubital tunnel syndrome and has been found to occur in 3–28% of human anatomic specimen elbows,[57,242] and in as many as 9% of patients undergoing surgical treatment for cubital tunnel syndrome.[243]

The clinical findings for an ulnar nerve entrapment depend on the location of the lesion and may include:[244]

- activity-related pain or paresthesias involving the fourth and fifth digits, accompanied by pain that may extend proximally or distally on the medial aspect of the elbow;
- pain or paresthesias worse at night;
- decreased sensation in the ulnar distribution of the hand;
- progressive inability to separate the fingers;
- loss of grip power and dexterity;
- atrophy or weakness of the ulnar intrinsic muscles of the hand (late sign);
- clawing contracture of the ring and little fingers (late sign);[245]
- positive elbow flexion and pressure-provocative test;
- positive Wartenberg's sign and Froment's sign (see Chapter 18); and
- positive Tinel's sign at the elbow.

Conservative intervention is recommended for patients with intermittent symptoms and without changes in two-point discrimination or muscle atrophy. Activity modification with protection over the cubital tunnel with an elbow pad placed on the medial-posterior aspect,[244] limiting repetitive extreme elbow flexion, and night splinting at 40–60 degrees may be helpful.[58] In severe cases, the splint is worn during the day, or the elbow is cast at about 45 degrees. Exercises must not reproduce the distal nerve symptoms and may, therefore, initially need to be performed in limited arcs of motion.[173] For those patients who fail to respond to conservative management after 3–4 months, and who have muscle atrophy, persistent sensory changes, or persistent symptoms, surgical decompression, or an anterior transposition of the ulnar nerve is available.[66]

TABLE 17-11 Summary of Conservative Management for Nerve Entrapments

Nerve	Entrapment Site	Intervention
Median	Carpal tunnel Proximal forearm	Splint wrist in neutral position at night Stretching exercises for pronator teres Rest periods in supination
Ulnar	Guyon's canal Cubital tunnel	Splint wrist in neutral position at night Elbow pad Education: positioning in elbow extension and decreasing direct pressure on nerve Stretch the flexor carpi ulnaris
Radial (posterior interosseous)	Arcade of Fröhse	Positioning in supination and avoid repetitive pronation and supination activities
Radial (sensory)	Forearm	Positioning in supination and avoid repetitive pronation and supination activities
Brachial plexus	Supraclavicular	Avoid provocative positions Stretch shortened muscles and strengthen weakened scapular muscles

Median Nerve Entrapment (Humeral Supracondylar Process Syndrome)

Median nerve entrapment at the elbow is relatively rare, although it is often misdiagnosed as CTS.[97] The most proximal site at which the median nerve can be compressed is in the distal arm by the ligament of Struthers, an anatomic variant present in 0.7–2.7% of the population.[246] Very few cases of a ligament of Struthers neuropathy are described in the literature.[67,247,248] The patient may complain of pain in the wrist or medial forearm, which is exacerbated with full elbow extension or pronation of the forearm.[67,248] The patient may also report paresthesias in the index or long finger.[67]

In the antecubital area, there are three sites of potential median nerve entrapment.[97] One site is as the nerve passes under the lacertus fibrosus, or bicipital aponeurosis, a fascial band extending from the biceps tendon to the forearm fascia.[249] The second site is at the level of the pronator teres muscle after the nerve crosses the elbow. The third potential site is as the median nerve travels under the FDS. Compression of the median nerve at any one of these three sites constitutes what is described in the literature as the pronator syndrome (PS).

Pronator Syndrome. The patient typically complains of an insidious onset of pain that is usually felt on the anterior aspect of the elbow, radial side of the palm, and the palmar side of the first, second, third, and half of the fourth digits. There is often associated "heaviness" of the forearm.[97] Unlike CTS, there is no Tinel's sign at the wrist, and there are no nocturnal symptoms.[250,251] Pain can be reproduced with[64]

- pressure applied over the pronator teres 4 cm distal to the cubital crease with concurrent resistance against pronation, elbow flexion, and wrist flexion;[252]
- resisted supination (due to compression of the lacertus fibrosus); and
- resistance of the long finger flexors (due to compression by the FDS arch).

Diagnosis is confirmed electromyographically. PS typically responds well to activity modification (removing the causative activity), rest, NSAIDs, ice, and the restoration of proper flexibility and strength of the wrist flexors and forearm pronators. Rehabilitation will most benefit those cases in which compression is related to medial elbow tendinosis. In these cases, gentle massage along the fibers may aid in the breaking of adhesions. Surgical relief may be needed in recalcitrant cases.[250]

Anterior Interosseous Syndrome. Anterior interosseous syndrome was first described by Tinel in 1918 and was further delineated by Kiloh and Nevin in 1952.[250]

Potential sources of entrapment of the AIN include the Gantzer's muscle (an accessory head of the FPL), and the FCR muscle.[97,249,253]

Compression of the AIN results in forearm pain, and motor loss of the FPL, pronator quadratus, and the lateral half of the FDP, such that the patient is unable to perform the "OK" sign with the index finger and thumb. This must be differentiated from a rupture of the muscle or its tendon. No sensory changes occur, even though the AIN carries sensory information from the distal radioulnar joint, radiocarpal joint, and intercarpal joints.[254]

Pain and weakness are typically provoked with resisted flexion of the interphalangeal (IP) joint of the thumb and with the distal interphalangeal (DIP) joint of the index finger.

The differential diagnosis includes neuralgic amyotrophy, FPL tendon rupture, and index finger FDP rupture. Most cases of AIN syndrome typically resolve spontaneously.[255]

Although the PS and the AIN syndromes are relatively rare, it is important to be able to differentially diagnose the syndromes in cases of suspected CTS. Paresthesia is absent in AIN and present in both PS and CTS.[256] CTS involves paresthesia in the lateral 3½ digits, whereas PS involves paresthesia in the lateral 3½ digits and often in the distribution of the palmar cutaneous branch of the median nerve.[256] The paresthesia in CTS may be reproduced by compression over the wrist or Phalen's test, whereas PS requires compression at the pronator teres to reproduce paresthesia. Tinel's sign is present at the wrist in 80% of cases of CTS and is present at the pronator teres in PS in less than 50% of cases.[256] AIN syndrome is easily differentiated from CTS by the lack of paresthesia complaints.[256]

Radial Nerve Entrapment

The radial nerve is the most commonly injured peripheral nerve (see Chapter 3) and, because of its spiral course across the back of the mid-shaft of the humerus, and its relatively fixed position in the distal arm as it penetrates the lateral intermuscular septum, it is the most frequently injured nerve associated with fractures of the humerus.

A number of radial nerve entrapments are recognized and are named according to the location at which they occur. Four radial nerve entrapments are commonly cited: high radial nerve palsy, posterior interosseous nerve syndrome (PINS), radial tunnel syndrome (RTS), and superficial radial nerve palsy. The various symptoms of these entrapments can aid the clinician to determine the level of entrapment.

CLINICAL PEARL

There are motor and sensory involvements with the high radial nerve palsy, motor involvement with the PINS, pain with the RTS, and sensory disturbances with the superficial radial nerve palsy.[257] Symptoms of pain, cramping, and tenderness in the proximal posterior (dorsal) forearm, without muscle weakness, are associated with RTS, whereas PINS involves the loss of motor function of some or all of the muscles innervated by the PIN and is thus characterized by weakness.[257]

High Radial Nerve Compression. A spontaneous nerve compression may occur in the mid-arm at the level of the lateral head of the triceps due to strenuous muscular exercise.[258] A mid-shaft humerus fracture can result in a radial neuropathy at the spiral groove of the humerus in 14% of humeral fractures.[259] Regardless of the cause, a high radial nerve palsy will result in a loss of wrist extension, an inability to extend the fingers and thumb, and a decrease in sensibility of the first posterior (dorsal) web space.[257] Involvement of the triceps muscle is dependent on the level of compression. A cervical radiculopathy and thoracic outlet syndrome must be considered in the differential diagnosis.

Posterior Interosseous Nerve Syndrome. There are four potential sites of compression of the PIN as it traverses through the radial tunnel:[68,71,257,260]

- The fibrous bands that connect the brachialis to the brachioradialis.[73,261]
- The vascular leash of Henry, a fan of blood vessels that cross the nerve at the level of the radial neck.[71,73,262]
- A medial proximal portion (leading edge) of the ECRB.[71,73]
- Between fibrous bands at the proximal and distal edge of the supinator.[263] The proximal border of the supinator, through which the radial nerve passes, is referred to as the arcade of Fröhse.

Symptoms of PIN entrapment include lateral elbow pain that radiates into the distal forearm and is aggravated by repetitive pronation and supination; most specifically resisted supination. Tenderness is noted 3–4 cm distal to the lateral epicondyles where the radial nerve crosses the radial head and penetrates the supinator muscle. PIN palsy produces an inability to extend the MCP joints of the thumb, index, long, ring, or small fingers either individually or in combination.[264,265] In addition, there is a loss of thumb IP extension and radial abduction of the thumb.[257] Since the PIN can innervate the ECRB prior to the nerve's entrance into the radial tunnel, this muscle may not be involved in the PIN palsy. Thus, when compression within the radial tunnel is sufficient to cause paralysis, but there is no palsy, the condition is termed PINS.[250]

Initial conservative intervention includes rest, activity modification, and the use of a cock-up splint. Regular gentle stretching of the wrist extensor muscles, with the elbow held in full extension, is begun after a spontaneous recovery.[250]

Radial Tunnel Syndrome. RTS involves compression of the deep branch of the radial nerve. Michele and Krueger[266] have been credited with recognizing RTS as a distinct entity and gave it the name radial PS. The term RTS was introduced by Roles and Maudsley,[73] who suggested that RTS was the cause of resistant tennis-elbow pain.

The same structures implicated in PIN compression syndrome can cause RTS although RTS is often thought of as a dynamic compression syndrome.[267] This is because compression of the nerve occurs during elbow extension, forearm pronation, and wrist flexion, which causes the ECRB and the fibrous edge of the superficial part of the supinator to tighten around the nerve. The symptoms from this compression can mimic those of tennis elbow, namely tenderness over the lateral aspect of the elbow, pain on passive stretching of the extensor muscles, and pain on resisted extension of the wrist and fingers.[73,267] Men and women are equally affected, and the compression appears to be common in the fourth to sixth decades of life.[71]

Pain, which is poorly localized over the radial aspect of the proximal forearm, is the most common primary presenting symptom in RTS. In fact, it is the only nerve compression syndrome in which the signs and symptoms are not based on the nerve distribution.[268]

Upon palpation, maximal tenderness is usually elicited over the radial tunnel, some 5 cm distal to the lateral epicondyle, anterior to the radial neck. Resisted middle finger extension,[73] which tightens the fascial origin of the ECRB, and resisted supination of the forearm with the elbow fully extended[71] should reproduce the pain at the point of maximal tenderness. Positioning the arm in elbow extension, forearm pronation, and wrist flexion produces significant compression of the radial nerve.[250]

Conservative intervention should focus on education to avoid the provocative positioning of the arm into forceful extension and supination of the wrist and forearm and should include rest, stretching, and splinting.[73,269]

If a wrist immobilization splint is used, it is fitted in 45 degrees of extension for continual wear.

Surgical intervention is reserved for patients whose symptoms are not relieved by conservative intervention.

Radial Sensory Nerve Entrapment. The term Wartenberg's syndrome[270] or cheiralgia paresthetica is used to describe a mononeuritis of the superficial radial nerve, which can become entrapped where it pierces the fascia between the brachioradialis and ECRL tendons.[249,257] Symptoms include shooting or burning pain along the posterior-radial forearm, wrist, and thumb, associated with wrist flexion and ulnar deviation.[257] These symptoms can lead the clinician to believe that the first carpometacarpal joint and/or tendons of the anatomic snuffbox are involved, and that de Quervain's disease is present.

Musculocutaneous Nerve Entrapment

The brachialis is a pure elbow flexor, whereas the biceps brachii is an elbow flexor and supinator of the forearm.[46,271] With complete loss of motor function of these two muscles due to a lesion of the musculocutaneous nerve, functional elbow flexion strength can still be obtained with contraction of the brachioradialis and pronator teres.[272] The ECRL, FCU, FCR, and palmaris longus may also assist in flexing the elbow.[273] The brachioradialis has a better mechanical advantage when the elbow is flexed to 90 degrees and is more active when the forearm is in the pronated or neutral position.[273] The pronator teres can produce full elbow flexion, but this is accompanied by forearm pronation.[272,274] Thus, with a complete musculocutaneous nerve palsy, full antigravity elbow flexion can still be obtained but is strongest with the elbow flexed at 90 degrees and the forearm pronated.

Acute Compartment Syndrome

See Chapter 5.

Myofascial Pain Dysfunction

Elbow pain, when not related to the joint or to microtearing of the common flexor or extensor tendons, is commonly referred into the elbow from a number of sources, including myofascial. Even if microtearing is present, trigger points can also be present in the relevant muscles, placing a chronic strain on that tendon.

Supinator

This muscle refers pain and tenderness primarily to the lateral epicondyle of the elbow, but also to the posterior (dorsal)

web space between the thumb and index finger. According to Travell and Simons,[275] each of the common sites for tennis elbow can be accounted for by trigger points in the supinator, ECRL, and triceps muscles.

Supinator pain referral is activated by playing tennis with an extended elbow, which does not allow the biceps brachii to take part in the supination required to control the head of the tennis racquet.[276]

Triceps Brachii

A trigger point in the medial head of the triceps is a common cause of lateral elbow pain from the lateral side of this muscle or of medial elbow pain from the medial side of this muscle.[276]

INTEGRATION OF PRACTICE PATTERNS 4G AND 4I: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, AND RANGE OF MOTION, ASSOCIATED WITH FRACTURES AND BONY OR SOFT-TISSUE SURGICAL PROCEDURES

Radial Head Fractures

Radial head fractures and dislocations are traumatic injuries (except for the occurrence of congenital radial head dislocations), usually from a FOOSH with the force of impact transmitted up the hand through the wrist and forearm to the radial head, which is forced into the capitellum. Both of these conditions require adequate treatment to prevent disability from stiffness, deformity, posttraumatic arthritis, nerve damage, or other serious complications.[277] T ese fractures and dislocations may be isolated just to the radial head (and neck) and the lateral elbow (and proximal forearm), or they may be part of a combined complex fracture pattern, involving other structures of the elbow, and even the distal humerus, or forearm and wrist. Blunt or penetrating trauma rarely causes radial head injury. T e wrist, especially the distal radioulnar joint, may be damaged simultaneously, and the presence of wrist pain, grinding, or swelling should be determined. T e presence of bleeding, even with small puncture wounds, should alert the clinician to the possibility of open injury. Neurovascular symptoms of numbness, tingling, or loss of sensation should be identified to rule out nerve or vascular injury. T e presence of severe pain should alert the clinician to the possibility of compartment syndrome.

Patients with radial head fractures and dislocations present with localized swelling, tenderness, and decreased motion. T e clinician should palpate the elbow, especially the radial head, feeling for deformity, and the wrist should be examined, especially feeling for the stability of the distal radioulnar joint. All three major nerves of the forearm are at risk of elbow fractures and dislocations, so the clinician should also carefully assess neurovascular function for all of the nerves of the forearm and hand.

Radial head fractures present several challenges, as the radial head is a secondary stabilizer for valgus forces at the elbow as well as a restraint against longitudinal forces along the forearm.[278] Compromise of the MCL makes the radial head a more important stabilizer of the elbow.[5,278,279] A successful outcome correlates directly with the accuracy of anatomic reduction, restoration of mechanical stability that allows early motion, and consideration of the soft tissues. Surgical options for radial head fractures or dislocations include closed reduction with casting or early motion or open reduction with internal fixation (ORIF), replacement, or resection. Open management (including internal fixation, replacement, or excision depending on the fracture) is associated with a better long-term function.

In the Mason classification, the fracture is a type I if it is undisplaced and is generally treated nonoperatively with a splint or a sling for 3 days, and active elbow flexion exercises being initiated immediately. T e fracture is type II if a single fragment is displaced, but may still be treated nonoperatively if the displacement is minimal. A type III fracture is comminuted and usually requires operative intervention but may occasionally be treated closed with early motion if the radial head is not reconstructible.

Following immobilization, as much early mobilization as the patient can tolerate is the key to a favorable outcome. Strengthening, initially involving isometric exercises, begins at 3 weeks and progresses to concentric exercises at 5–6 weeks. Heavy resistance is not performed until after 8 weeks, or when adequate healing is demonstrated on radiographs. What follows is a postfracture or postsurgical protocol for type I fracture, or a type II or III fracture that has been stabilized with ORIF.[193]

Acute Phase

During the acute phase, the goals are to decrease pain and inflammation, regain full wrist and elbow ROM, and to retard muscular atrophy. Active-assisted and active ROM exercises are initiated at the elbow with the goal to regain a minimum of 15–105 degrees after 2 weeks. Gripping exercises using putty can be initiated in addition to isometric strengthening exercises of the elbow and wrist. Finally, concentric strengthening exercises for the wrist can be initiated.

Subacute Phase

T e goals during this phase are to maintain full elbow ROM, progress to elbow strengthening, and to gradually increase functional demands. Shoulder strengthening exercises are initiated and progressed that focus on the rotator cuff while the ROM exercises for the elbow are continued. T e active-assisted ROM and passive ROM exercises are initiated into supination–pronation to tolerance.

Chronic Phase

T e goals during this phase are to maintain full elbow ROM, increase strength, power, and endurance, and to gradually initiate sporting activities as appropriate. Eccentric elbow flexion–extension and plyometric exercises are initiated and continued until about 12 weeks.

Fractures with radial head surface involvement of more than 30%, fracture fragment displacement, and type III characteristics require management by an orthopaedic surgeon.[170]

TABLE 17-12 Classification of Monteggia Fracture Dislocations

Type	Description	Equivalent(s)	%
Type I	Anterior dislocation of the radial head and anterior angulation of the ulna fracture	Radial head or neck fracture instead of dislocation	60
Type II	Posterior dislocation of the radial head and posterior angulation of the ulna fracture	Posterior elbow dislocation. Radial head or neck fracture instead of dislocation	105
Type III	Lateral dislocation of the radial head with proximal ulna fracture	Radial head or neck fracture instead of dislocation	20
Type IV	Anterior dislocation of the radial head and proximal shafts of both bones fractured at same level	Radial head or neck fracture instead of dislocation	5

Data from Rabin SI. Radial Head Fractures. Available at: http://www.emedicine.com/orthoped/topic276.htm, 2005.

Monteggia Fracture

Monteggia fracture–dislocations are a particular type of radial head injury, involving a combination of a dislocation of the proximal end of the radius and a fracture of the ulna. Instead of the radial head dislocation, the radial head or neck may be fractured. These lesions typically result from a direct blow to the forearm or a FOOSH injury with the arm positioned in either hyperextension or hyperpronation. The classification of Monteggia fracture–dislocations is outlined in Table 17-12.

Although relatively rare, these fractures can present with serious problems and poor functional outcomes without proper care.[280,281] Such complications include damage to the posterior branch of the radial nerve, AIN, and the ulnar nerve, as well as nonunion and poor AROM.[280]

For Monteggia fracture–dislocations, best treatment includes open reduction internal fixation of the ulna diaphyseal fracture. Following the surgery, the elbow is immobilized for about 4 weeks in 90–120 degrees of elbow flexion, after which AROM exercises for elbow flexion and forearm supination are initiated. AROM into extension beyond 90 degrees begins 4–6 weeks postoperatively.

Coronoid Fracture

The coronoid forms a significant portion of the articular surface of the proximal ulna. It serves as an important attachment site for muscles and ligaments about the elbow and is essential for elbow stability.[1] Coronoid fractures, which are most commonly seen with high-energy injuries, are classified according to the size of the fragment type:[1,282]

- Type I: Tip avulsion. These fractures are generally stable and can be treated as simple dislocations with early motion.
- Type II: involves less than 50% of the height of the coronoid.

  Many of these are unstable and require ORIF.
- Type III: involve more than 50% of the height of the coronoid and frequently are accompanied by an instability of the elbow. ORIF or a hinged external fixator may be required to maintain the reduction.

Essex–Lopresti Fractures

This type of fracture is defined as a fracture of the radial head with proximal radius migration and disruption of the distal radioulnar joint and interosseous membrane,[283] which typically results from a FOOSH injury.[284]

Gentle AROM for forearm rotation is initiated about 6 weeks after surgery and immobilization in a Muenster cast.

Panner's Disease

Panner's disease (osteochondrosis deformans or osteochondritis) is an aseptic or osteonecrosis of the epiphysis.[285] Although related to direct trauma or to changes in the circulation, the actual etiology is unknown. Panner's disease is rarely seen before the age of 5 years and after the age of 16 years, and it almost exclusively (90%) affects boys. The main presenting symptoms are a pain at the lateral aspect of the elbow, swelling, and a limitation of elbow movement in a noncapsular pattern. If a displaced fragment is present, there is often a painless limitation of elbow extension, with a soft end-feel, but a hard end-feel when flexion is limited.[12]

Conservative intervention involves rest from throwing or impact-loading stress, with a short period of splint immobilization sometimes being necessary. The exercise progression is based on clinical findings and patient tolerance.

Olecranon Fracture

An olecranon process fracture is fairly common due to its subcutaneous location and is usually caused by either a high- or a low-energy injury, such as a fall backward onto the elbow or a FOOSH injury, which produces passive elbow flexion combined with a sudden powerful contraction of the triceps muscle, resulting in an avulsion fracture of the olecranon.[286,287]

The classic signs of an avulsion fracture involving the triceps is a loss of active elbow extension; a palpable gap, pain, and swelling at the fracture site; and a large hematoma developing into diffuse ecchymosis.[288]

The focus of the intervention for the nondisplaced or minimally displaced fractures is to allow restoration of the articular surfaces and maintaining triceps function while allowing an early ROM. The elbow is immobilized in a posterior splint or elbow immobilizer, with the elbow flexed at 90 degrees. Pronation and supination are started at 2–3 days, and pain-free flexion and extension motions begin at 2 weeks. The ROM exercises avoid full flexion for up to 2 months, and resistance exercises are avoided for up to 3 months. Protected immobilization should continue until there is evidence of union (□6 weeks).

All other fractures require an ORIF or excision of the bone fragments with repair of the extensor mechanism.[280,286,287,289] Rehabilitation following the surgical procedure is dependent on the extent of the surgery and the length of the immobilization, although the emphasis on regaining early motion remains the same.

Pathologic Bone Formation

Pathologic bone formation about the elbow occurs in several distinct forms, which include heterotopic ossification, myositis ossificans, periarticular calcification, and ectopic ossification.[290]

Heterotopic ossification is defined as the formation of mature lamellar bone in nonosseous tissues.

Myositis ossificans refers to heterotopic ossification that forms in inflammatory muscle. Although heterotopic ossification and myositis ossificans are radiographically and histologically similar, these processes are distinguished by their anatomic locations.[291]

Periarticular calcification refers to collections of calcium pyrophosphates within soft tissues such as the collateral ligaments or joint capsule.

T e term ectopic ossification includes heterotopic ossification and myositis ossificans. Since most cases of pathologic bone formation about the elbow consist of heterotopic ossification and myositis ossificans, ectopic ossification is the most appropriate descriptive term for this process.

Ectopic ossification about the elbow can result from direct injury, neural axis trauma, burns, and genetic disorders,[292] although direct elbow trauma is the most common cause.[293] Although elbow ectopic ossification may be asymptomatic, it frequently causes severe elbow stiffness or even ankylosis, and a resultant loss of function.[86,102]

Regan and Reilly[294] outlined following three factors that predispose the elbow to posttraumatic stiffness:

- T e high degree of articular congruity
- T e conformity of the elbow joint
- T e covering of the anterior joint capsule by the brachialis, predisposing it to posttraumatic ectopic ossification.

  Posttraumatic elbow ectopic ossification typically begins to form 2 weeks after trauma, surgery, burn, or neurologic insult,[294–296] resulting in localized tissue swelling and tenderness, hyperemia, and pain.

Mobilization after elbow injury often is delayed, because it is difficult to achieve rigid internal fixation of comminuted elbow fractures. Furthermore, posttraumatic elbow stiffness may occur despite early aggressive motion and prophylactic measures.

Elbow stiffness may develop 1–4 months after an initial phase of motion recovery after injury.[297] T e patient's chief complaint may be pain, stiffness, instability, sensory loss, weakness, or locking. If the pain is present, it is located anteriorly, in the middle third of the arm.

Limited active and passive elbow flexion and extension are characteristics of ectopic ossification formation about the elbow. However, in some patients, active and passive elbow motion may remain normal, especially in the early phase. However, even with aggressive intervention, including static and dynamic splinting and frequent active and passive ROM exercises, elbow motion may diminish. Strength testing reveals weak and painful elbow flexion and extension, and the end-feels of elbow ROM become rigid or abrupt. Once the ectopic ossification matures, usually at 3–9 months after the injury, elbow ROM remains stable as long as the active and passive ROM program is continued.

Ectopic ossification about the elbow may lead to delayed nerve palsy. T e ulnar nerve is most commonly affected; however, tardy median and radial palsies have also been reported.[298–300] T is complication may occur several months or many years after the formation of ectopic bone.

Plain radiographs establish the diagnosis of ectopic ossification, define its location, and show its maturity. Radiographs show ectopic ossification as early as 2 weeks after injury, and joint incongruity, osteophytes, and/or malunion will also be apparent.

Nearly all patients who present with elbow stiffness and ectopic ossification should be started on an aggressive, active motion program to combat the progressive loss of motion that occurs during ectopic ossification maturation. In some patients, elbow motion may improve; however, in others, loss of motion occurs, and ankylosis may result. Active exercises, passive exercises, continuous passive motion, dynamic splinting, and static splinting have all been advocated, although some authors suggest that passive elbow exercises enhance elbow ectopic ossification formation and exacerbate elbow stiffness,[301] even though there is little evidence to support this belief. Until there is a prospective study comparing patients with elbow injuries treated with passive stretching with patients treated without passive stretching, the relationship between passive elbow motion and ectopic ossification formation will remain unclear. However, the passive force should be applied slowly and progressively so as not to cause any further damage to the soft tissues and thereby provoke an exacerbation.

Unless there is a contraindication, all patients are started on an active and active-assisted ROM program.

Splinting is also commonly used to restore elbow ROM. Spring-loaded hinged dynamic splints may be used to counteract flexion and extension contractures. Patients are instructed to wear these splints for six 1-hour sessions daily and while they sleep. If flexion and extension are limited, the patient is issued a dynamic flexion splint and a dynamic extension splint and instructed to alternate use of them. Turnbuckle splints also are available and are typically used for rigid contractures. T is splint allows the patient to impart a static constant stretch to the soft tissues by tightening the turnbuckle.[293]

Elbow ectopic ossification can be prevented in many cases with prophylactic measures. Patients who sustain an elbow injury and have a risk factor for ectopic ossification should be treated to prevent this complication. Two forms of prophylaxis are available:

- Chemotherapeutic agents. T ese include NSAIDs.

  NSAIDs have been shown to decrease the incidence and severity of ectopic ossification about the hip. No studies exist regarding its effect on elbow ectopic ossification.

- Low-dose external beam radiation. Clinical studies showed that this modality inhibits ectopic ossification formation after total hip arthroplasty.[302,303]

PEDIATRIC PATHOLOGY

Acquired and congenital pediatric conditions of the elbow are described in Chapter 30.

Supracondylar Fracture of Humerus

This type of fracture, which occurs most commonly in children, involves the flat and flared distal metaphysis of the humerus, as a result of hyperextension or a fall on a flexed elbow. The forces are transmitted through the elbow joint to the distal humerus. The distal humeral fragment is usually posteriorly displaced (extension type). Sometimes, a "follow-through" of fragments results in a proximal fragment piercing the anterior periosteum, brachialis muscle, and possibly the brachial artery and median nerve (flexion type). If the brachial artery is pierced, the injury is potentially limb threatening.

The child typically presents with marked swelling of the elbow with an obvious deformity and ecchymosis. Because of the nature of this condition, peripheral circulation and nerve function must be assessed.

The intervention is dependent on severity. Nondisplaced fractures are immobilized in a simple sling or shoulder immobilizer, with the elbow flexed for 3 weeks, whereas displaced fractures require closed reduction and immobilization in a cast that does not constrict circulation, for 3 weeks. During the period of immobilization, the patient is closely monitored for changes in peripheral circulation. Following the period of immobilization, if the postreduction evaluation is acceptable, AROM exercises are initiated in an effort to regain full extension. Strengthening of the biceps and triceps is also addressed.

THERAPEUTIC TECHNIQUES

TECHNIQUES TO INCREASE JOINT MOBILITY

A number of techniques exist to increase joint mobility and ROM from general techniques to very specific techniques.

Passive Accessory Mobilizations

With some slight variations, the same techniques that are used to examine the passive accessory motions of the elbow complex can be used to mobilize the joints, with the clinician varying the amplitude and the velocity of the technique (i.e., grade) of the mobilizations based on the intent of the treatment, patient response, the stage of tissue healing, and the irritability of the joint.

Ulnohumeral

Distraction/Compression

These are general techniques that can be used to improve overall elbow motion into flexion and extension.

Medial Glide. This technique is commonly used as part of the intervention for medial epicondylosis.

Lateral Glide. This technique is commonly used as part of the intervention for lateral epicondylosis.

Radiohumeral

Anterior Glide. This technique can be used to improve elbow flexion (Fig. 17-36).

Posterior Glide. This technique can be used to improve elbow extension (see Fig. 17-36).

Distraction

This technique is commonly used as part of the intervention for a humeroradial joint compression positional fault (Fig. 17-37).

Compression

This technique is commonly used as part of the intervention for a humeroradial joint distraction positional fault (Fig. 17-37).

Proximal Radioulnar Joint

Anteromedial/Posterolateral Glide

The clinician glides the radial head anteromedially (to increase supination)/posterolaterally (to increase pronation) at the proximal radioulnar joint (see Fig. 17-38).

Mobilizations with Movements

To Increase Motion at the Elbow and for Tennis Elbow

The patient is positioned in supine with the involved arm on the bed, and the forearm supinated. A belt is wrapped around the posterior aspect of the clinician and around the patient's forearm so that the belt edge is level with the elbow joint (Fig. 17-80).[304,305] Using one hand, the clinician stabilizes the patient's humerus, while the other hand supports the patient's forearm and wrist (see Fig. 17-80). From this position, the ulna is glided laterally as the clinician gently moves their hips backward. Adjustments in the direction of the mobilization glide are made with respect to the carrying angle of the elbow. If there is no pain, the patient actively flexes or extends their elbow while the mobilization force is maintained. The active motion can be progressed to resisted wrist extension or resisted gripping performed during the mobilization.

Transverse Frictional Massage

TFM is used to treat a number of soft-tissue structures around the elbow.

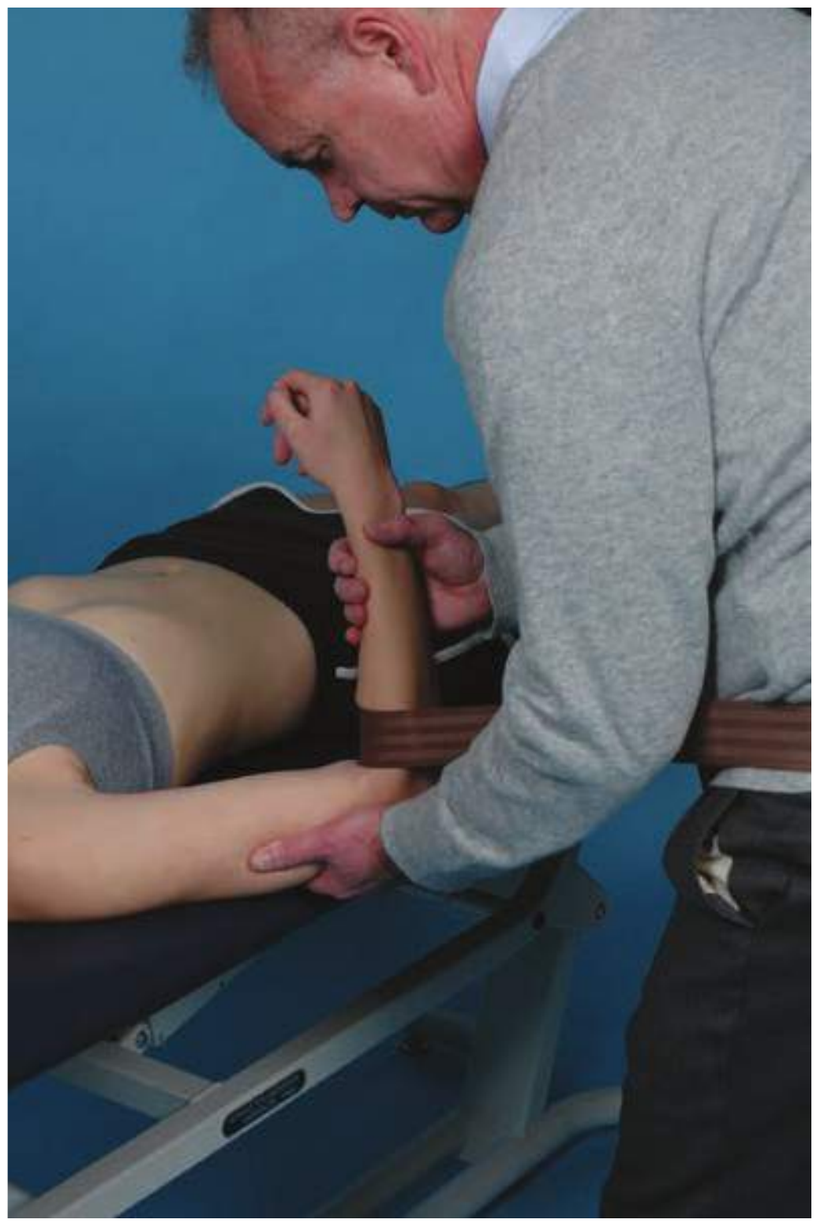

FIGURE 17-80 Mobilizations with movement to increase elbow motion.

FIGURE 17-81 TFM to brachialis muscle belly.

Strain or Overuse of the Brachialis Muscle Belly

Although uncommon, lesions of the brachialis muscle belly are most often seen in long-distance cross-country skiers with inadequate training. In the following example, the right brachialis is treated.

The patient is positioned next to the short side of the treatment table, sitting, with the elbow in 90 degrees of flexion and the forearm resting on the table in maximal supination. The clinician sits next to the long side of the treatment table diagonally facing the patient. The clinician locates the site of the lesion by palpation. In most cases, the involved site is directly in the middle (between medial and lateral) of the muscle belly, at the level of the biceps musculotendinous junction. The clinician places the middle finger just lateral to the musculotendinous junction of the brachialis (Fig. 17-81). The other hand holds the patient's forearm. The brachialis musculotendinous junction is passively moved medially, as far as possible, with the finger. After exerting pressure posteriorly, the clinician performs TFM in a lateral direction.

Strain or Overuse of the Muscle Belly—Musculotendinous Junction of the Biceps

Lesions of the biceps muscle belly or musculotendinous junction can occur as a result of carrying a heavy object or from forceful throwing activities. In the following example, the right biceps tendon is treated.

The patient is positioned next to the short side of the treatment table, sitting, with the elbow in 90 degrees of flexion and the forearm resting on the table in supination. The clinician sits next to the long side of the treatment table diagonally facing the patient. The clinician locates the site of the lesion by palpation. This is done by means of a pinch grip between the clinician's thumb and index finger of the right hand, which grasps the posterior aspect of the muscle belly, while the other hand fixes the patient's forearm. The transverse friction occurs through a "flat" pinching together of the thumb and index finger. Simultaneous extension of the wrist can be added to pull the muscle belly fibers transversely through the fingers.

The biceps musculotendinous junction is treated in much the same way.

Insertion Tendinopathy of the Triceps. Transverse friction is indicated for lesions at the musculotendinous junction (rare), the tendon, or the teno-osseous insertion of the triceps. Insertion tendinopathy of the triceps can occur as a result of chronic abuse or macrotrauma.

The patient is positioned prone on the treatment table, with the upper arm resting on the table and the forearm hanging over the edge of the table. The clinician sits next to the patient at the patient's involved side. The exact site of the lesion is confirmed by palpation. With one hand, the clinician holds the patient's elbow in slightly more than 90 degrees of flexion. The fingers of the other hand are placed at the site of the lesion (Fig. 17-82).

Static stretching of the triceps is combined with the transverse friction.

Insertion Tendinopathy at the Medial Humeral Epicondyle (Golfer's Elbow). The patient sits with the involved arm elevated sideways to just below the horizontal. The elbow is extended and the forearm, supinated. The clinician sits on a chair or stool next to the patient. If the right elbow is to be treated, the clinician stabilizes the patient's forearm and holds the elbow in slight flexion. To determine the most painful

FIGURE 17-82 TFM to triceps.

site of the lesion, the tip of the index finger carefully palpates the anterior plateau of the medial humeral epicondyle (Fig. 17-83). During the friction, the joint position of the finger does not change. The friction motion consists of minimal wrist extension and an even smaller amount of adduction of the arm.

Tendinopathy of the Extensor Carpi Radialis Brevis. The patient is positioned, sitting, next to the short end of the treatment table. The upper arm is positioned in 45 degrees of abduction, with the elbow in approximately 80 degrees of flexion and the forearm in pronation. The clinician sits diagonally facing the patient. The tendon of the ECRB brevis is located. In the pronated forearm, the ECRB tendon runs over the radial head (Fig. 17-84). In most cases, the tendon felt is, in fact, the common tendon of the ECRB and the extensor digitorum. Sometimes, two tendons are palpated; the medial one is the ECRB. TFM is performed by moving the finger in a medial-to-lateral direction over the tendon.

FIGURE 17-83 TFM of the medial epicondyle.

FIGURE 17-84 TFM at the radial head for ECRB.

Techniques to Increase Soft-Tissue Extensibility

An increase in flexibility is achieved through a routine stretching program that may be instituted early in the course of treatment, with emphasis on stretching the entire hand, forearm, and shoulder complex. Stretching should follow the application of local heat such as that afforded by a hot pack, ultrasound or transverse friction massage. Patients should be taught how to perform these techniques on themselves at the earliest opportunity.

In each of the following techniques, the stretch is maintained for approximately 30 seconds.

Biceps

The patient stands by a table and places the back of the hand on the tabletop with the forearm supinated. The elbow is gradually extended, and the forearm is moved into further supination (Fig. 17-85).

Elbow and Wrist Flexors

The patient is positioned in standing. A stretching strap is secured to the patient's foot and grasped by the hand of the involved side. Maintaining the forearm in a supinated position and the elbow extended as far as possible, the patient raises their arm out to the side (Fig. 17-51) until a stretch it felt.

Wrist and Finger Extensors

Stretching of the ECRB is always combined with stretching of the ECRL and extensor digitorum and is indicated in all types of tennis and golfer's elbow.

The patient is positioned in sitting. The upper arm is held horizontally, with the elbow flexed 90 degrees, the forearm pronated, and the wrist flexed. The patient uses the left hand to grasp their right hand and positions the wrist in maximal flexion and ulnar deviation, with the forearm in maximal pronation (Fig. 17-86). The elbow is brought very slowly into extension.

Stretch for Golfer's Elbow

The function of the long wrist flexors is flexion of the elbow, pronation of the forearm, and flexion of the wrist. The patient

FIGURE 17-85 Biceps stretch.

sits on a chair, with the involved arm elevated approximately 60 degrees. The elbow is slightly flexed, the forearm supinated, and the wrist extended (Fig. 17-52). The patient brings the wrist and fingers into as much extension as possible using the uninvolved hand (see Fig. 17-52). While holding the wrist

FIGURE 17-86 Wrist and finger extensor stretch.

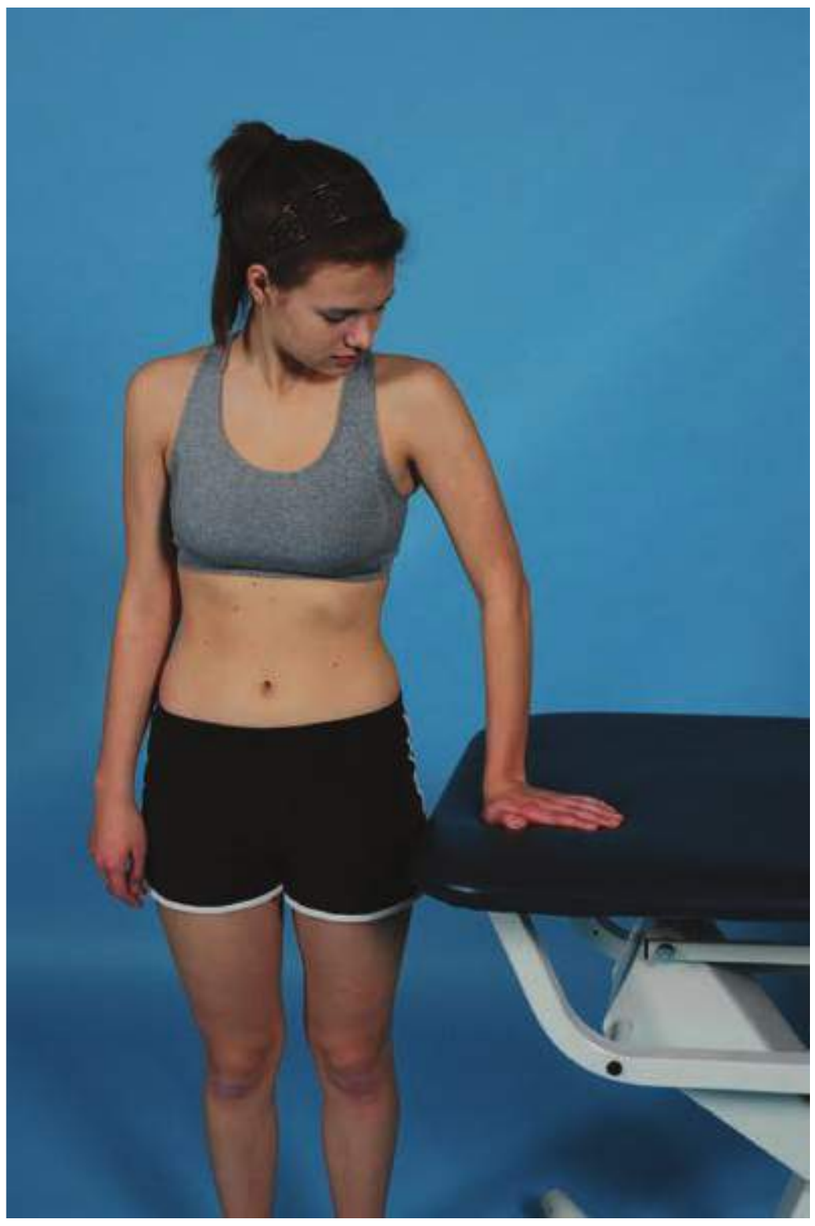

FIGURE 17-87 Weight-bearing wrist flexor stretch.

in maximal extension, the clinician very slowly extends the patient's elbow. As soon as pain or muscle guarding occurs, the motion is stopped, and the elbow is brought slightly back into more flexion. If the pain disappears after a few seconds, the elbow can be brought further into extension.

Weight-Bearing Wrist Flexor Stretch

This stretch is performed by asking the patient to position the hand palm side down on a table and to position the elbow in slight flexion, the wrist into maximal ulnar deviation and extension, and the forearm in maximal pronation (Fig. 17-87). Being careful to avoid pain and muscle splinting, the patient slowly straightens the elbow. The stretch should be held for approximately 40 seconds. At this point, the patient can gently pull the fingers up from the table to stretch the flexor muscles of the palm. Against very slight resistance (performed by the other hand), the arm is then brought back to the original position. This stretching procedure is repeated six times before repeating the entire procedure.

High-Velocity, Low-Amplitude Thrusting

Mills' Manipulation

This technique is designed to break adhesions of the common extensor tendon and let the orbicular ligament slip back to its normal position.[12] The Mills, manipulation is used instead of slowly stretching the tissues during the last few degrees of maximal elbow extension.

This manipulation is indicated only for certain patients, namely, those

- who demonstrate full active and passive elbow extension with a normal end-feel; and
- whose elbow demonstrates only a slight limitation of motion with a myofascial end-feel.

Prior to the manipulation, transverse frictions should be applied to the site in order to soften the scar.

The patient is positioned in sitting, with the clinician standing behind the patient's shoulder (see Fig. 17-42). The patient's wrist is flexed. Maintaining the position of the patient's wrist, the clinician extends the elbow. The Mills, maneuver involves a forcible extension of the elbow while simultaneous digital pressure is exerted over the point of maximum tenderness. If the wrist flexion is not maintained, the force will be through the elbow joint. Mills stressed the need to elicit an audible click during the procedure, although in practice many normal elbows can be made to click by the same maneuver,[306] indicating that the click is probably coincidental.

A modification to the patient position can be used for this manipulation. The patient is positioned in supine, with their arm off the edge of the table. The clinician adjusts the table height so that the patient's elbow joint can be rested on their thigh, while the clinician's foot is in contact with the floor. The patient's arm is then placed in slight shoulder extension and full internal rotation (palm down). In this position, the various tendons can be tested as to their level of involvement by having each one contract. The involved tendon is then softened up using transverse friction before the manipulation is applied using the aforementioned positions. The patient's elbow is then slightly raised off the clinician's thigh and then dropped quickly back onto the thigh.

Following the manipulation, exercises to stretch the scar should be carried out.

CASE STUDY

LATERAL ELBOW PAIN

HISTORY

History of Current Condition

A 43-year-old female patient presents with complaints of left lateral elbow pain, which she reports having for about a year. The patient describes the onset of elbow pain as gradual and attributes it to her work as an electronics assembler, where she spends the day pulling out plugs. Over time, the pain has worsened to the point where it hurts all of the time. Although the patient has tried a course of anti-inflammatories, they were discontinued due to an adverse reaction. The patient has been placed on light duty at work, with a lifting restriction of 10 lb.

Past History of Current Condition

No past history of left elbow pain.

Past Medical and Surgical History

Unremarkable.

Medications

None.

Living Environment

Lives in a two-story house.

Occupational, Employment, and School

Assembly line worker. High school education.

Functional Status and Activity Level

The patient's goals were to decrease pain with activities of daily living and to be able to return to work without pain.

Health Status (Self-Report)

In general good health, but pain interferes with tasks at home and at work.

Questions

1. What is the most common diagnosis characterized by lateral elbow pain?
2. What can a history of gradual onset tell the clinician?
3. What can a history of repetitive activity tell the clinician?
4. What findings do you expect to note in the physical examination in terms of palpation, resistive tests, and special tests?
5. What additional questions would you ask to help rule out referral of pain from the cervical spine or shoulder?
6. List the various diagnoses that could present with these signs and symptoms, and the tests you would use to rule out each one.
7. Does this presentation and history warrant an upper quarter scanning examination? Why or why not?

MEDIAl El bo w PAIN

HISTORY

History of Current Condition

A 23-year-old apprentice carpenter was seen in the clinic with complaints of right elbow pain, which he reported having for the last few months. The patient described the onset of medial elbow pain as gradual and attributed it to his work, where he spends most of the day using carpentry tools. Over time, the pain had worsened to the point where it hurt all of the time. The patient went to see his physician who prescribed a course of anti-inflammatory medications and physical therapy and placed the patient on light duty at work.

Past History of Current Condition

No past history of elbow pain.

Past Medical and Surgical History

Unremarkable.

Medications

Ibuprofen, 800 mg a day.

Functional Status and Activity Level

The patient's goals were to decrease pain with activities of daily living and recreational sports and to be able to return to work without pain.

Health Status (Self-Report)

In general good health, but pain interferes with tasks at home and at work.

Questions

1. What structure(s) do you suspect to be at fault with complaints of medial elbow pain?
2. What is the probable mechanism of injury for this patient?
3. What type of activities would you expect to exacerbate this condition?
4. What additional questions would you ask?
5. List the various diagnoses that could present with these signs and symptoms and the tests you would use to rule out each one.

CHAPTER 18

The Forearm, Wrist, and Hand

CHAPTER OBJECTIVES

At the completion of this chapter, the reader will be able to:

1. Describe the anatomy of the joints, ligaments, muscles, blood, and nerve supply that comprise the forearm, wrist, and hand.
2. Describe the biomechanics of the forearm, wrist, and hand, including open- and close-packed positions, normal and abnormal joint barriers, and stabilizers.
3. Describe the purpose and components of the tests and measures for the forearm, wrist, and hand.
4. Describe the relationship between muscle imbalance and functional performance of the forearm, wrist, and hand.
5. Perform a comprehensive examination of the forearm, wrist, and hand, including palpation of the articular and soft-tissue structures, specific passive mobility, and passive articular mobility tests, and stability tests.
6. Outline the significance of the key findings from the tests and measures and establish a diagnosis.
7. Summarize the various causes of the forearm, wrist, and hand dysfunction.
8. Develop self-reliant intervention strategies based on clinical findings and established goals.
9. Evaluate the intervention effectiveness in order to progress or modify an intervention.
10. Plan an effective home program and instruct the patient in same.

OVERVIEW

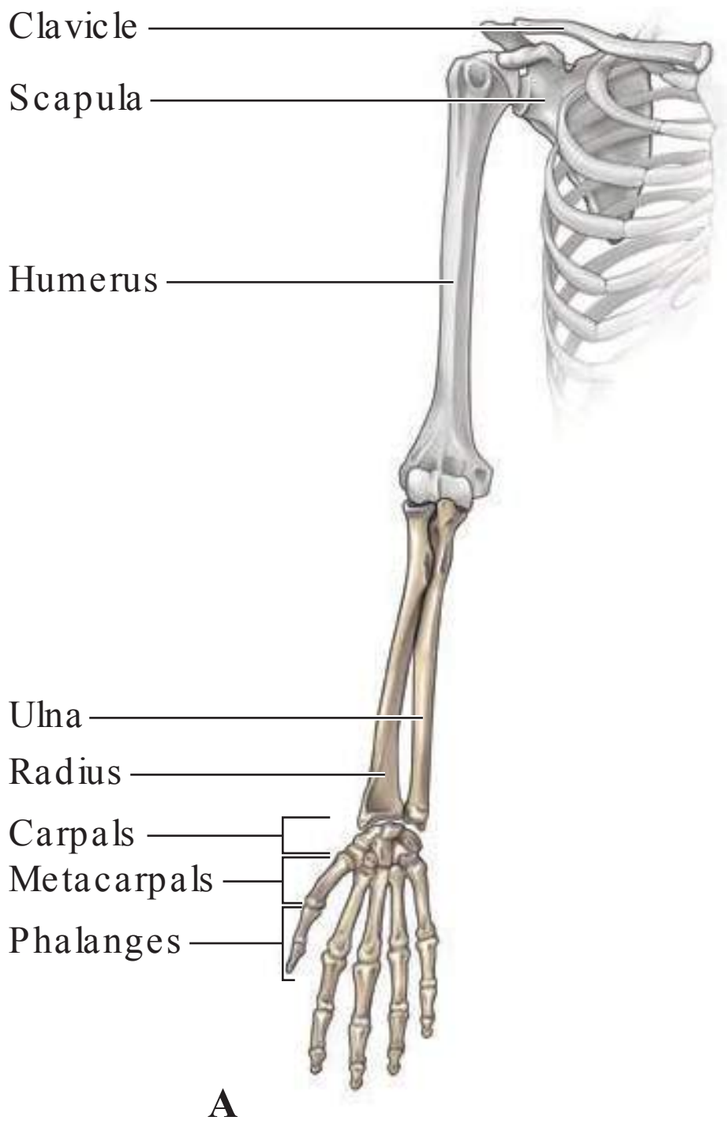
A hand is a very personal thing. It is the interface between the patient and his or her world. It is an emblem of strength, beauty, skill, sexuality, and sensibility. When it is damaged, it becomes a symbol of vulnerability of the whole patient.

—Paul W. Brand (1914–2003)

In a sense, the shoulder, elbow, and wrist joints (Fig. 18-1) are merely mechanical devices that contribute to the usefulness of the hand.[1] The correct synchronization of these biological devices, coupled with patient motivation, produces a remarkable level of dexterity and precision.

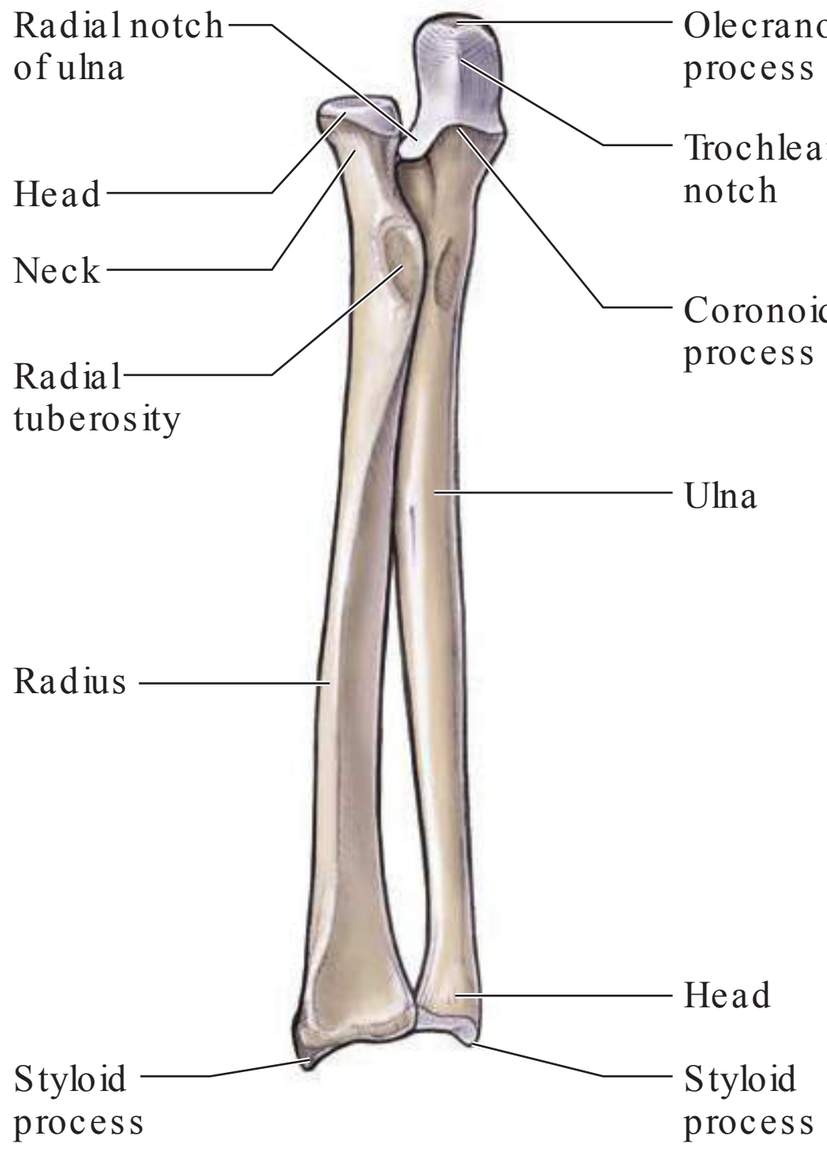
The carpus, or wrist, represents a highly complex anatomic structure, comprising a core structure of 8 bones; more than 20 radiocarpal, intercarpal, and carpometacarpal (CMC) joints; 26 named intercarpal ligaments; and 6 or more parts of the triangular fibrocartilage complex (TFCC).[2] While these structures can be differentiated anatomically, they are functionally interrelated with movement in one joint having an effect on the motion of neighboring joints. This relationship extends as far as the elbow.

The hand accounts for about 90% of upper limb function.[3] The thumb, which is involved in 40–50% of hand function, is the more functionally important of the digits.[3] The index and middle fingers are each involved in about 20% of hand function, and are the second most important, with the ring finger being the least important. The middle finger is the strongest finger and is important for both precision and power functions.[3]



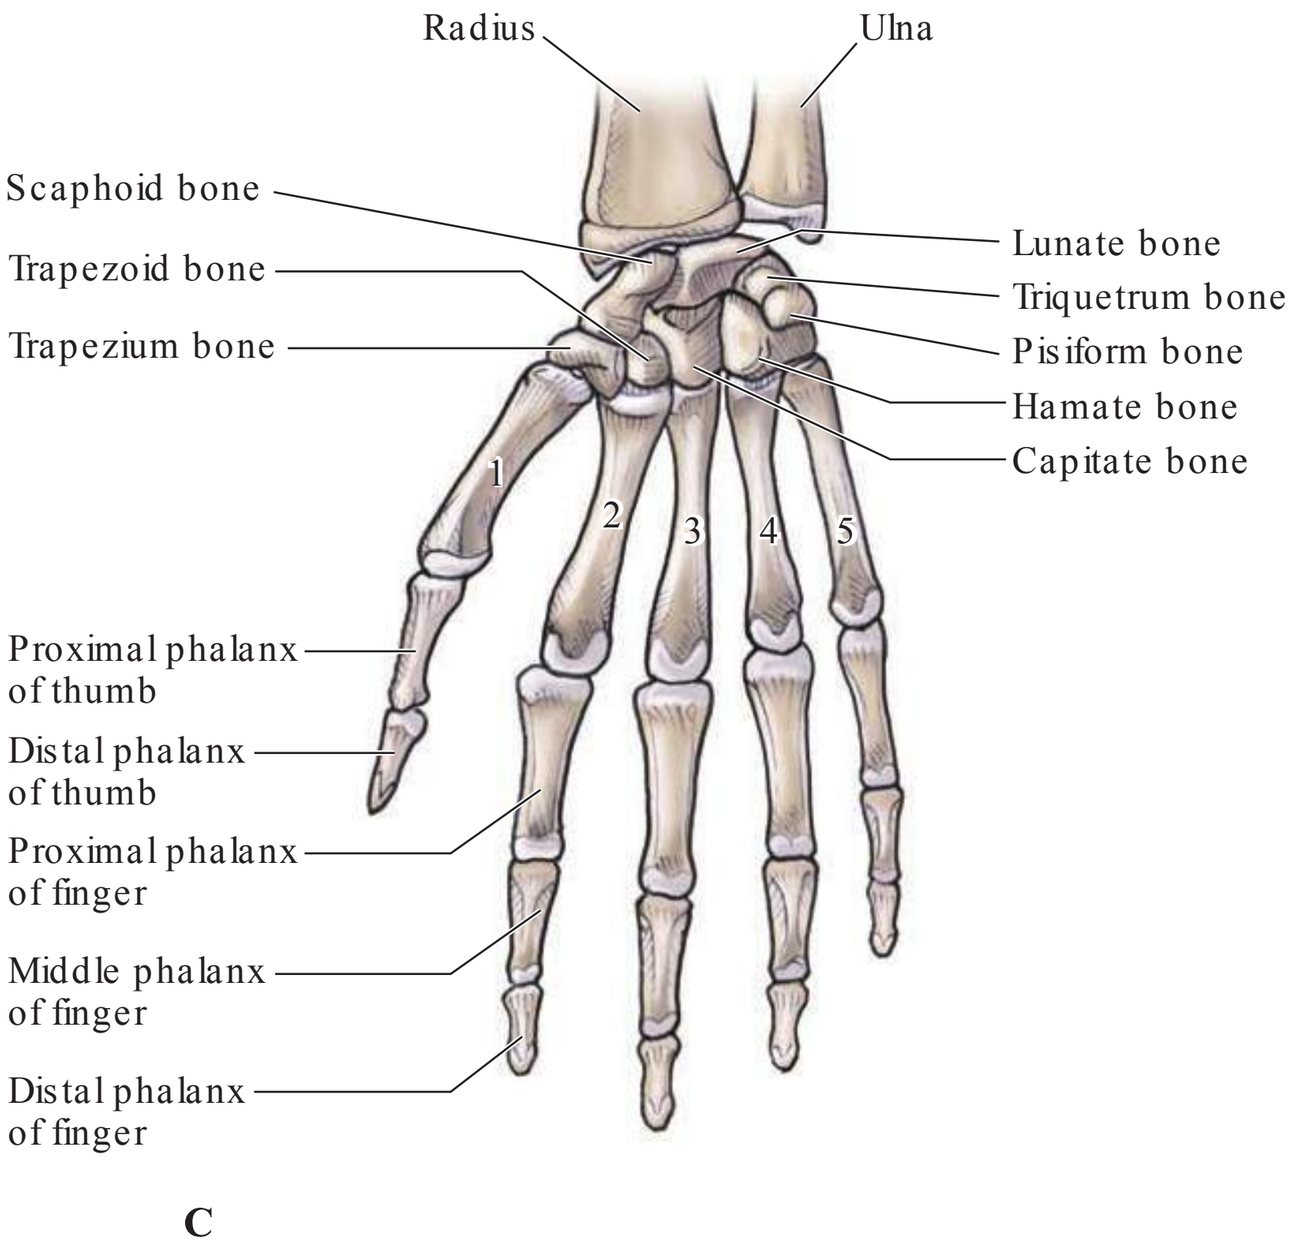
The following sections describe the respective bones, joints, soft tissues, and nerves, detailing both their individual and collective functions. For simplicity's sake, the forearm, wrist, and hand are separated into their various compartments.

ANATOMY



Distal Radioulnar Joint

The distal radioulnar joint (DRUJ) plays a significant role in wrist and forearm function. The DRUJ is a uniaxial pivot joint that joins the distal radius and ulna and an articular disk (Fig. 18-1). The articular disk, known as the TFCC, assists in binding the distal radius and is the main stabilizer of the DRUJ (see the next section).[4]



At its distal end, the radius widens to form a broad, concave articular surface. The articular surface has an ulnar inclination in the frontal plane, which averages 23 degrees, and an anterior (palmar) inclination in the sagittal plane, which averages 11 degrees.[5] The distal end of the ulna expands slightly laterally into a rounded head and medially into an

FIGURE 18-1 Arm, wrist, and hand joint structures. (Reproduced, with permission, from Chapter 29. Overview of the Upper Limb. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

ulnar styloid process (Fig. 18-1). The rounded head of the ulnar head contacts both the ulnar notch of the radius laterally and the TFCC distally.[6] The ulnar styloid process is approximately one-half inch shorter than the radial styloid process, resulting in more ulnar deviation than radial deviation being available.[6] The articular capsule, which attaches to the articular margins of the radius and ulna and to the disk enclosing the inferior radioulnar joint, is lax. Anterior (palmar) and posterior (dorsal) radioulnar ligaments strengthen the capsule anteriorly and posteriorly. Forearm supination tightens the anterior capsule and pronation tightens the posterior part, adding to the overall stability of the wrist.[7]

T e DRUJ functions to transmit the loads from the hand to the forearm.

CLINICAL PEARL

The resting or open-packed position for the DRUJ is 10 degrees of supination.

The close-packed position for the DRUJ is 5 degrees of supination.

The capsular pattern for the DRUJ is pain at extremes of pronation/supination.

Triangular Fibrocartilage Complex

T e TFCC essentially comprises a fibrocartilage disk interposed between the medial proximal row and the distal ulna within the medial aspect of the wrist.[8] T e primary function of the TFCC is to enhance joint congruity and to cushion against compressive forces. Indeed, the TFCC transmits about 20% of the axial load from the hand to the forearm.[7] T e broad base of the disk is attached to the medial edge of the ulnar notch of the radius, and its apex is attached to the lateral aspect of the base of the ulnar styloid process. T e disk's anterior and posterior borders are thickened.

A number of ligaments originate from the TFCC and provide support to it. T ese include the ulnolunate and ulnotriquetral ligaments, the ulnar collateral, and the radioulnar ligaments. Other structures that lend support to the TFCC include the following:

- T e ulnocarpal ligaments.
- T e sheath of the extensor carpi ulnaris (ECU) tendon, which is the only wrist tendon that broadly connects to the TFCC.

Both the superior and the inferior articular surfaces of the TFCC are smooth and concave.[8] T e disk separates the distal ulna from direct contact with the carpals but allows gliding between the carpals, disk, and ulna during forearm pronation and supination.[8,9]

T e TFCC is innervated by branches of the posterior interosseous, ulnar, and posterior (dorsal) sensory ulnar nerves.[9]

The Wrist

T e wrist comprises the distal radius and ulna, eight carpal bones, and the bases of five metacarpals (Fig. 18-1). T e carpal bones lie in two transverse rows. T e proximal row contains (lateral to medial) the scaphoid (navicular), lunate, triquetrum, and pisiform. T e distal row holds the trapezium, trapezoid, capitate, and hamate.

Radiocarpal Joint

T e radiocarpal joint, a biaxial ellipsoid joint, is formed, by the large, articular concave surface of the distal end of the radius, the proximal carpal row, and the TFCC. T e lunate and triquetrum articulate with the TFCC. A radial styloid process projects distally from the lateral side of the radius. A cartilage-covered ulnar notch occupies the distal medial side of the radius.[10] Posteriorly, a posterior (dorsal) (Lister) tubercle arises near the center of the radius, forming a pulley around which the extensor pollicis longus (EPL) tendon passes.[9] Lister tubercle is a common site of attritional changes and potential tendon rupture.[11]

CLINICAL PEARL

The resting or open-packed position for the radiocarpal joint is neutral with slight ulnar deviation.

The close-packed position for the radiocarpal joint is full extension with radial deviation.

The capsular pattern for the radiocarpal joint is flexion and extension equally limited.

The Carpals

Scaphoid

T e scaphoid (Fig. 18-1) is the largest of the proximal carpal row bones, and its shape resembles that of a boat or canoe (thus the old term navicular).[9] T e scaphoid bone links the proximal and distal carpal rows and helps provide stability to the wrist joint.

T e scaphoid is tethered to the proximal carpal row by a number of strong ligamentous attachments, and two-thirds of its surface area is articular. T e proximal surface of the scaphoid is convex and articulates with the radius. T e medial surface is concave and articulates with the capitate.[10] T e articulating surface for the lunate is flat. T e distal surface consists of two convex facets for articulation with the trapezium and trapezoid (the scaphotrapeziotrapezoid joint).[9] T e round tubercle on the inferolateral part of its anterior (palmar) surface serves as the attachment of the flexor retinaculum and the abductor pollicis brevis (APB).[10] T e blood vessels to this bone enter the scaphoid at or distal to the wrist. T is configuration predisposes a fracture on the proximal aspect to aseptic necrosis.[12] In addition, as the scaphoid plays a critical role in coordinating and stabilizing movements between the proximal and the distal rows of the carpals, damage to the intrinsic and extrinsic ligaments that support the scaphoid can result in persistent pain and dysfunction with loading activities.[13–15]

Lunate

T e lunate (Fig. 18-1) articulates between the scaphoid and the triquetrum in the proximal carpal row. Its smooth convex proximal surface articulates with the radius and the TFCC at the lunate fossa.[10] Its lateral surface contains a flat semilunar facet for the scaphoid. T e medial surface articulates with the triquetrum. T e distal surface is deeply concave and articulates with the edge of the hamate in adduction and the medial aspect of the capitate.[10]

Triquetrum

T e triquetrum (Fig. 18-1) is a pyramid-shaped bone. It articulates with the pisiform on its distal anterior (palmar) surface at the pisiform–triquetral joint.[10] T e almost square distal–medial surface of the triquetrum articulates with the concavo–convex surface of the hamate. T e ulnar collateral

ligament (UCL) attaches to the medial and posterior (dorsal) surfaces of the triquetrum.[10] The proximal surface of the triquetrum articulates with the TFCC in full adduction.[9] The lateral surface of the triquetrum articulates with the lunate.

Pisiform

The pisiform (Fig. 18-1), as its name implies, is shaped like a "P" with a posterior (dorsal) flat articular facet for the triquetrum.[10] The pisiform, formed within the tendon of the flexor carpi ulnaris (FCU), is a sesamoid bone and serves as an attachment for the flexor retinaculum, abductor digiti minimi (ADM), UCL, pisohamate ligament, and pisometacarpal ligament. The pisiform also functions to increase the flexion moment of the FCU.[9]

As mentioned, the pisiform articulates with the anterior (palmar) surface of the triquetral and is thus separated from the other carpal bones, all of which articulate with their neighbors. The pisiform is closely related to the ulnar artery and nerve on its radial border, the nerve being the closer.[16]

Trapezium

The trapezium (Fig. 18-1) has a groove on its medial anterior (palmar) surface which contains the tendon of the FCR.[10] To its margins are attached two layers of the flexor retinaculum. The opponens pollicis (OP) is between the flexor pollicis brevis (FPB) distally and the APB proximally.[10] The lateral surface serves as an attachment site for the radial collateral ligament and capsular ligament of the first CMC joint. The distal articulating surface of the trapezium is saddle shaped. Medially, its concave surface articulates with the trapezoid, whereas more distally its convex surface articulates with the second metacarpal base.[10] Proximally, its concave surface articulates with the scaphoid.

Trapezoid

The trapezoid (Fig. 18-1) is small and irregular. The distal surface articulates with the grooved second metacarpal base. The medial surface articulates via a concave facet with the distal part of the capitate. The lateral surface of the trapezoid articulates with the trapezium, and its proximal surface articulates with the scaphoid bone.[10]

Capitate

The capitate (Fig. 18-1) is the most central and the largest of the carpal bones. Its distal aspect articulates with the third metacarpal base. Its lateral border articulates with the medial side of the second metacarpal base.[10] The convex proximal head of the capitate articulates with the lunate and scaphoid. The medial surface of the head articulates with the lunate, and the lateral aspect of the head articulates with the scaphoid.[10] Medially, the capitate articulates with the hamate.

With its central location, the capitate serves as the keystone of the proximal transverse arch. This arch is important to the prehensile activity of the hand.[9,17,18]

Hamate

The hamate (Fig. 18-1) is a cuneiform bone and contributes to the medial wall of the carpal tunnel. To the hook (hamulus) of the hamate is attached the flexor retinaculum. The hamate articulates with three carpal bones and two metacarpals.[9] The medial surface articulates with the triquetrum and by association with the pisohamate ligament, the pisiform. The lateral surface articulates with the capitate.[10] On its distal aspect, the hamate articulates with the fourth and fifth metacarpal heads.

CLINICAL PEARL

The resting or open-packed position for the intercarpal joint is neutral or slight flexion.

The close-packed position for the intercarpal joint is full extension.

There is no recognized capsular pattern of the intercarpal joints.

Midcarpal Joints

The midcarpal joint lies between the two rows of carpals. It is referred to as a "compound" articulation because each row has both a concave and a convex segment. Wrist flexion, extension, and radial deviation are mainly midcarpal joint motions. Approximately 50% of the total arc of wrist flexion and extension occur at the midcarpal level with more flexion (66%) occurring than extension (34%).[19]

The proximal row of the carpals is convex laterally and concave medially. The scaphoid, lunate, trapezium trapezoid, and triquetrum present with a concave surface to the distal row of carpals. The scaphoid, capitate, and hamate present a convex surface to a reciprocally arranged distal row.

CLINICAL PEARL

The resting or open-packed position for the midcarpal joint is neutral or slight flexion with ulnar deviation.

The close-packed position for the midcarpal joint is full extension with ulnar deviation.

The capsular pattern for the midcarpal joint is an equal limitation of flexion and extension.

First CMC Joint

The thumb is the most important digit of the hand and greatly magnifies the complexity of human prehension.[20,21] Functionally, the sellar (saddle-shaped) CMC joint is the most important joint of the thumb and consists of the articulation between the base of the first metacarpal and the distal aspect of the trapezium.

The articular surfaces of the trapezium and the proximal end of the first metacarpal are reciprocally shaped. Three other adjacent articulations are functionally related to this joint, which include the joints between the trapezium and the scaphoid, the trapezium and the trapezoid, and the base of the first metacarpal and the radial side of the base of the second metacarpal.[20,21]

Motions that can occur at this joint include flexion/extension, adduction/abduction, and opposition, the latter of which includes varying amounts of flexion, internal rotation, and anterior (palmar) adduction (see "Biomechanics"). Although the joint capsule of the first CMC joint is large

and relatively loose, motions at the joint are controlled and supported by muscle actions and by at least five ligaments: anterior oblique, ulnar collateral, intermetacarpal, posterior oblique, and radial collateral. In general, most of the thumb ligaments are placed on tension with abduction, extension, and opposition.[20,21]

CLINICAL PEARL

The resting or open-packed position of the first CMC joint is midway between abduction and adduction, and midway between flexion and extension.

The close-packed position of the first CMC joint is full opposition.

The capsular pattern of the first metacarpal joint is thumb abduction, then extension.

Other CMC Joints

The distal borders of the distal carpal row bones articulate with the bases of the metacarpals, thereby forming the CMC joints. The CMC articulations of the fingers permit only gliding movements. The CMC joints progress in mobility from the second to the fifth, with the second and third metacarpal joints being relatively immobile, and thus the primary stabilizing joints of the hand. The fourth and fifth CMC joints are more mobile to permit the hand to adapt to objects of different shapes during grasping.

Stability for the CMC joints is provided by the anterior (palmar) and posterior (dorsal) CMC and intermetacarpal ligaments. While the trapezoid articulates with only one metacarpal, all of the other members of the distal carpal row combine one carpal bone with two or more metacarpals.

CLINICAL PEARL

The resting or open-packed position of the CMC joints of the fingers is midway between flexion and extension.

The close-packed position of the CMC joints of the fingers is full flexion.

The capsular pattern of the CMC joints of the fingers is equal limitation in all directions

Metacarpophalangeal Joints

The five metacarpals resemble miniature versions of the long bones of the body, with elongated shafts and expanded ends. The metacarpophalangeal (MCP) joint of the thumb is a hinge joint. Its bony configuration, which resembles the interphalangeal (IP) joints, provides it with some inherent stability. In addition, support for the joint is provided by anterior (palmar) and collateral ligaments. The MCP joint of the thumb consists of a convex surface on the head of the metacarpal and a concave surface on the base of the phalanx. The area of the articulating surface is increased by the presence of a volar plate, which allows a greater range of motion than would be available otherwise. Approximately 75–80 degrees of flexion is available at this joint. The extension movements, as well as the abduction and adduction motions, are negligible. Traction, gliding, and rotatory accessory movements are also present.

The second through fifth metacarpals articulate with the respective proximal phalanges within biaxial joints. Their widened, proximal bases articulate with the carpals and with one another in plane joints.[10] Their biconvex distal heads are broader anteriorly than posteriorly, the significance of which is discussed later.

The MCP joints allow flexion–extension and medial–lateral deviation associated with a slight degree of axial rotation. The design of the MCP joint allows for great amplitude of movement, at the expense of stability.

Approximately 90 degrees of flexion is available at the second MCP, with the amount of available flexion progressively increasing toward the fifth MCP. Active extension at these joints is 25–30 degrees while 90 degrees can be obtained passively. A loss of flexion and extension at the CMC joint of the little finger reduces the amount of opposition available, resulting in dysfunction of the prehensile pattern and difficulty in making a fist.[6] Approximately 20 degrees of abduction/adduction can occur in either direction at the MCP, with more being available in extension than in flexion. Abduction–adduction movements of the MCP joints are restricted in flexion and free in extension.

CLINICAL PEARL

The resting or open-packed position of the MCP joints is slight flexion.

The close-packed position of the MCP joints is full opposition (thumb)/full flexion (fingers).

The capsular pattern of the MCP joints is flexion, then extension

The joint capsules are attached to the articular margins of the metacarpals and phalanges and surround the MCP joints. The joint capsule of these joints is relatively lax and redundant but is endowed with collateral ligaments that pass posterior to the joint axis for flexion/extension of the MCP joints (Fig. 18-11). Although, these collateral ligaments are lax in extension, they become taut in approximately 70–90 degrees of flexion of the MCP joint.[22]

CLINICAL PEARL

Contracture of the collateral ligaments is a major cause of loss of MCP flexion. The MCP joints should never, under any circumstances, be immobilized in extension or hyperextension by a retraction of the collateral ligaments, which would result in their locking.[23] Instead, the fingers should be splinted with the MCP joints flexed to 70–90 degrees.

The posterior (dorsal) hood apparatus reinforces (or replaces) the posterior (dorsal) joint capsules. The fibrocartilaginous volar plates reinforce the anterior (palmar) aspects of the joints (Fig. 18-12). The volar plates attach firmly to the phalangeal bases but connect only loosely to the metacarpal heads by membranous fibers. Their posterior (dorsal) surface

contributes to the joint area, whereas their anterior (palmar) surface channels the finger flexor tendons.[23]

The asymmetry of the metacarpal heads as well as the difference in length and direction of the collateral ligaments also explains the rotational movement of the proximal phalanx during flexion–extension and why the ulnar deviation of the digits normally is greater than the radial deviation.[23] The rotary movements that occur are called conjunct rotations. The index finger has a conjunct rotation of internal rotation with abduction and flexion, whereas the ring and little finger each have a conjunct rotation of external rotation with abduction and flexion. The middle finger is not thought to have a conjunct rotation.

CLINICAL PEARL

In contrast to the IP articulations, which are stable throughout most of their range of movements, the MCP joints are stable only in flexion.[23]

IP Joints

Adjacent phalanges articulate in hinge joints that allow motion in only one plane: sagittal. The congruency of the IP joint surfaces contributes greatly to IP joint stability. In addition, the IP joints are surrounded by joint capsules that are attached to the articular margins of the phalanges.

Proximal Interphalangeal Joint

The proximal interphalangeal (PIP) joint is a hinged joint capable of flexion and extension. The supporting ligaments and tendons provide the bulk of the static and dynamic stability of this joint as it travels through a normal range of 110 degrees.[22,24–27] The capsule surrounding the articular surface of the joint is composed of the volar plate, lateral and accessory collateral ligaments, and extensor expansion.

The proximal IP joint is stable in all positions. The configuration of the volar plate allows it to function as a static restraint to hyperextension and to influence the mechanical advantage of the flexor tendons at the initiation of PIP joint flexion.[22] The volar plate also increases the surface area. This allows for a greater range of motion than would be available otherwise.

The thick collateral ligaments (true and accessory) of the PIP joint combine with the volar plate to provide lateral stability: the collateral ligaments of the PIP joints are maximally taut at 25 degrees of finger flexion.[22] For this reason, the IP joints are usually splinted in 25 degrees of flexion following surgery to prevent joint contractures. The splinting position is changed as the patient resumes function.

The flexor tendon system at the level of the PIP joint is less complex than the extensor mechanism and contributes very little to injuries about the PIP joint.[22]

The phalangeal bases effectively form a sellar surface, with bone projections allowing for a wide range of accessory movements to accommodate the gripping of a large array of irregular surfaces.

The motions available at these joints consist of approximately 110 degrees of flexion at the PIP joints and 90 degrees at the thumb IP joint. Extension reaches 0 degrees at the PIP joints and 25 degrees at the thumb IP joint. Traction, gliding, and accessory movements also occur at the IP joints.

Distal Interphalangeal Joints

The distal interphalangeal (DIP) joint has similar structures as the PIP joint but less stability and allows some hyperextension. The motions available at these joints consist of approximately 90 degrees of flexion and 25 degrees of extension. Traction, gliding, and accessory movements also occur at the DIP joints.

CLINICAL PEARL

The resting or open-packed position for the IP joints is slight flexion.

The close-packed position for the IP joints is full extension.

The capsular pattern of the IP joints is flexion, extension.

Carpal Ligaments

Excessive migration of the carpal bones is prevented by strong ligaments (Table 18-1) and by the ulnar support provided by the TFCC. The major ligaments of the wrist are depicted in Figure 18-2.

The ligaments of the wrist provide support for the region. These ligaments can be divided into two types: extrinsic and intrinsic (Table 18-1). The extrinsic anterior (palmar) ligaments provide the majority of wrist stability. The intrinsic ligaments serve as rotational restraints, binding the proximal row into a unit of rotational stability.[28] The proximal row of carpals has no muscle insertions. Its stability depends entirely on the capsular and interosseous ligaments between the scaphoid,

TABLE 18-1 Ligaments of the Wrist

Interosseous	Intrinsic Midcarpal	Extrinsic Radiocarpal/ Ulnocarpal
Distal row	Posterior (dorsal)	Posterior (dorsal)
Trapezium trapezoid	Scaphotriquetral	Posterior (dorsal) radiocarpal
Trapezoid capitate	Posterior (dorsal) intercarpal	
Capitohamate		
Proximal row	Anterior (palmar)	Anterior (palmar)
Scapholunate	Scaphotrapeziotrapezoid	Radioscaphocapitate
Lunotriquetral	Scaphocapitate	Long radiolunate
Triquetrocapitate	Short radiolunate	
Triquetrohamate	Radioscapholunate	
		Ulnolunate Ulnotriquetral Ulnocapitate

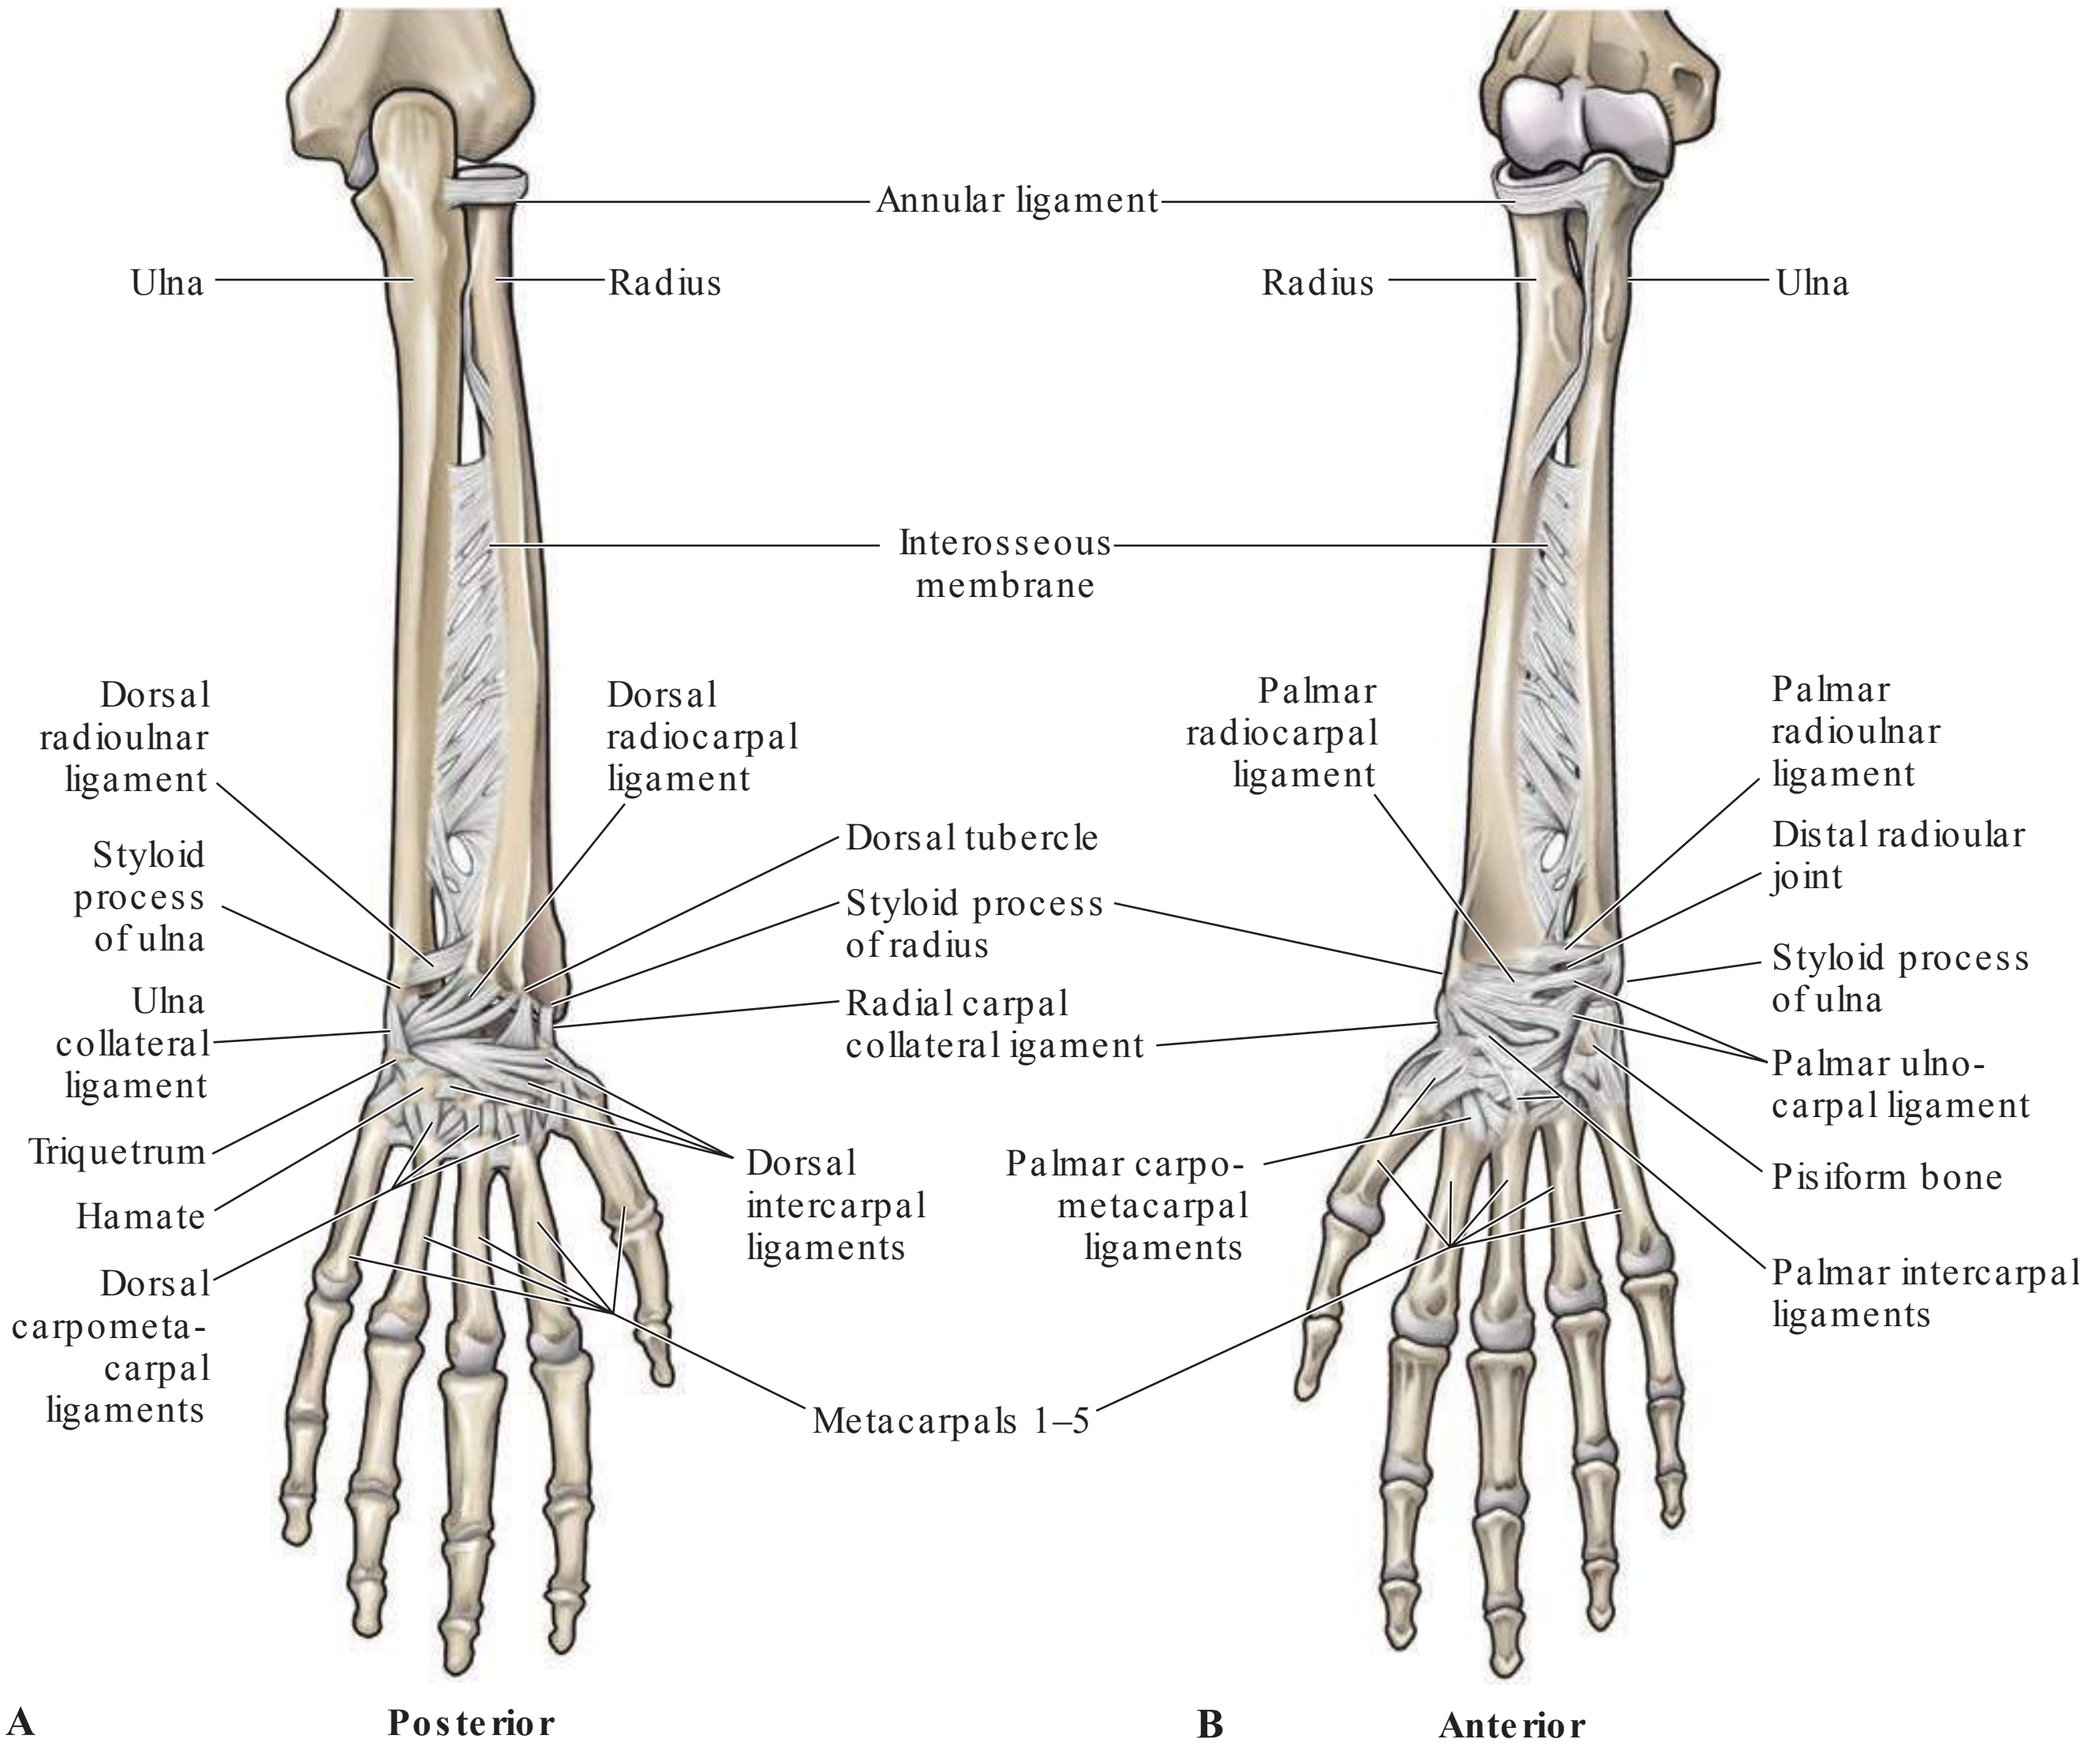

FIGURE 18-2 The major ligaments of the wrist. (Reproduced, with permission, from Chapter 32. Forearm. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

lunate, and triquetrum.[29] The ligaments between the proximal and the distal carpal rows provide support, centering especially on the capitate.[10] The midcarpal ligaments, which are longer than the interosseous ligaments, cross the midcarpal joint and connect bones of the distal and proximal rows on both the posterior (dorsal) and the anterior (palmar) surfaces.[9] No midcarpal ligaments directly attach to the lunate.

Antebrachial Fascia

The antebrachial fascia is a dense connective tissue that encases the forearm and maintains the relationships of the tendons that cross the wrist. The fascia is firmly attached to the subcutaneous border of the ulna, from which it sends a septum to the radius. This septum divides the forearm into an anterior compartment and a posterior compartment (see "Muscles of the Wrist and Forearm").

The Extensor Retinaculum

At the point where the tendons cross the wrist, there is a ligamentous structure called a retinaculum that appears to lay over the tendons and their sheaths (Fig. 18-3). This retinaculum serves to prevent the tendons from "bowstringing" when the tendons turn a corner at the wrist.[30] The extensor retinaculum extends from the lateral border of the distal radius across the posterior (dorsal) surface of the distal forearm onto the posterior surface of the distal ulna and ulnar styloid process. It then wraps part way around the ulna to attach to the triquetrum and pisiform bones. The retinaculum and the underlying bones form six tunnel-like structures called fibro-osseous compartments on the dorsum of the wrist (Fig. 18-3). The compartments, from lateral to medial, contain the tendons of

- abductor pollicis longus (APL) and extensor pollicis brevis (EPB)
- extensor carpi radialis longus (ECRL) and brevis (ECRB)
- EPL
- extensor digitorum (ED) (four tendons) and extensor indicis (EI) (not shown in Fig. 18-3)
- extensor digiti minimi (EDM)
- ECU

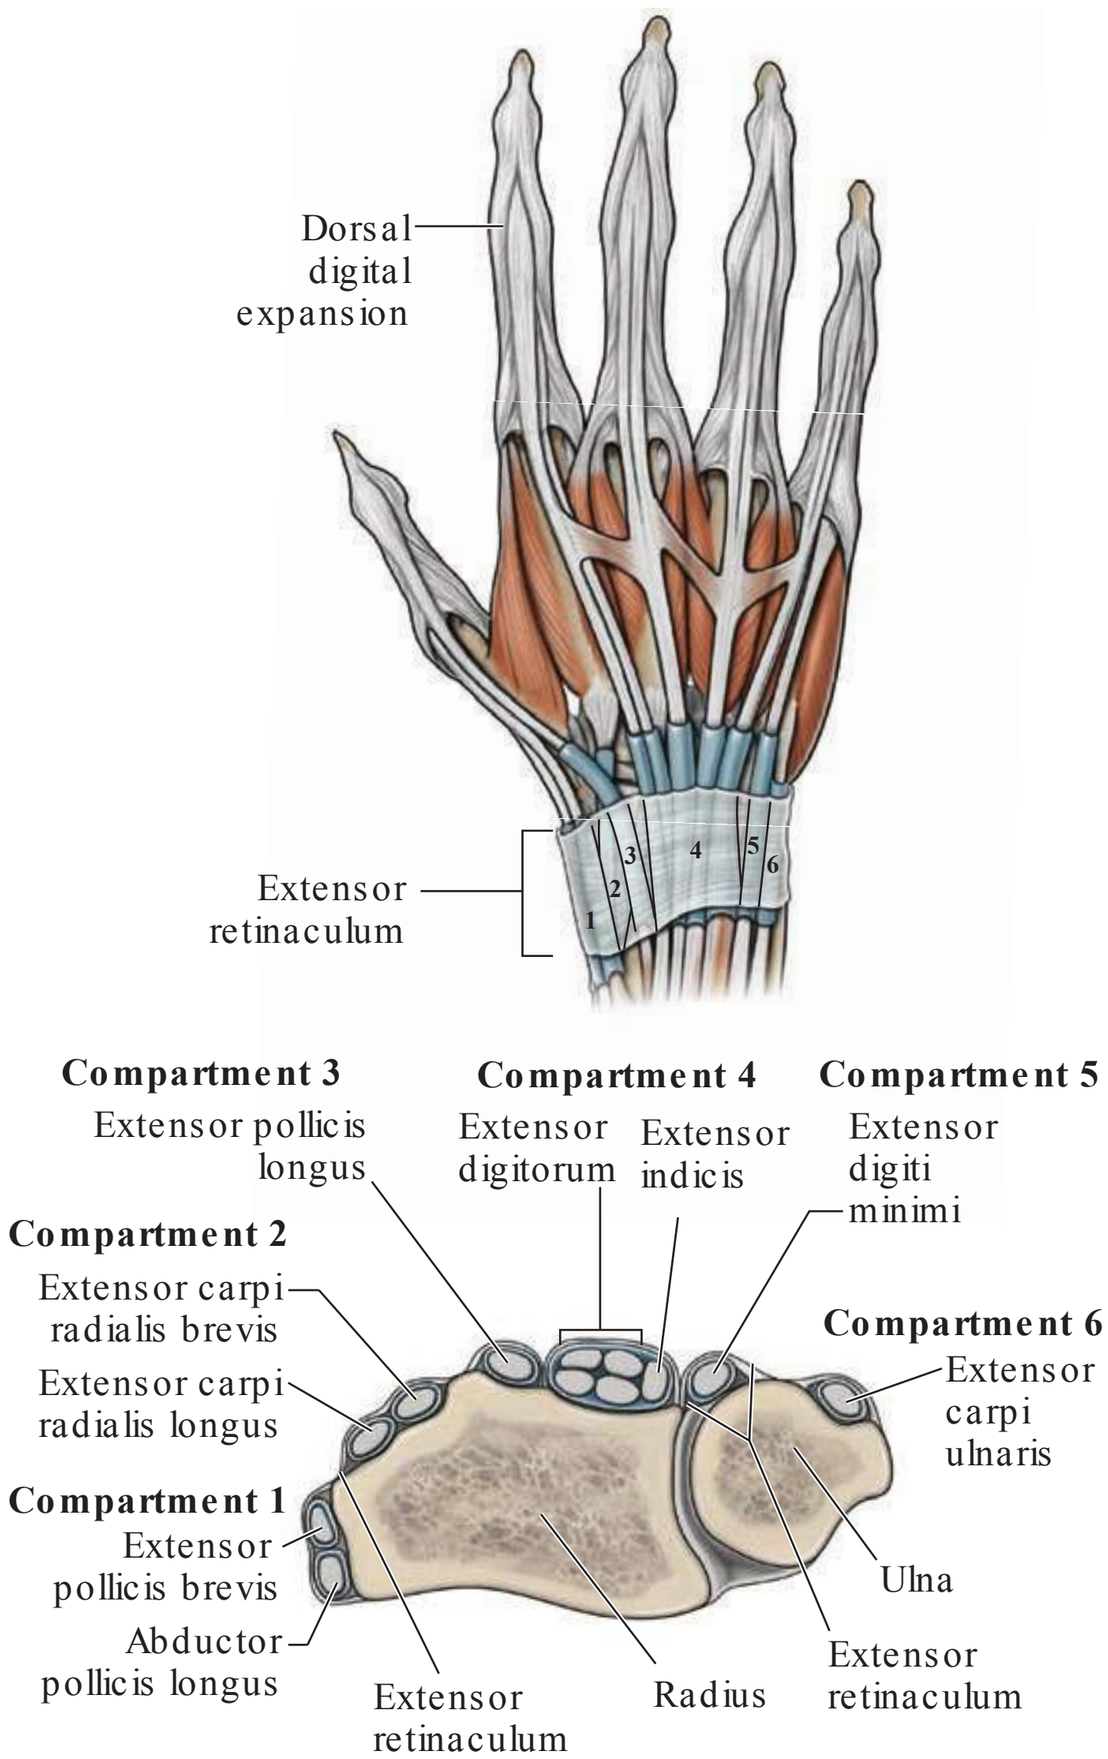

FIGURE 18-3 Extensor retinaculum and extensor tendons. (Reproduced, with permission, from Chapter 33. Hand. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

As these tendons pass through the compartments, they are invested with synovial sheaths.

The posterior (dorsal) compartments serve to enhance the efficiency and effectiveness of the wrist and finger extensors (see "Extensor Hood") (Fig. 18-4). Proximal to the metacarpal heads, juncture tendineae connect the four tendons of the ED muscles, limiting their independent motion.[6] For example, flexion of the middle and little fingers restricts extension of the ring finger MCP joint because the juncture tendineae pulls the ring finger extensor tendon distally. Conversely, extension of the ring finger exerts an extensor force upon its neighbors, such that they can be actively extended even if the middle and little finger extensor tendons are severed proximal to the juncture.[6]

The Flexor Retinaculum

The flexor retinaculum (transverse carpal ligament) spans the region between the pisiform, hamate, scaphoid, and trapezium, transforming the carpal arch into a tunnel, through which the median nerve and some of the tendons of the hand pass (Fig. 18-5). The proximal attachment of the retinaculum is at the tubercle of the scaphoid and the pisiform. The hook of the hamate and the tubercle of the trapezium serve as its distal attachment. The retinaculum also[6]:

- serves as an attachment site for the thenar and hypothenar muscles
- helps maintain the transverse carpal arch
- acts as a restraint against bowstringing of the extrinsic flexor tendons, and
- protects the median nerve.

In the condition known as carpal tunnel syndrome (CTS), the median nerve is compressed in this relatively unyielding space (see "Intervention Strategies"). The structures that pass deep to the flexor retinaculum (Fig. 18-5) include

- flexor digitorum superficialis (FDS),
- flexor digitorum profundus (FDP),
- flexor pollicis longus (FPL), and
- flexor carpi radialis (FCR).

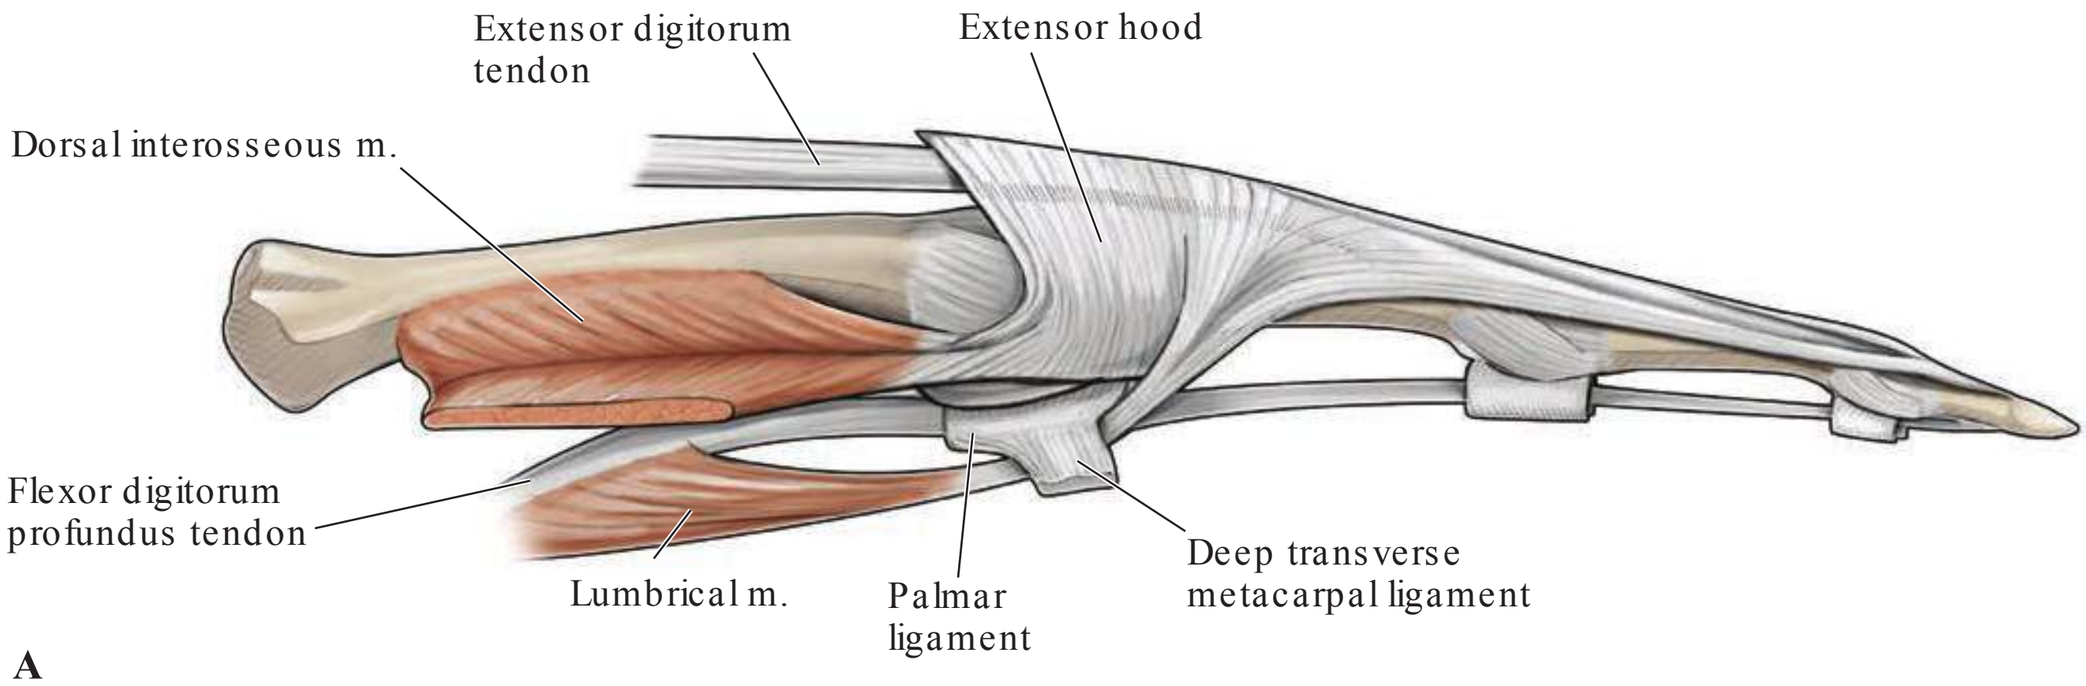

FIGURE 18-4 Extensor hood and smaller ligaments of the hand. (Reproduced, with permission, from Chapter 33. Hand. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

The structures that pass superficial to the flexor retinaculum include

- the ulnar nerve and artery,
- the tendon of the palmaris longus, and
- the sensory branch (anterior (palmar) branch) of the median nerve.

Fibrous sheaths between the distal anterior (palmar) crease and the PIP joints bind the flexor tendons to the fingers. Some surgeons refer to the area where the sheaths contain two tendons as "no man's land."[6]

Carpal Tunnel

The carpal tunnel serves as a channel for the median nerve and nine flexor tendons (Fig. 18-5). The floor of the tunnel is formed by the anterior (palmar) radiocarpal ligament and the anterior (palmar) ligament complex. As mentioned previously, the roof of the tunnel is formed by the flexor retinaculum. The radial and ulnar are formed by carpal bones (hook of hamate and trapezium, respectively). The median nerve divides into a motor branch and distal sensory branches within the tunnel.

Tunnel of Guyon

The tunnel of Guyon is located superficial to the flexor retinaculum, between the hook of the hamate and the pisiform bones. The anterior (palmar) carpal ligament, palmaris brevis muscle, and the anterior (palmar) aponeurosis form its roof. Its floor is formed by the flexor retinaculum (transverse carpal ligament), pisohamate ligament, and pisometacarpal ligament.[6] The tunnel functions as a passageway for the ulnar nerve and artery into the hand.

Phalanges

The 14 phalanges each consist of a base, shaft, and head (Fig. 18-1). Two shallow depressions, which correspond to the pulley-shaped heads of the adjacent phalanges, mark the concave proximal bases. Two distinct convex condyles produce the pulley-shaped configuration of the phalangeal heads.[6]

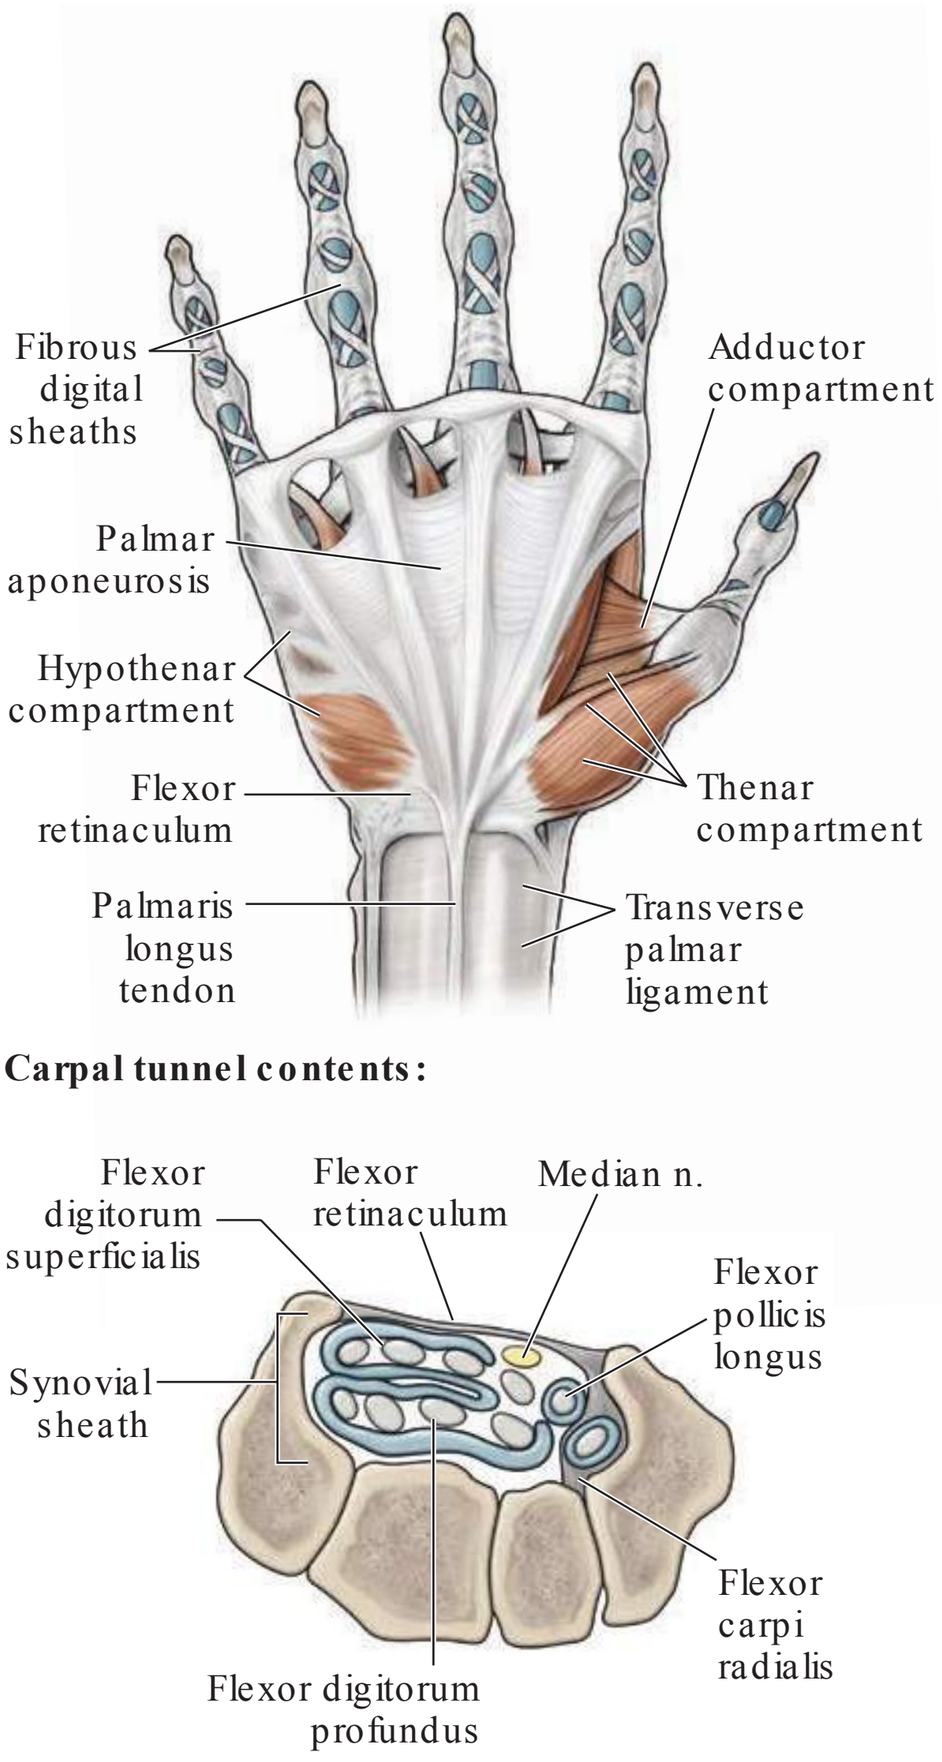

FIGURE 18-5 Flexor retinaculum and flexor tendons. (Reproduced, with permission, from Chapter 33. Hand. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

Anterior (Palmar) Aponeurosis

The anterior (palmar) aponeurosis, which consists of a dense fibrous structure continuous with the palmaris longus tendon and fascia covering the thenar and hypothenar muscles, is located just deep to the subcutaneous tissue (Fig. 18-5). The aponeurosis travels distally to attach to the transverse metacarpal ligaments and flexor tendon sheaths. The aponeurosis offers some protection for the ulnar artery and nerve, and digital vessels and nerves. From the central region of the palm, the aponeurosis continues toward the fingers and splits into four slips. As these slips approach the MCP joints, they split and wrap around the tendons of their respective digit. Dupuytren contracture is a fibrotic condition of the anterior (palmar) aponeurosis that results in nodule formation or scarring of the aponeurosis and which may ultimately cause finger flexion contractures (see "Intervention Strategies").

Extensor Hood

At the level of the MCP joint, the tendon of the ED fans out to cover the posterior (dorsal) aspect of the joint in a hood-like structure (Fig. 18-4). A complex tendon that covers the posterior (dorsal) aspect of the digits is formed from a combination of the tendons of insertion from the ED, EI, and EDM. The distal portion of the hood receives the tendons of the lumbricals and interossei over the proximal phalanx. The tendons of the intrinsic muscles pass anterior (palmar) to the MCP joint axes but posterior (dorsal) to the PIP and DIP joint axes (Fig. 18-6). Between the MCP and the PIP joints, the complete, complex ED tendon (after all contributions have been received) splits into three parts: a central slip and two lateral bands[6]:

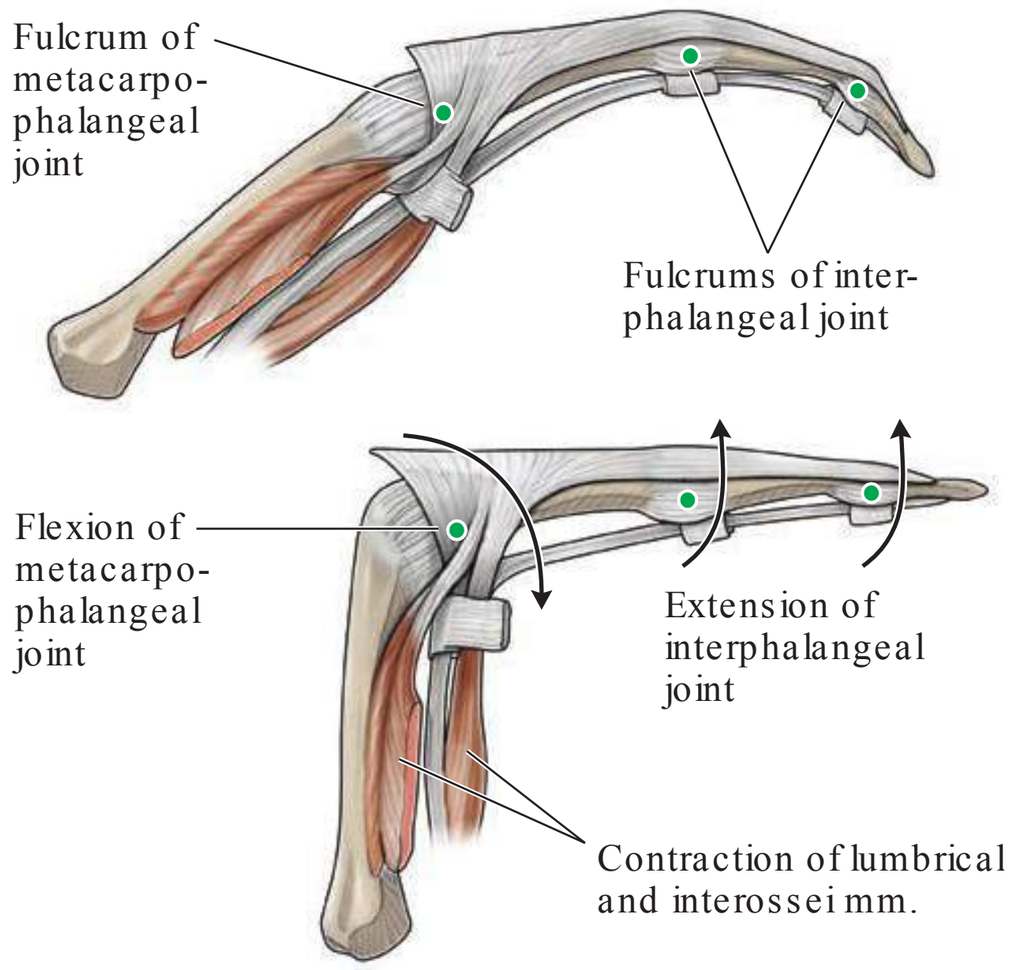

FIGURE 18-6 The tendons of the intrinsic muscles in relation to the joints. (Reproduced, with permission, from Chapter 33. Hand. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

- A central band. This band inserts into the proximal posterior (dorsal) edge of the middle phalanx.
- The lateral bands. These bands rejoin over the middle phalanx into a terminal tendon, which inserts into the proximal posterior (dorsal) edge of the distal phalanx. Rupture of the tendon insertion into the distal phalanx produces a "mallet" finger (see "Intervention Strategies"). The lateral bands, comprised of the fibers from both extrinsic and intrinsic tendons, are prevented from dislocating posteriorly (dorsally) by the transverse retinacular ligaments, which link them to the volar plates of the PIP joints.[6]

The arrangement of the muscles and tendons in this expansion hood creates a cable-like system that provides a mechanism for extending the MCP and IP joints and allows the lumbrical and possibly interosseous muscles to assist in the flexion of the MCP joints.

Stretching or laxity of these supporting structures allows "bowstringing" of the lateral bands, which transmit excessive extension force to the PIP joint.[6]

The oblique retinacular ligament (Landsmeer ligament) assists in the extensor hood mechanism. The ligament attaches between the PIP volar plate, where it is anterior (palmar) to

the PIP joint axis, and the terminal tendon, where it is posterior (dorsal) to the DIP joint axis. T is relationship to the PIP and DIP joints is essentially the same as that of the intrinsic muscles (lumbricals and interosseous) to the MCP and PIP joints—when the PIP joint extends, the oblique retinacular ligament exerts a passive extensor force on the DIP joint, and when the PIP joint flexes, it allows the DIP joint to flex.[31]

PIP joint position also may influence DIP joint position through lateral band action. T e lateral bands normally slip palmarly upon PIP joint flexion, decreasing the excursion required for full DIP joint flexion. If scar tissue tethers the lateral bands so that they do not move palmarly, then simultaneous full flexion at both the PIP and the DIP joints at the same time is not possible.[6]

Synovial Sheaths

Synovial sheaths can be thought of as long narrow balloons filled with synovial fluid, which wrap around a tendon so that one part of the balloon wall (visceral layer) is directly on the tendon, while the other part of the balloon wall (parietal layer) is separate.[30] During wrist motions, the sheaths move longitudinally, reducing friction.

At the wrist, the tendons of both the FDS and the FDP are essentially covered by a synovial sheath and pass posterior (dorsal) (deep) to the flexor retinaculum. T e FDP tendons are posterior (dorsal) to those of the FDS.

In the palm, the FDS and FDP tendons are covered for a variable distance by a synovial sheath.

At the base of the digits, both sets of tendons enter a "fibro-osseous tunnel" formed by the bones of the digit (head of the metatarsals and phalanges) and a fibrous digital tendon sheath on the anterior (palmar) surface of the digits.

Flexor Pulleys

Annular (A) and cruciate (C) pulleys restrain the flexor tendons to the metacarpals and phalanges and contribute to fibro-osseous tunnels through which the tendons travel.[11] T e A1 pulley arises from the MCP joint and volar plate; A2 from the proximal phalanx; A3 from the PIP joint volar plate; A4 from the middle phalanx; and A5 from the DIP joint volar plate.[11] T e C1 pulley originates near the head of the proximal phalanx; C2 near the base of the middle phalanx; and C3 near the head of the middle phalanx.[11]

T e pulley system of the thumb includes the A1 arising from the MCP joint anterior (palmar) plate, A2 from the IP joint anterior (palmar) plate, and the oblique pulley from the proximal phalanx.[11]

Anatomic Snuffbox

T e anatomic snuffbox (Fig. 18-7) is a depression on the posterior (dorsal) surface of the hand at the base of the thumb, just distal to the radius. T is structure can be observed during active radial abduction of the thumb. T e radial border of the snuffbox is formed by the tendons of the APL and EPB while the ulnar border is formed by the tendon of the EPL. T e deep branch of the radial artery and the tendinous insertion of the ECRL are along the floor of the snuffbox.

FIGURE 18-7 Anatomic snuffbox.

Underneath these structures, the scaphoid and trapezium bones are found.

CLINICAL PEARL

Tenderness with palpation in the anatomic snuffbox suggests a scaphoid fracture, but also can present in minor wrist injuries or other conditions.[4]

MOBILE ARCH SYSTEMS

T e bones and soft tissues of the hand form a number of functional arches of the hand that provide a perfect balance of force distribution in an equiangular spiral. T e arches of the hand, which are all concave palmarly, serve to enhance prehensile function. T is prehensile function is best illustrated by the ability of the human hand to grasp an egg. A number of arches are commonly recognized:

- T e transverse arch. T e proximal, relatively immobile transverse arch is formed by the anterior (palmar) concavity of the carpal bones.[6] T is carpal arch, deepened by the anterior (palmar) projections of the scaphoid and trapezium laterally and the pisiform and hamate medially, should correspond to the concavity of the wrist. T e distal transverse arch is more mobile and is defined by the alignment of the metacarpals. T is arch allows the hand to adapt to objects held in the palm.[11]
- T e metacarpal arch. T is arch, formed by the metacarpal heads, is a relatively mobile transverse arch.
- T e longitudinal arch. T is is specifically the arch of the middle finger and the arch of the index finger. T e longitudinal arch, which contributes to powerful gripping, spans the hand lengthwise, with its keystone at the MCP joints.[6]
- T e oblique arches. T ese arches are formed by the thumb in opposition to the other fingers.

TABLE 18-2 Muscles of the Wrist and Hand: Their Actions and Nerve Supply

Action	Muscles	Nerve Supply
Wrist extension	Extensor carpi radialis longus	Radial
	Extensor carpi radialis brevis	Posterior interosseous
	Extensor carpi ulnaris	Posterior interosseous
Wrist flexion	Flexor carpi radialis	Median
	Flexor carpi ulnaris	Ulnar
Ulnar deviation of wrist	Flexor carpi ulnaris	Ulnar
	Extensor carpi ulnaris	Posterior interosseous
Radial deviation of wrist	Flexor carpi radialis	Median
	Extensor carpi radialis longus	Radial
	Abductor pollicis longus	Posterior interosseous
	Extensor pollicis brevis	Posterior interosseous
Finger extension	Extensor digitorum communis	Posterior interosseous
	Extensor indicis	Posterior interosseous
	Extensor digiti minimi	Posterior interosseous
Finger flexion	Flexor digitorum profundus	Anterior interosseous, lateral two digits Ulnar, medial two digits Median
	Flexor digitorum superficialis	Median
	Lumbricals	First and second: median Third and fourth: ulnar
	Interossei	Ulnar
	Flexor digiti minimi	Ulnar
Abduction of fingers	Posterior (dorsal) interossei	Ulnar
	Abductor digiti minimi	Ulnar
Adduction of fingers	Anterior (palmar) interossei	Ulnar
Thumb extension	Extensor pollicis longus	Posterior interosseous
	Extensor pollicis brevis	Posterior interosseous
	Abductor pollicis longus	Posterior interosseous

Muscles of the Wrist and Forearm

The muscles of the forearm, wrist, and hand (Table 18-2) (Figs. 18-8 to 18-10) can be subdivided into 19 intrinsic muscles and 24 extrinsic muscles. The intrinsic muscles are located entirely within the hand; they arise and insert within the hand. The extrinsic muscles, whose muscle bellies lie proximal to the wrist, originate in the forearm and insert within the hand.[4] The flexors, which are located in the anterior compartment, flex the wrist and digits while the extensors, located in the posterior compartment, extend the wrist and the digits.

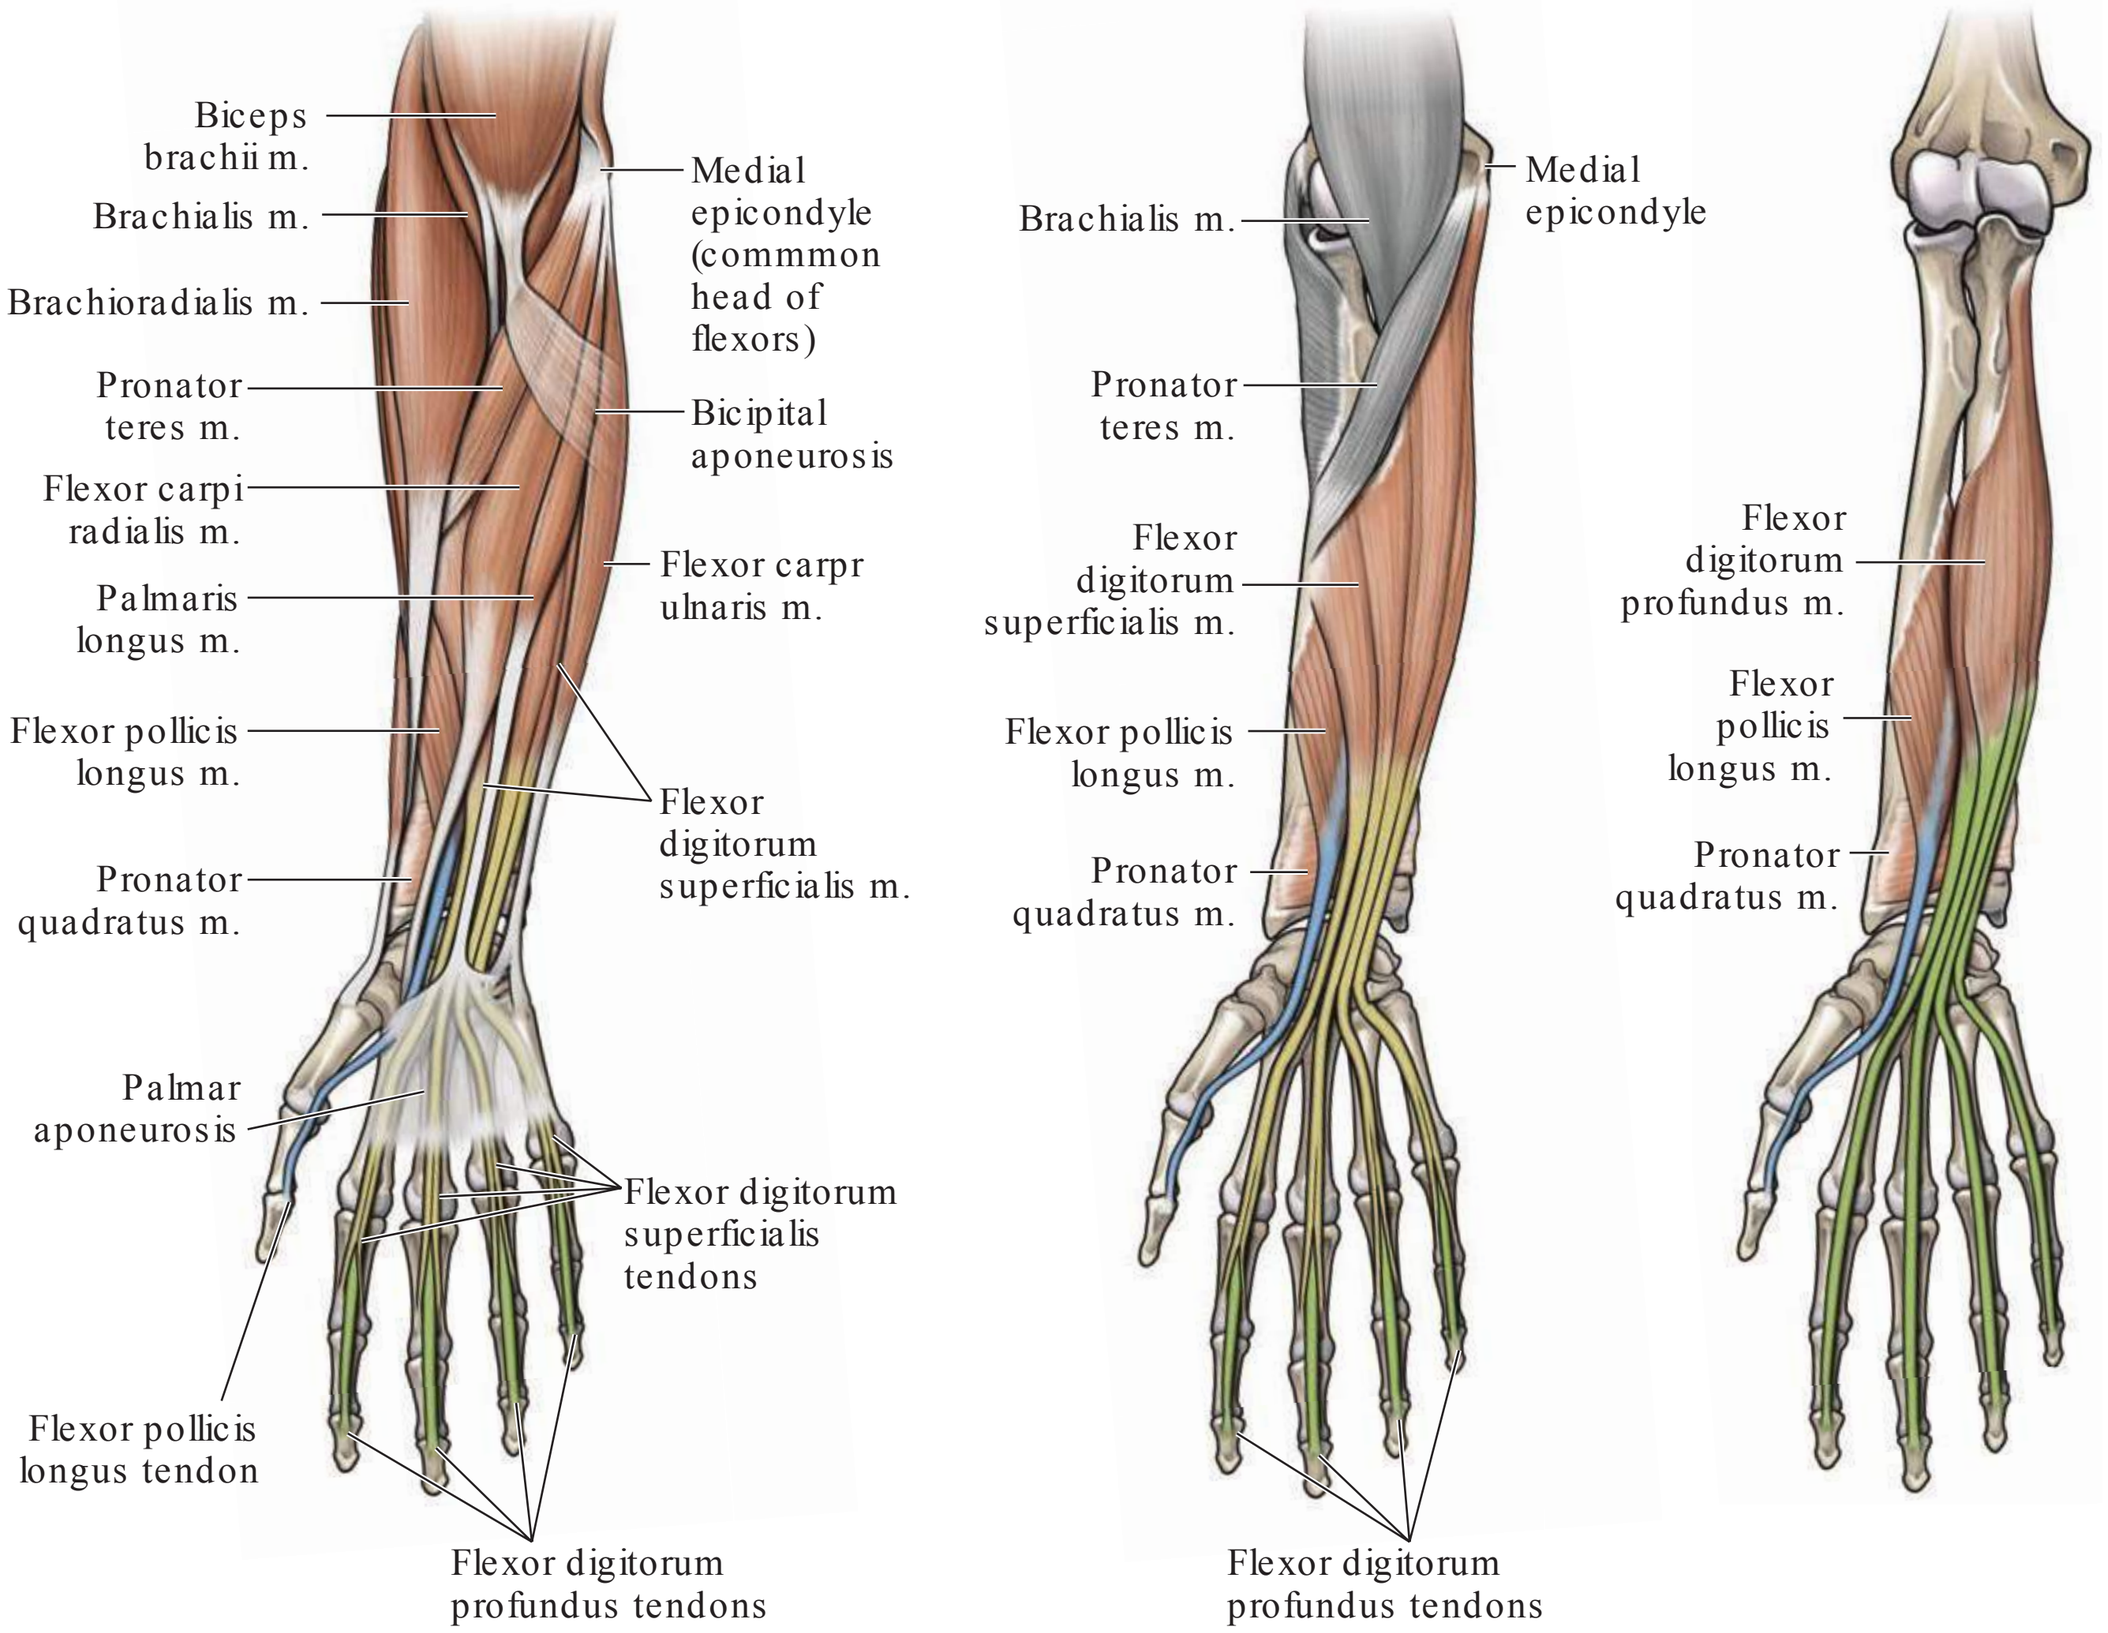

FIGURE 18-8 Muscles of the forearm, wrist, and hand. (Reproduced, with permission, from Chapter 32. Forearm. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

The design of the extrinsic and intrinsic muscle groups provides for a large number of muscles to act on the hand without excessive bulkiness. The extrinsic tendons enhance wrist stability by balancing flexor and extensor forces and compressing the carpals.

The amount of tendon excursion determines the available range of motion at a joint. To calculate the amount of tendon excursion needed to produce a certain number of degrees of joint motion involves an appreciation of geometry. A circle's radius equals approximately 1 radian (57.29 degrees). The mathematical radius, which is equivalent to the moment arm, represents the amount of tendon excursion required to move the joint through 1 radian.[32] For example, if a joint's moment arm is 10 mm, the tendon must glide 10 mm to move the joint 60 degrees (approximately 1 radian) or 5 mm to move the joint 30 degrees (1/2 radian).[11]

Anterior Compartment of the Forearm

Superficial Muscles

Pronator Teres. The pronator teres is described in Chapter 17.

Flexor Carpi Radialis. The FCR originates from the medial humeral epicondyle as part of the common flexor tendon. It inserts on the anterior surface and base of the second metacarpal, possibly providing a slip to the third metacarpal. The FCR is innervated by the median nerve and functions to flex and radially deviate the wrist.

Palmaris Longus. The inconsistent palmaris longus arises from the medial humeral epicondyle as part of the common flexor tendon and inserts on the transverse carpal ligament and anterior (palmar) aponeurosis. It receives its innervation from the median nerve. The function of the palmaris longus is to flex the wrist, and it may play a role in thumb abduction in some people.[18]

Flexor Carpi Ulnaris. The FCU arises from two heads. The humeral head arises from the medial humeral epicondyle as part of the common flexor tendon, while the ulnar head arises from the proximal portion of the subcutaneous border of the ulna. The FCU inserts directly onto the pisiform, the hamate via the pisohamate ligament, and onto the anterior surface of the base of the fifth metacarpal, via the pisometacarpal ligament.

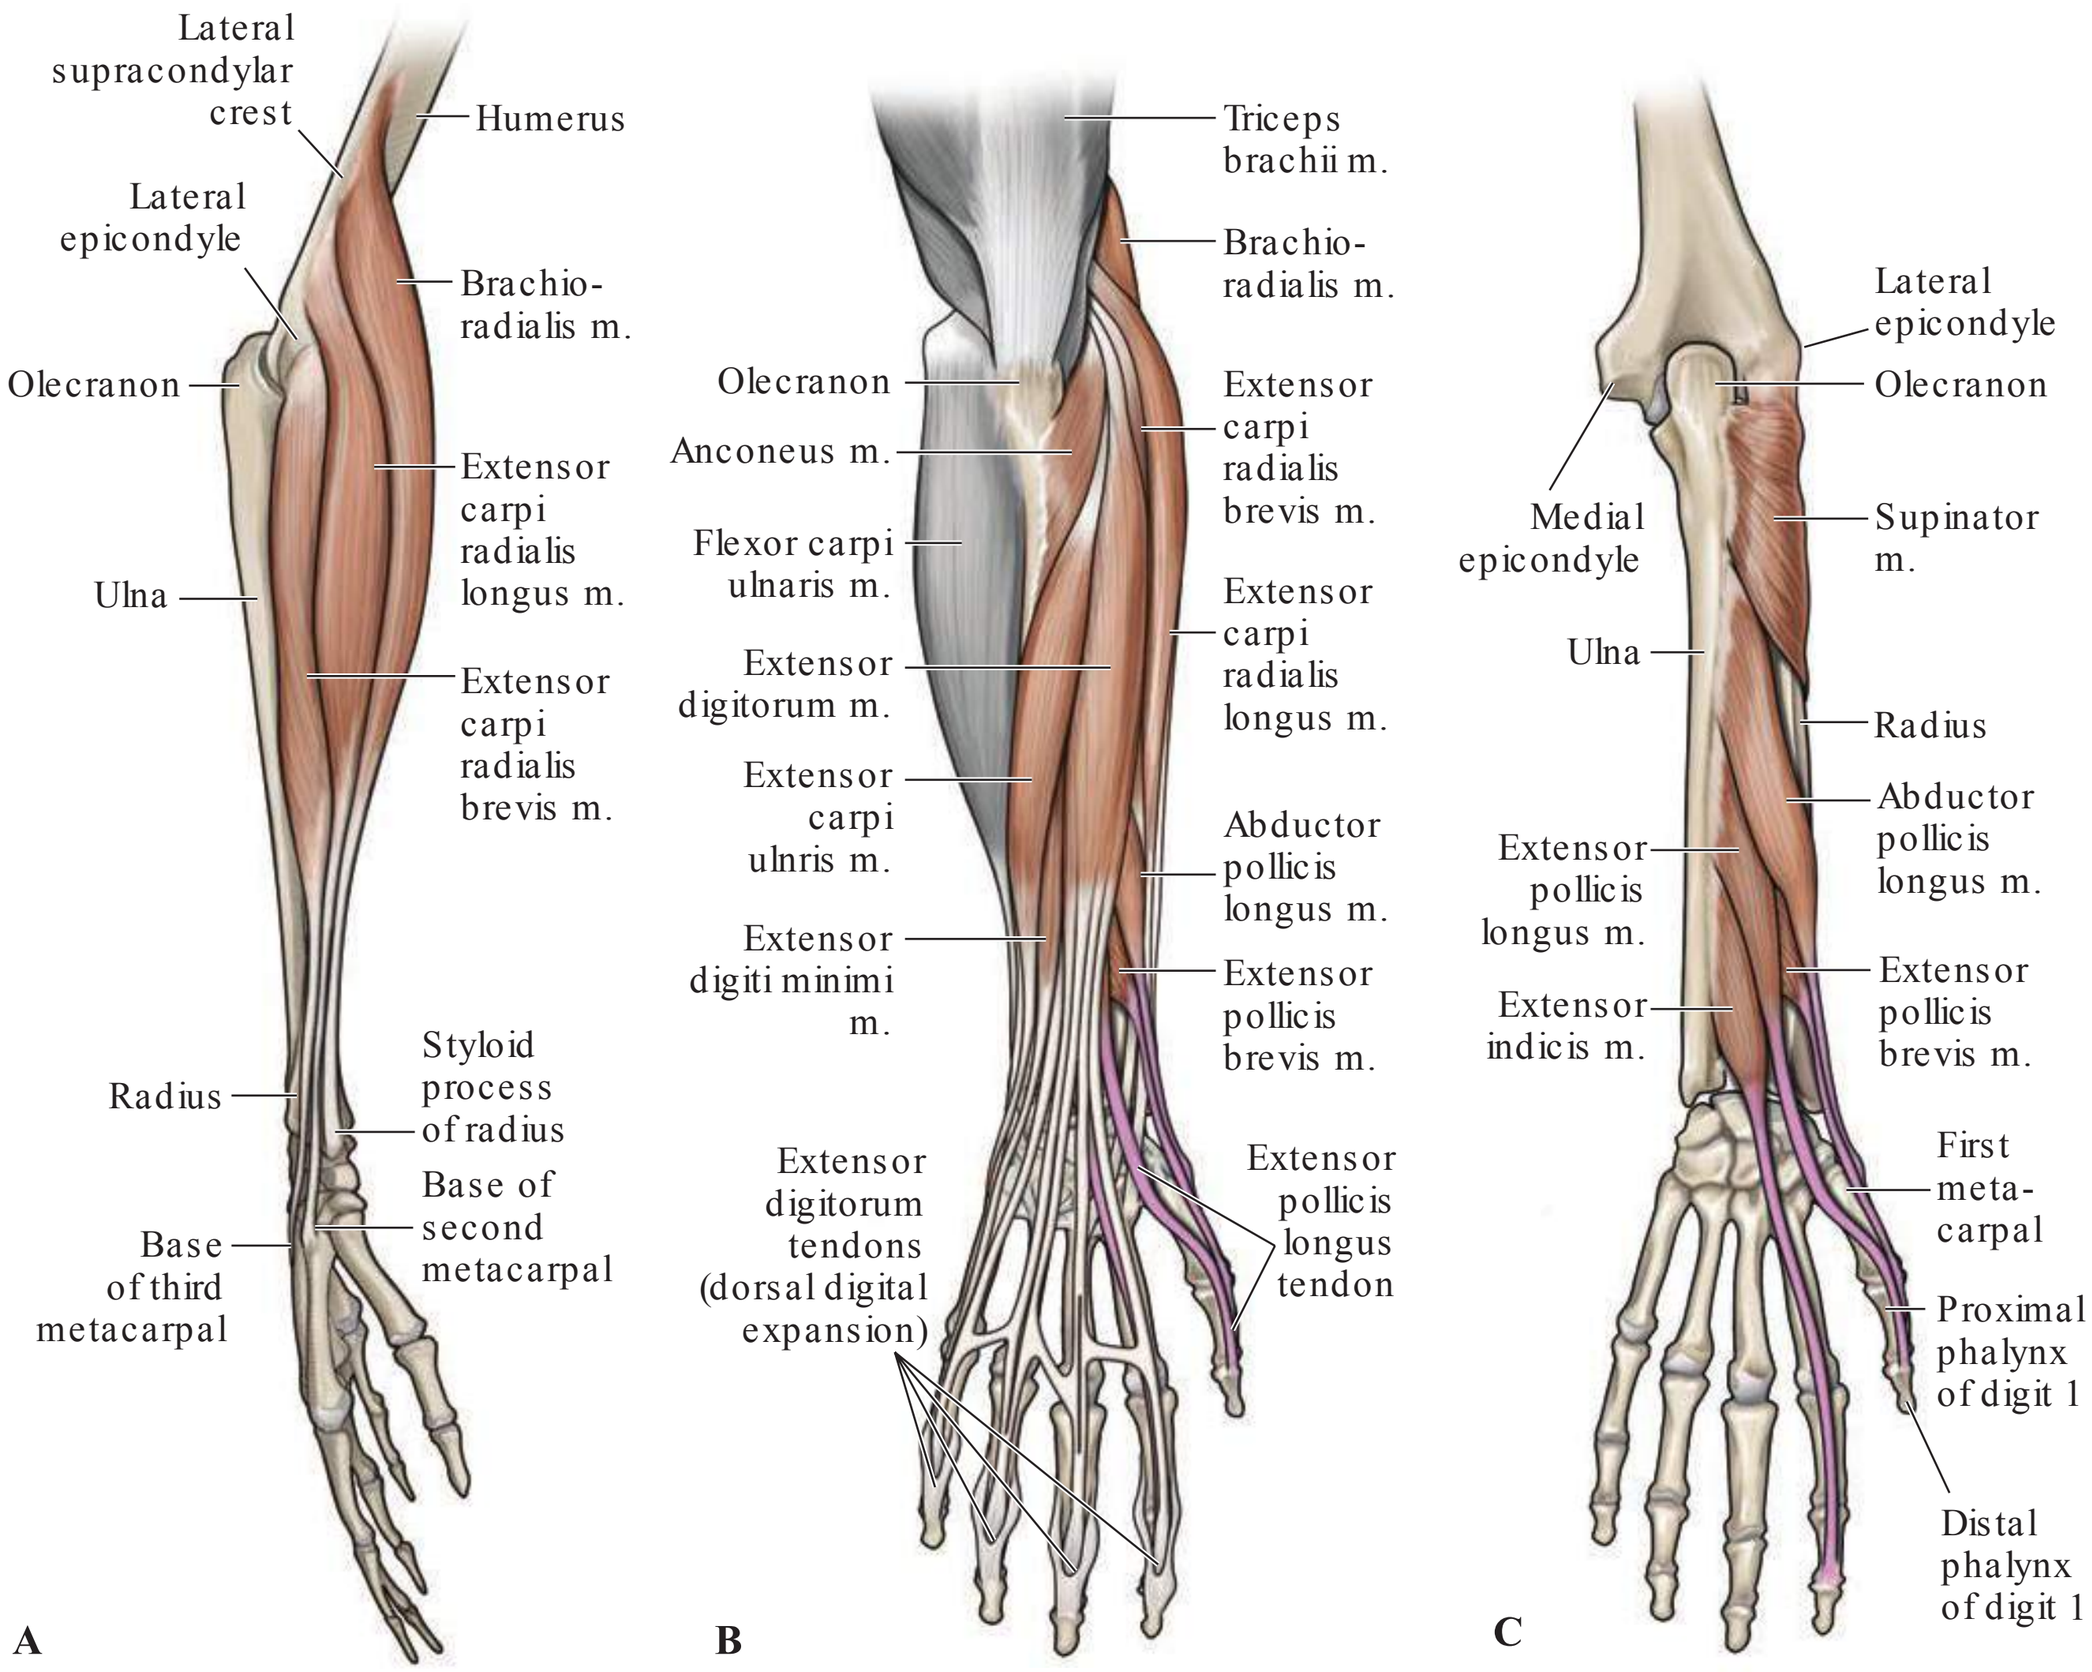

FIGURE 18-9 Muscles of the forearm, wrist, and hand. (Reproduced, with permission, from Chapter 32. Forearm. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

T e FCU is innervated by the ulnar nerve and functions to flex and ulnarly deviate the wrist.

Intermediate Muscle

Flexor Digitorum Superficialis. T e FDS has a three-headed origin. T e humeral head arises from the medial humeral epicondyle as part of the common flexor tendon. T e ulnar head arises from the coronoid process of the ulna. T e radial head arises from the oblique line of the radius. T e FDS inserts on the middle phalanx of the medial four digits via a split, "sling" tendon. T is muscle is innervated by the median nerve and serves to flex the proximal and middle IP joints of the medial four digits and assist with elbow flexion and wrist flexion. T e FDS possesses tendons that are capable of relatively independent action at each finger.

Deep Muscles

Flexor Pollicis Longus. T e FPL has its origin on the ventral surface of the radius, medial border of the coronoid process of the ulna, and the adjacent interosseous membrane. It inserts on the distal phalanx of the thumb. T e FPL is innervated by the anterior interosseous branch of the median nerve, and it functions to flex the thumb.

Flexor Digitorum Profundus. T e FDP arises from the medial and anterior (ventral) surfaces of the proximal ulna, the adjacent interosseous membrane, and the deep fascia of the forearm. T e FDP inserts on the base of the distal phalanges of the medial four digits. T e FDP has a dual nerve supply: the medial two heads are supplied by the ulnar nerve while the lateral two heads are supplied by the anterior interosseous branch of the median nerve. T e FDP functions to flex the DIP joints after the FDS flexes the second phalanges and assists with flexion of the wrist. T e tendons of the FDS and FDP are held against the phalanges by a fibrous sheath. At strategic locations along the sheath, the previously mentioned five dense annular pulleys (designated A1, A2, A3, A4, and A5) and three thinner cruciform pulleys (designated C1, C2, and C3) prevent tendon bowstringing.[33]

Unlike the FDS tendons, the FDP tendons cannot act independently. To isolate the PIP joint flexor function of these two muscles, a clinician holds the adjoining finger(s) in extension while the patient attempts to flex the finger being tested. T is

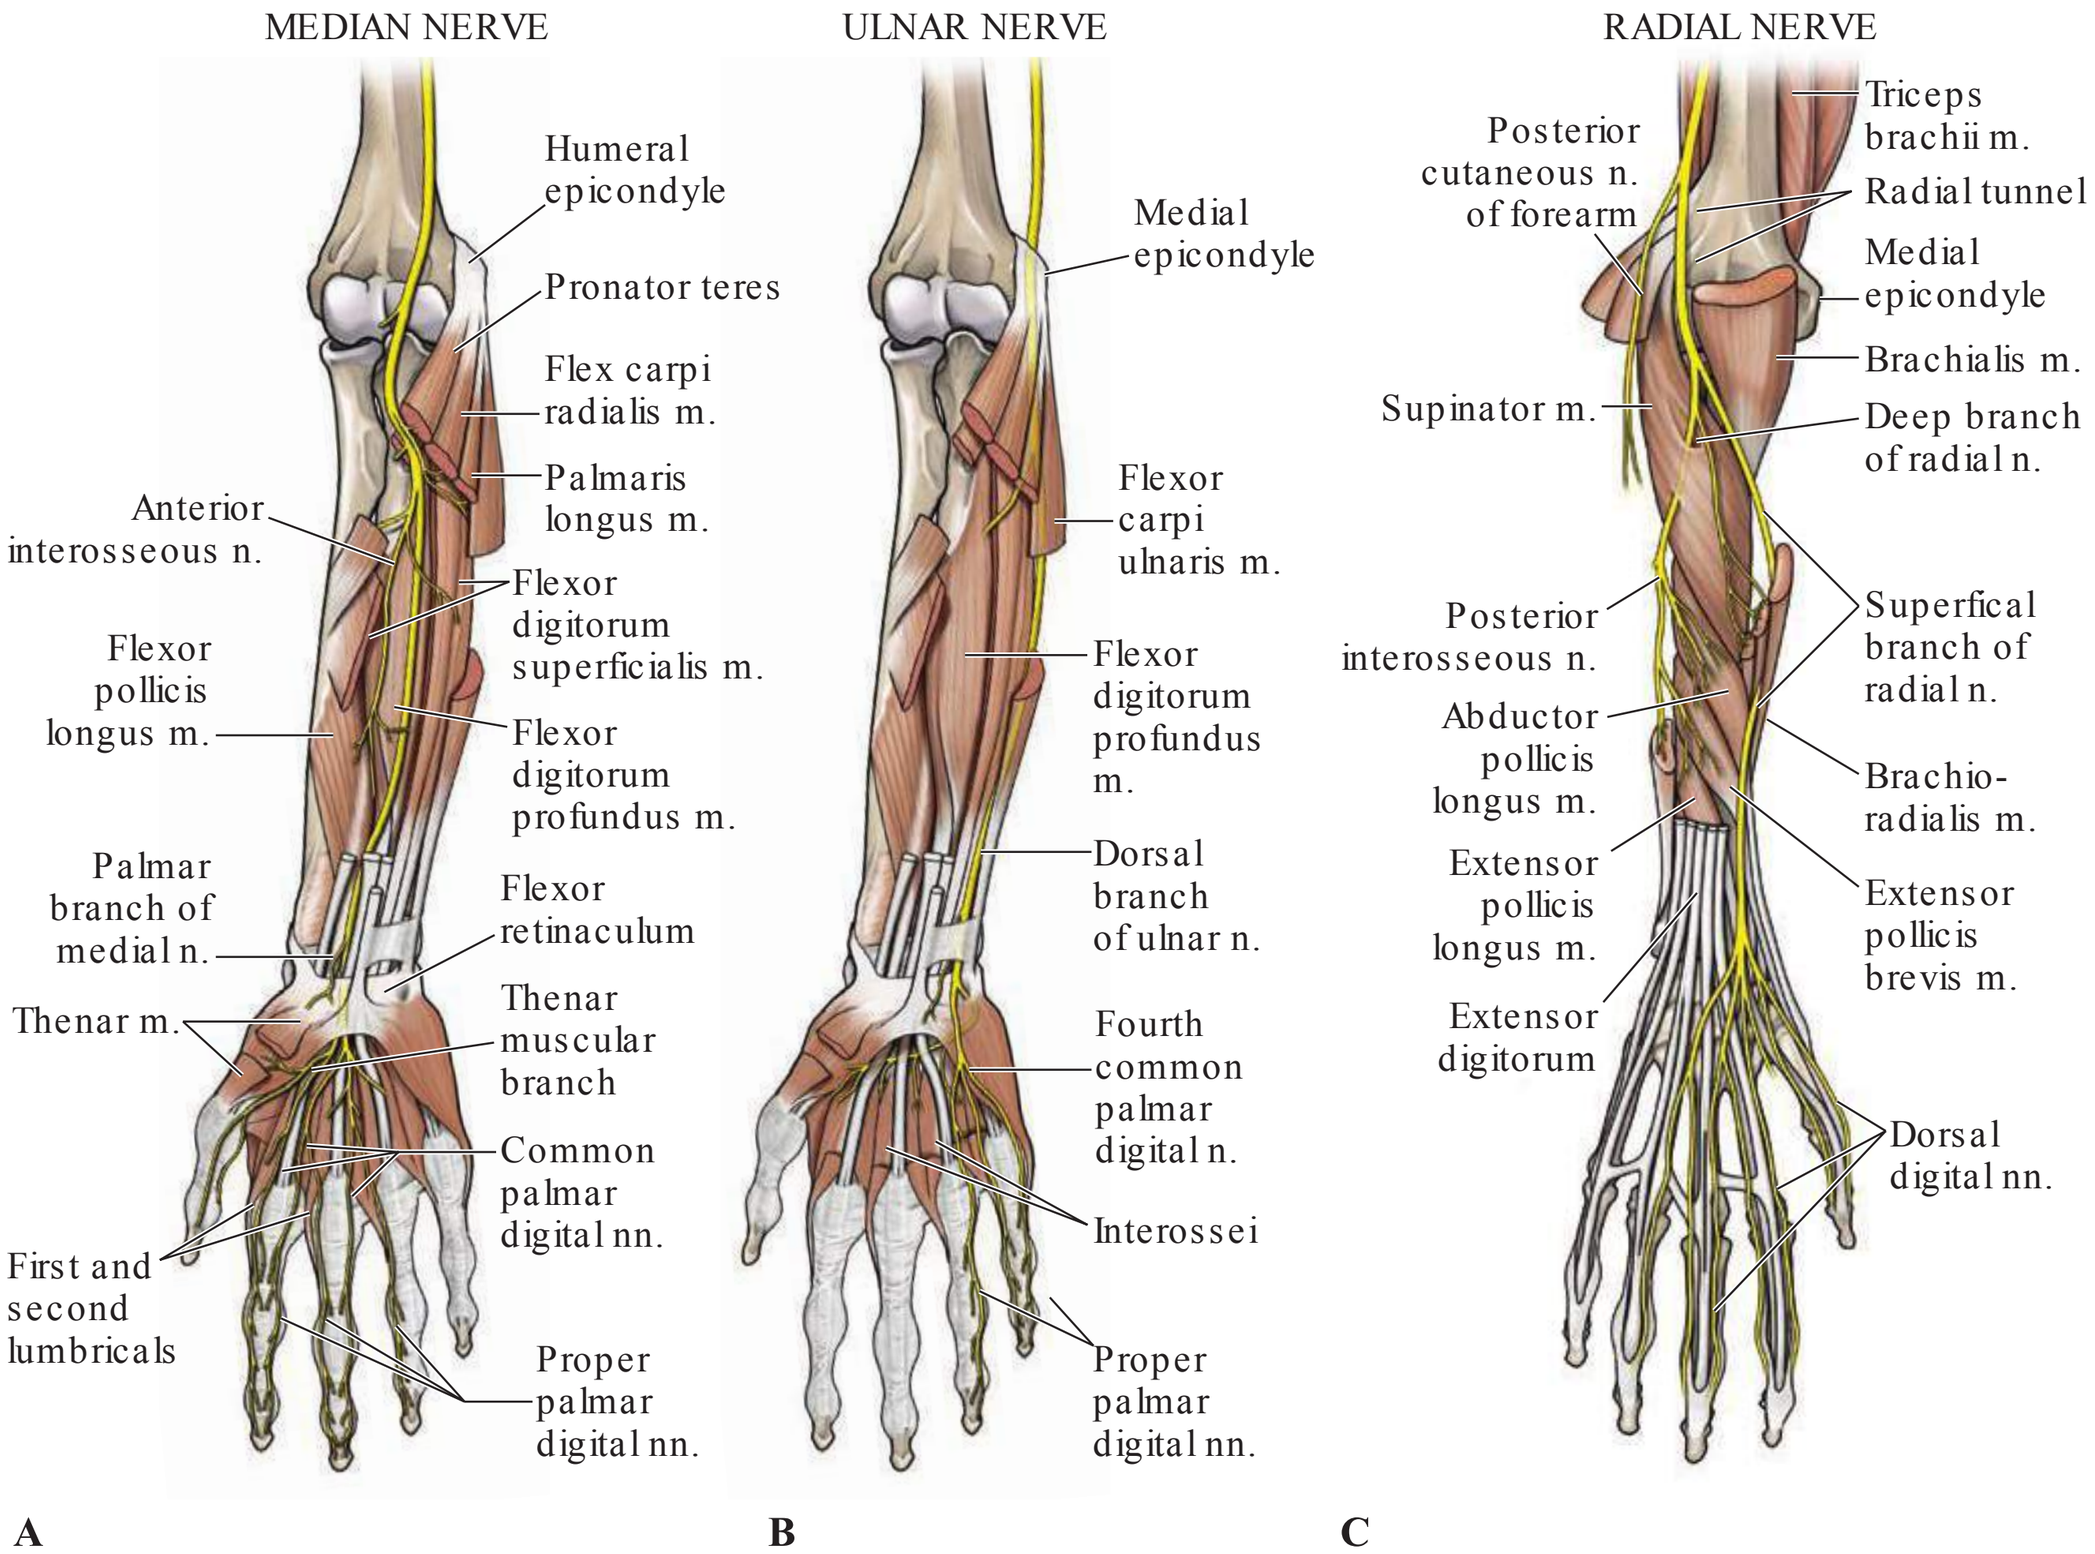

FIGURE 18-10 Muscles and nerve supply of the forearm, wrist, and hand. (Reproduced, with permission, from Chapter 32. Forearm. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

anchors the profundus muscle of the finger being tested distally and allows the superficialis muscle to act alone at the PIP joint.

Tendinous connections between the FDP and the FPL are a common anatomic anomaly, which have been linked to a condition causing chronic forearm pain, called Linburg syndrome,[34] although the association is by no means conclusive.[35]

Pronator Quadratus. The pronator quadratus arises from the anterior (ventral) surface and distal quarter of the ulna and inserts on the anterior (ventral) surface and distal quarter of the radius. The muscle functions to pronate the forearm, and it is innervated by the anterior interosseous branch of the median nerve. The pronator quadratus is well-designed biomechanically as an effective torque producer and a stabilizer of the DRUJ—its line of force is oriented almost perpendicular to the forearm's axis of rotation.[36]

Posterior Compartment of the Forearm

Superficial Muscles

Extensor Carpi Radialis Longus. The ECRL takes its origin at the supracondylar ridge of the humerus about 4–5 cm proximal to the epicondyle, and the thickest part of the muscle is proximal to the elbow joint. The ECRL inserts on the base of the second metacarpal and functions to extend and radially deviate the wrist. It also plays a role in elbow flexion, losing a part of its wrist action when the elbow is flexed.[23]

Extensor Carpi Radialis Brevis. The ECRB arises from the common extensor tendon on the lateral epicondyle of the humerus (see Chapter 17) and from the radial collateral ligament. It inserts on the posterior surface of the base of the third metacarpal bone and receives its nerve supply from the posterior interosseous branch of the radial nerve. The muscle stretches across the radial head during forearm pronation, resulting in increased tensile stress when the forearm is pronated, the wrist is flexed, and the elbow is extended. The more medial location of the ECRB compared to the ECRL makes it the primary wrist extensor, but it has also a slight action of radial deviation.

ED and EDM. The ED arises from the lateral humeral epicondyle, part of the common extensor tendon while the EDM arises from a muscular slip from the ulnar aspect of the ED muscle. The ED inserts on the lateral and posterior (dorsal) aspect of the medial four digits, while the EDM inserts on the proximal phalanx of the fifth digit. Both muscles are innervated by the posterior interosseous branch of the radial nerve. While the ED functions to extend the medial four digits, the EDM extends the fifth digit.

Extensor Carpi Ulnaris. The ECU arises from the common extensor tendon on the lateral epicondyle of the humerus and the posterior border of the ulna. It inserts on the medial side of the base of the fifth metacarpal bone. It is innervated by the posterior interosseous branch of the radial nerve. The ECU is an extensor of the wrist in supination and primarily causes ulnar deviation of the wrist in pronation, working in synergy with the FCU to prevent radial deviation during pronation.[23]

Extension of the wrist is dependent on three muscles:

- ECRL
- ECRB
- ECU

The ECRB and ECRL are commonly considered to be similar muscles, but in fact they differ in many respects and have very different moment arms of extension.[37] The ECRB, because of its origin on the epicondyle, is not affected by the position of the elbow, so that all of its action is on the wrist, making it the most effective extensor of the wrist (because it has the greatest tension and the most favorable moment arm).[23] Taken together, both ECR tendons comprise about 10% of the muscle mass of the forearm and 76% of the muscle mass of the extensors of the wrist.[38] The ECRL has longer muscular fibers, mostly at the level of the elbow. The ECRL only becomes a wrist extensor after radial deviation is balanced against the ulnar forces of the ECU.

The ECU, the antagonist of the EPL, has the weakest moment of extension, which becomes zero when the wrist is in complete pronation.

Deep Muscles

Abductor Pollicis Longus. The APL arises from the posterior (dorsal) surface of the proximal portion of the radius, ulna, and interosseous membrane and inserts on the anterior (ventral) surface of the base of the first metacarpal. The APL is innervated by the posterior interosseous branch of the radial nerve and functions in the abduction, extension, and external rotation of the first metacarpal.

Extensor Pollicis Brevis. The EPB arises from the posterior (dorsal) surface of the radius and interosseous membrane, just distal to the origin of the APL. It inserts on the posterior (dorsal) surface of the proximal phalanx of the thumb via the extensor expansion. The EPB is innervated by the posterior interosseous branch of the radial nerve and functions to extend the proximal phalanx of the thumb.

Extensor Pollicis Longus. The EPL arises from the posterior (dorsal) surface of the midportion of the ulna and interosseous membrane. It inserts on the posterior (dorsal) surface of the distal phalanx of the thumb via the extensor expansion. The EPL is innervated by the posterior interosseous branch of the radial nerve. It functions in the extension of the distal phalanx of the thumb and is thus involved in the extension of the middle phalanx and the MCP joint of the thumb.

Extensor Indicis. The EI arises from the posterior (dorsal) surface of the ulna, distal to the other deep muscles, and inserts on the extensor expansion of the index finger. It is innervated by the posterior interosseous branch of the radial nerve and is involved in the extension of the proximal phalanx of the index finger.

Muscles of the Hand

The muscles of the hand (Fig. 18-11) are those that originate and insert within the hand and are responsible for fine finger movements.

Short Muscles of the Thumb

Abductor Pollicis Brevis. The APB arises from the flexor retinaculum and the trapezium bone and inserts on the radial aspect of the proximal phalanx of the thumb. It is innervated by the median nerve and functions to abduct the first metacarpal and proximal phalanx of the thumb.

Flexor Pollicis Brevis. The FPB arises from two heads. The superficial head arises from the flexor retinaculum and the trapezium bone while the deep head arises from the floor of the carpal canal. The FPB inserts on the base of the proximal phalanx of the thumb. The superficial head receives its innervation from the median nerve while the deep head is innervated by the ulnar nerve. The FPB functions to flex the proximal phalanx of the thumb.

Opponens Pollicis. The OP arises from the flexor retinaculum and the trapezium bone and inserts along the radial surface of the first metacarpal. The OP is innervated by the median nerve and functions to flex, rotate, and slightly abduct the first metacarpal across the palm to allow for the opposition with each of the other digits.

Adductor Pollicis. The adductor pollicis (AP) arises from two heads. The transverse head originates from the ventral surface of the shaft of the third metacarpal, while the oblique head originates from the trapezium, trapezoid, and capitate bones, and the base of the second and third metacarpal bone. The AP inserts on the ulnar side of the base of the proximal phalanx of the thumb and is innervated by the deep branch of the ulnar nerve. The AP functions to adduct the thumb and aids in thumb opposition.

Short Muscles of the Fifth Digit

Abductor Digiti Minimi. The ADM arises from the pisiform bone and the tendon of the FCU. It inserts on the ulnar aspect of the base of the proximal phalanx of the fifth digit, together with the flexor digiti minimi (FDM) brevis. It is innervated by the deep branch of the ulnar nerve and functions to abduct the fifth digit.

Flexor Digiti Minimi. The FDM originates from the flexor retinaculum and the hook of the hamate bone. It inserts on the ulnar aspect of the base of the proximal phalanx of the fifth digit, together with the ADM. It is innervated by the deep branch of the ulnar nerve and functions to flex the proximal phalanx of the fifth digit.

Deep branches of the ulnar artery and nerve enter the thenar mass and course into the deep region of the hand by passing between the ADM and the FDM.

Opponens Digiti Minimi. The opponens digiti minimi (ODM) arises from the flexor retinaculum and the hook of the hamate bone and inserts on the ulnar border of the shaft of the fifth metacarpal bone. It is innervated by the deep branch of the ulnar nerve and functions to provide a small amount of flexion and external rotation of the fifth digit.

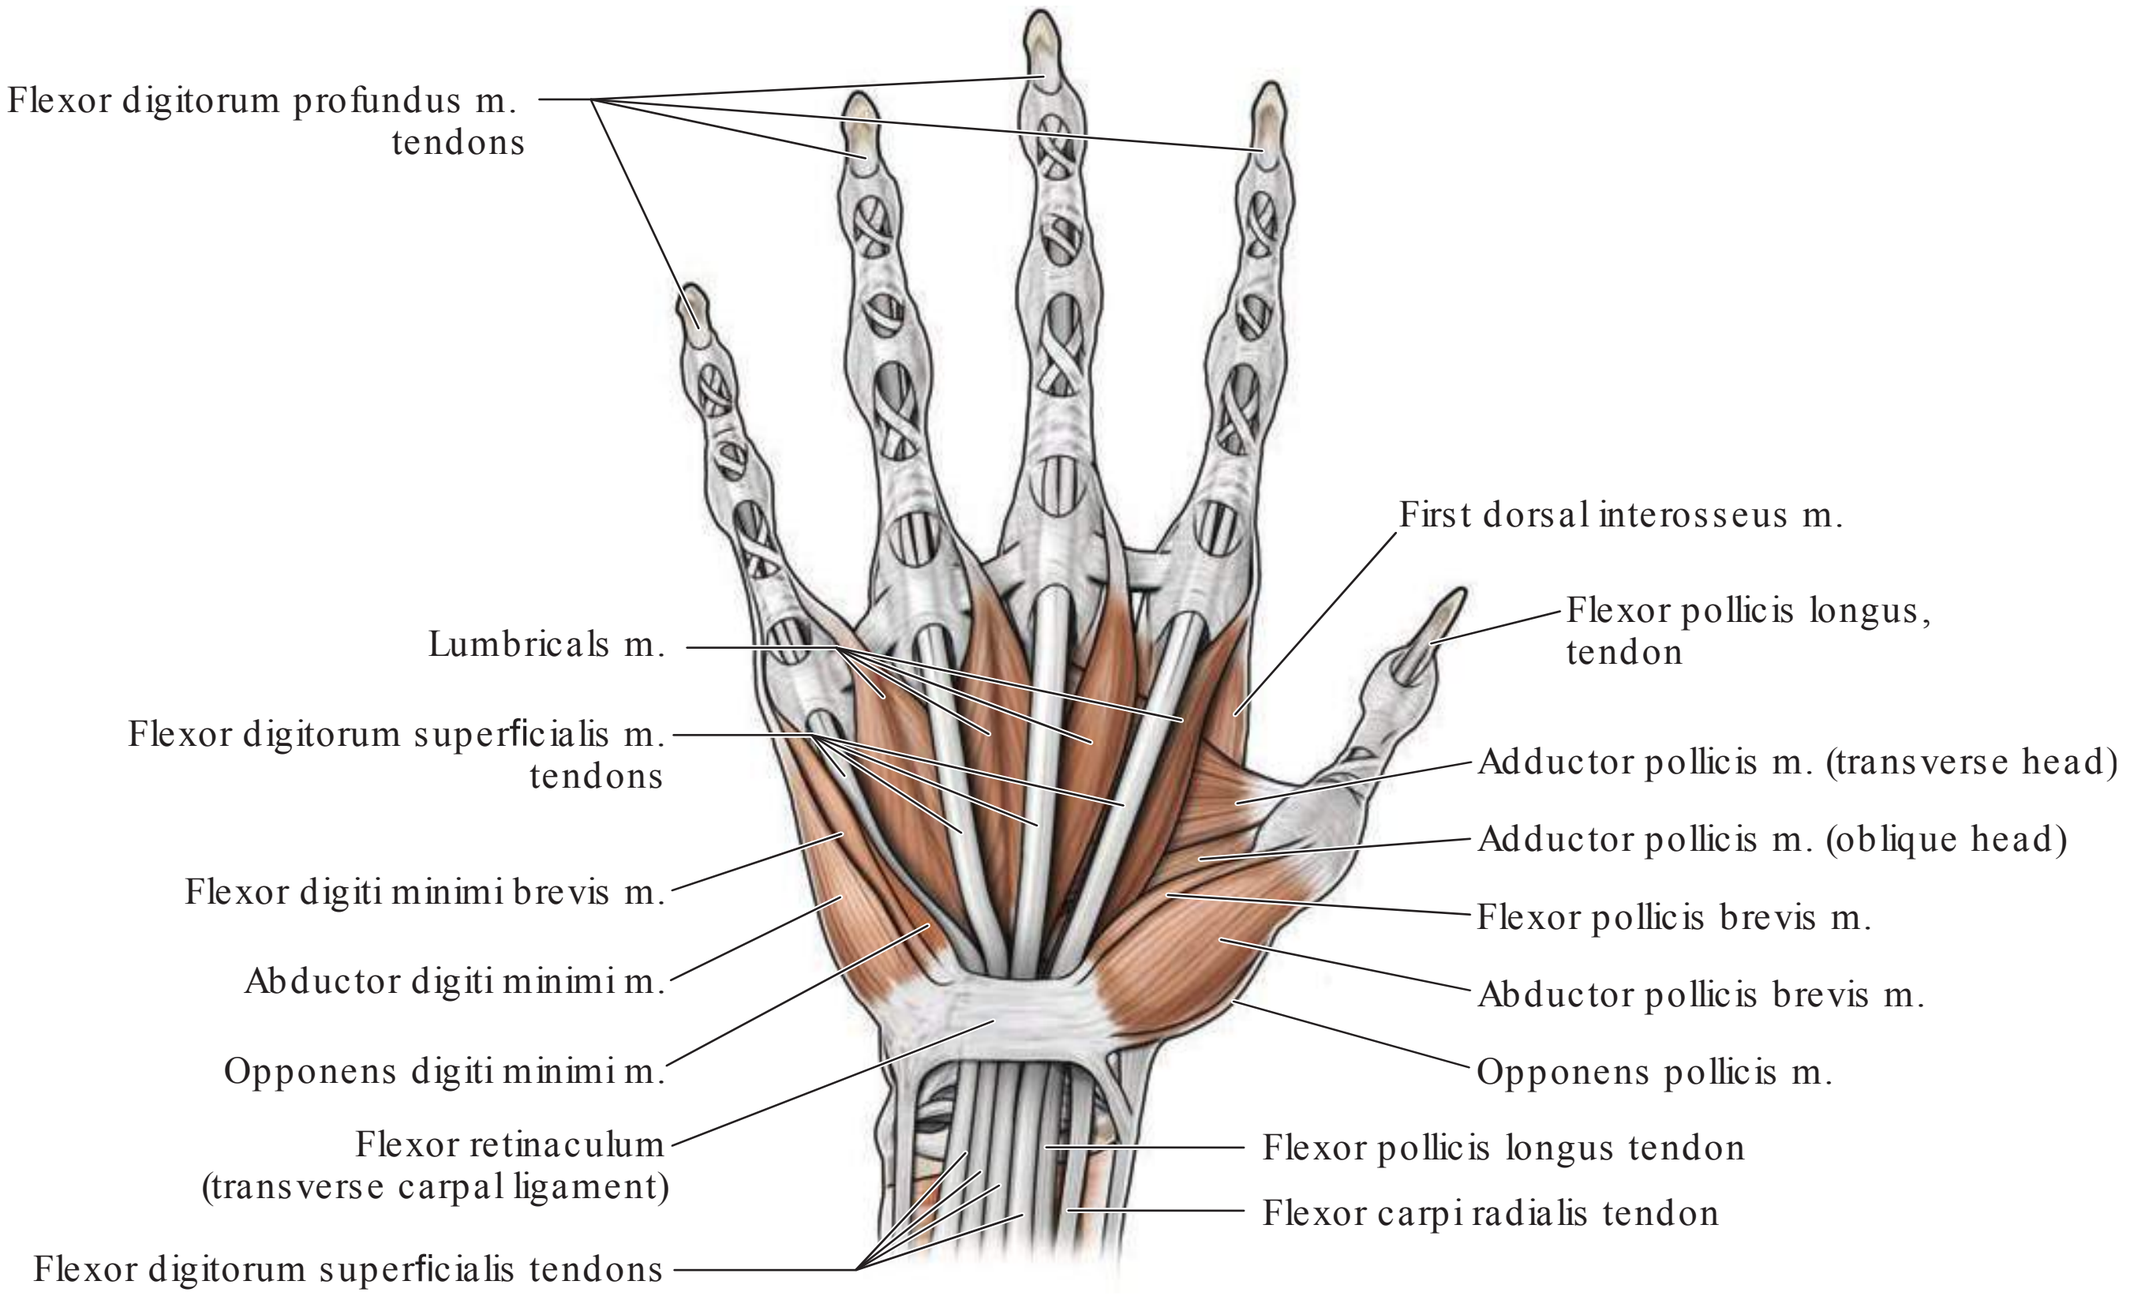

FIGURE 18-11 Muscles of the hand. (Reproduced, with permission, from Chapter 33. Hand. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

Interosseous Muscles of the Hand

The interossei muscles of the hand are divided by anatomy and function into anterior (palmar) and posterior (dorsal) interossei.

Anterior (Palmar) Interossei

The three anterior (palmar) interossei have a variety of origins and insertions. The first interosseous originates from the ulnar surface of the second metacarpal bone and inserts on the ulnar side of the proximal phalanx of the second digit. The second anterior (palmar) interosseous arises from the radial side of the fourth metacarpal bone and inserts on the radial side of the proximal phalanx of the fourth digit. The third anterior (palmar) interosseous originates from the radial side of the fifth metacarpal bone and inserts on the radial side of the proximal phalanx of the fifth digit. The anterior (palmar) interossei are innervated by the deep branch of the ulnar nerve, and each muscle functions to adduct the digit to which it is attached toward the middle digit. The anterior (palmar) interossei also function to extend the distal and then the middle phalanges.

Posterior (Dorsal) Interossei

The four posterior (dorsal) interossei have a similarly varied origin and insertion as their anterior (palmar) counterparts. The posterior (dorsal) interossei originate via two heads from adjacent sides of the metacarpal bones. The first posterior (dorsal) interosseous muscle inserts into the radial side of the proximal phalanx of the second digit. The second inserts into the radial side of the proximal phalanx of the third digit. The third inserts into the ulnar side of the proximal phalanx of the third digit and the fourth inserts into the ulnar side of the proximal phalanx of the fourth digit. The posterior (dorsal) interossei receive their innervation from the deep branch of the ulnar nerve. The posterior (dorsal) interossei abduct the index, middle and ring fingers from the midline of the hand.

Lumbricals

The lumbrical muscles are usually four small intrinsic muscles of the hand that originate from the FDP tendons and insert into the posterior (dorsal) hood apparatus. Occasionally, more than four lumbricals are found in one hand.[39]

During contraction, they pull the FDP tendons distally, thus possessing the unique ability to relax their own antagonist.[6] They function to perform the motion of IP joint extension with the MCP joint held in extension and can assist in MCP flexion.[23]

The lumbrical muscles also serve an important role in the proprioception of the hand, providing feedback about the position and movement of the hand and finger joints.[6]

In instances of lumbrical spasm or contracture, attempts to flex the fingers via the profundus result in transmission of force through the lumbricals into the extensor apparatus, producing extension rather than flexion.[6] A "lumbrical plus" deformity occurs if there is excessive lumbrical force, or if there is imbalance of opposing forces, which produces exaggerated lumbrical action (i.e., MCP joint flexion and IP joint extension).[6]

The lumbricals have dual innervation. Lumbricals I and II are innervated typically by the median nerve while the third and fourth lumbricals are innervated by the ulnar nerve.

Neurology

The three peripheral nerves that supply the skin and muscles of the wrist and hand include the median, ulnar, and radial nerves (Fig. 18-12).

Median Nerve

The median nerve enters the forearm by coursing anteriorly through the medial aspect of the cubital fossa and passing deep to the lacertus fibrosis, between the heads of the pronator teres muscle. Below the elbow, muscular branches leave the nerve and innervate the FCR, palmaris longus, and pronator teres muscles. The anterior interosseous branch innervates the pronator quadratus, FPL, and the FDP to the index finger and middle fingers and sometimes the ring finger.

Approximately 8 cm proximal to the wrist, the median nerve gives off a sensory branch, the anterior (palmar) cutaneous nerve that passes superficial to the flexor retinaculum and remains outside the carpal tunnel. This nerve innervates the skin of the central aspect of the palm, over the thenar eminence. The rest of the median nerve passes distally to the wrist, where it enters the carpal tunnel, which passes deep to the flexor retinaculum.

The nerve enters the hand through the carpal tunnel, deep to the tendon of the palmaris longus and in between the tendons of the FPL and FDS (the more radial of the two). From this point, the nerve divides into two branches: a motor branch which passes posterior (dorsal) to the flexor retinaculum and a sensory branch.

Motor Branch. This short branch enters the thenar eminence, where it usually supplies the APB and OP muscles, the FPB (occasionally), and the first and second lumbrical muscles.

Sensory Branch. The sensory anterior (palmar) digital branch innervates the anterior (palmar) surface and posterior (dorsal) aspect of the distal phalanges of the thumb, second and third fingers, and the radial half of the forefinger.

A number of median nerve entrapment syndromes exist (refer to "Peripheral Nerve Entrapment"), each with their own clinical features and functional implications. For example, entrapment of the median nerve in the carpal tunnel may result in numbness, pain, or paresthesia of the fingers and thumb and may severely hinder a patient's ability to perform precision maneuvers due to loss of critical sensory and motor function in the thumb, index, and middle fingers.

Ulnar Nerve

The ulnar nerve has been referred to as the nerve of fine movements of the hand. The ulnar nerve originates from the inferior roots of the brachial plexus (C8–T1). Two branches of the ulnar nerve arise in the midforearm:

- The anterior (palmar) cutaneous branch. The anterior (palmar) cutaneous branch supplies a portion of the skin over the hypothenar eminence.
- The posterior (dorsal) cutaneous branch. About 8–10 cm proximal to the ulnar styloid process, the posterior (dorsal) cutaneous branch of the ulnar nerve splits from the main trunk. The posterior (dorsal) cutaneous branch terminates into two posterior (dorsal) digital branches that supply sensation to the posterior (dorsal) and ulnar aspect of the middle phalanx of the ring and little fingers.[40]

Before reaching the wrist, the ulnar nerve branches to innervate the FDP and the FCU.

At the wrist, the ulnar nerve emerges just lateral to the tendon of the FCU as it passes superficial to the flexor retinaculum. The ulnar nerve passes into the hand via the tunnel of Guyon, where it divides into its superficial and deep, terminal branches. The deep (motor) branch supplies the FDM, ADM, ODM, AP, palmaris brevis, third and fourth lumbricals, deep head of the FPB, and the interossei. The superficial branch, which is primarily sensory with the exception of its innervation to the palmaris brevis, divides into three branches.[40] The first of these three branches is a sensory branch to the ulnar aspect of the little finger, and the second is a sensory branch to the central ulnar anterior (palmar) area. The third branch often referred to as the common digital nerve, innervates the fourth intermetacarpal space. The common digital nerve further divides into two proper digital nerves supplying the ulnar portion of the ring finger and the radial portion of the little finger.[40]

A number of ulnar nerve entrapment syndromes exist (refer to "Peripheral Nerve Entrapment"), each with their own clinical features and functional implications.

Radial Nerve

As the radial nerve enters the cubital fossa, it typically splits into a superficial and deep branch. The superficial branch typically courses distally along the lateral border of the forearm under cover of the brachioradialis muscle and tendon. At the wrist, this branch divides into four to five digital branches, which provide cutaneous and articular innervation. The cutaneous innervation includes the lateral two-thirds of the dorsum of the hand and the posterior (dorsal) lateral 2½ fingers to the proximal phalanx.

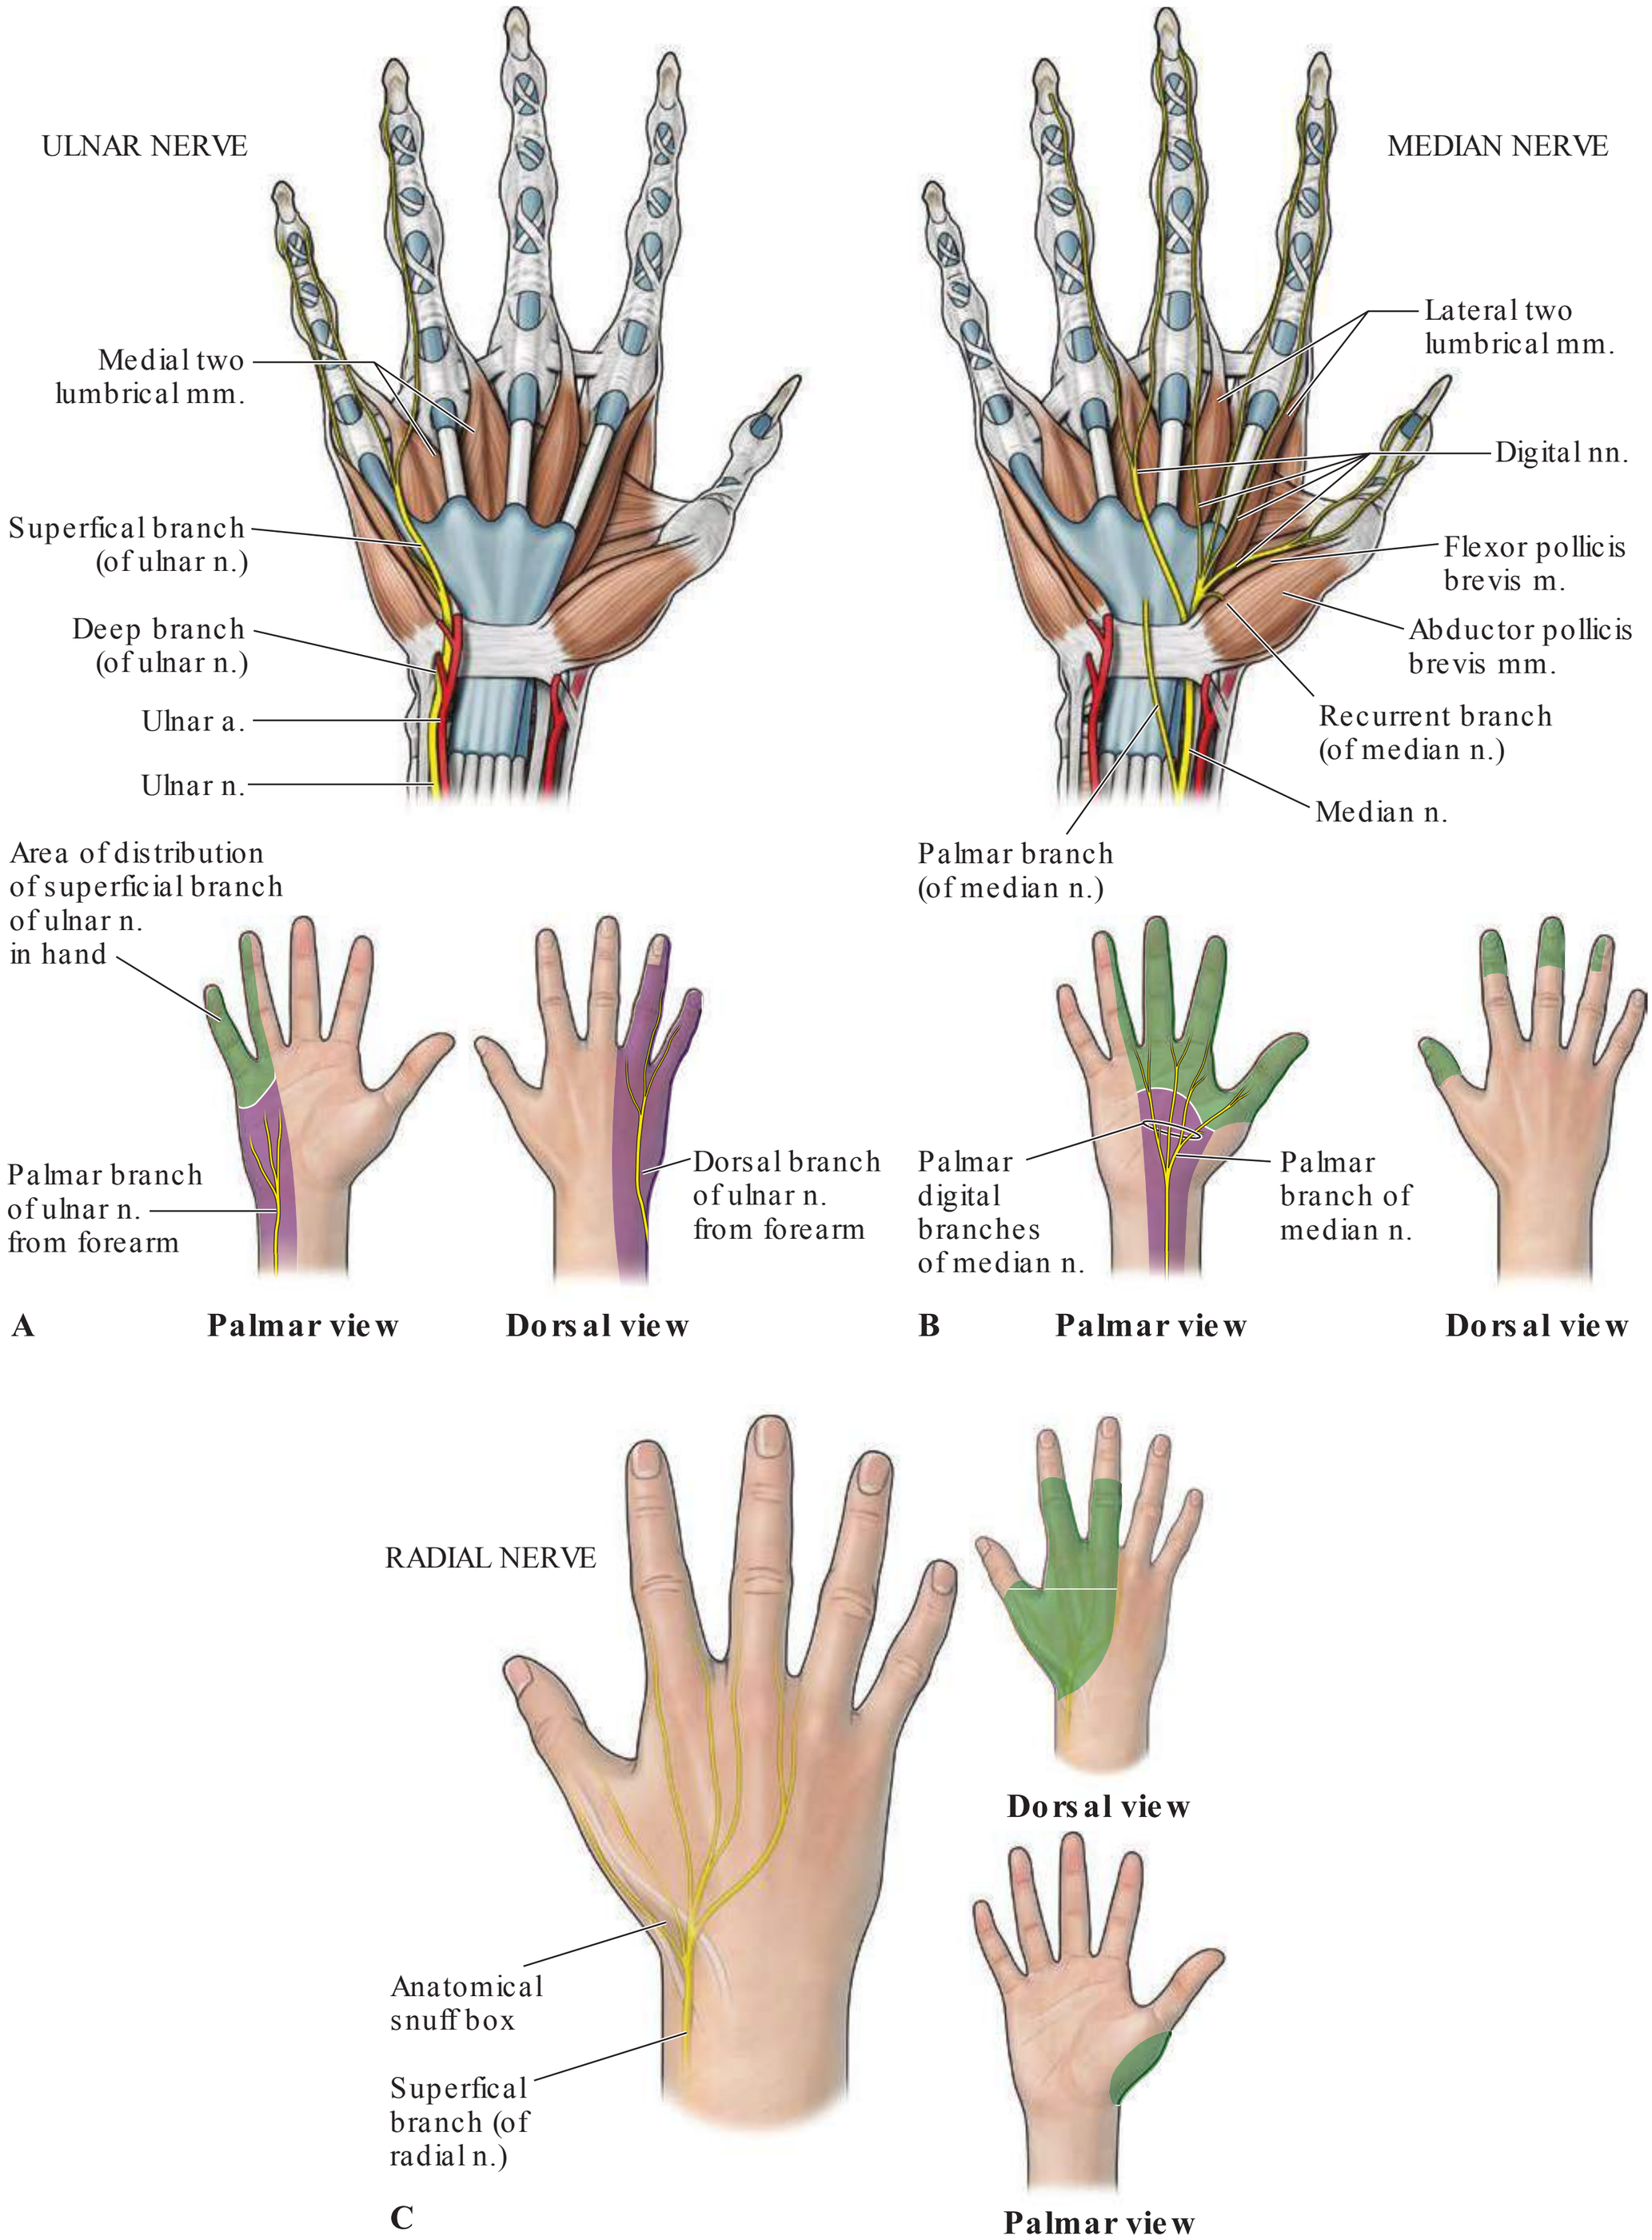
All of the motor branches of the radial nerve are located in the forearm. The deep branch (posterior interosseous nerve) typically penetrates the anterior (ventral) surface of, and passes through the supinator muscle. It reaches the deep region of the posterior forearm by passing through the arcade of Fröhse. The nerve courses subcutaneously from the midportion of the forearm to an area adjacent to the styloid process of the radius and terminates on the posterior aspect of the wrist.

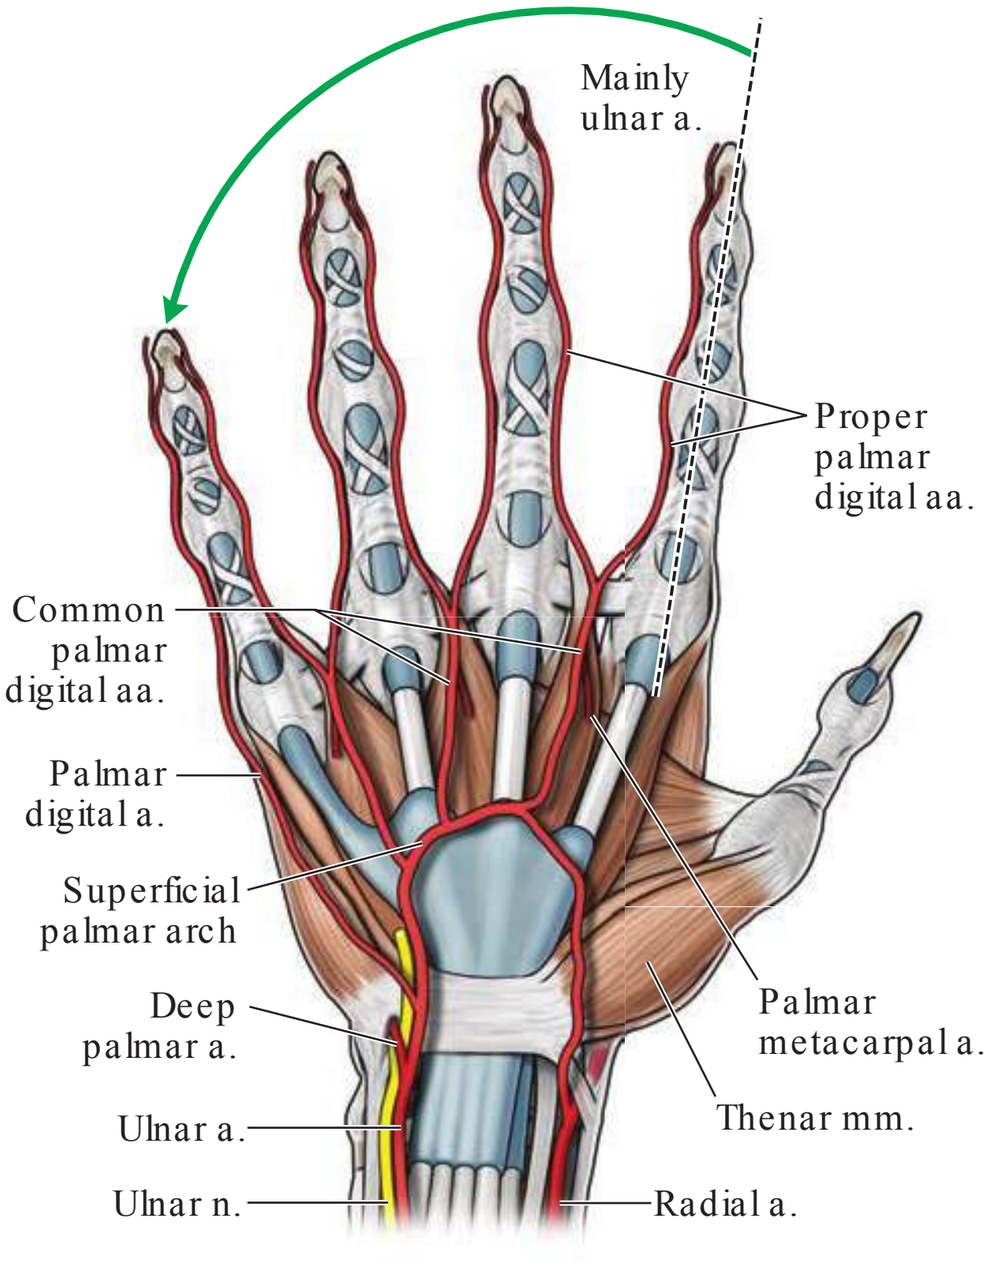
CLINICAL PEARL

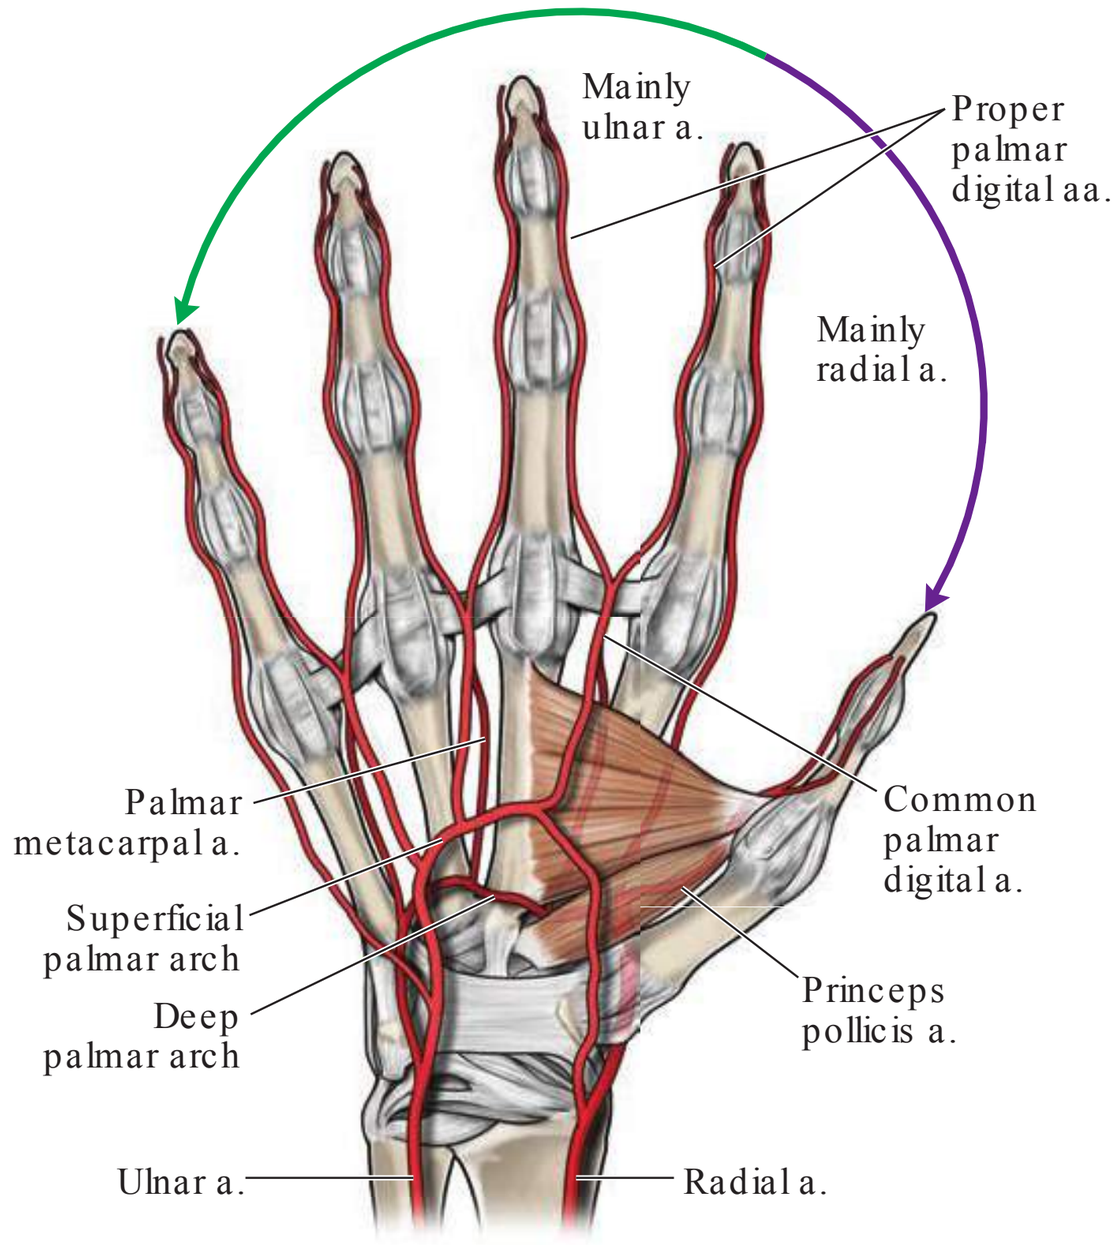
Radial nerve entrapment (refer to "Peripheral Nerve Entrapment") may result in a loss of extension at the wrist and MCP joints of the fingers, and thumb extension and abduction. Since the wrist extensor muscles are synergists and stabilizers for the finger flexor muscles during gripping, this loss can significantly hamper hand function.

Vasculature of the Wrist and Hand

The brachial artery bifurcates at the elbow into radial and ulnar branches, which are the main arterial branches to the hand (Fig. 18-13).







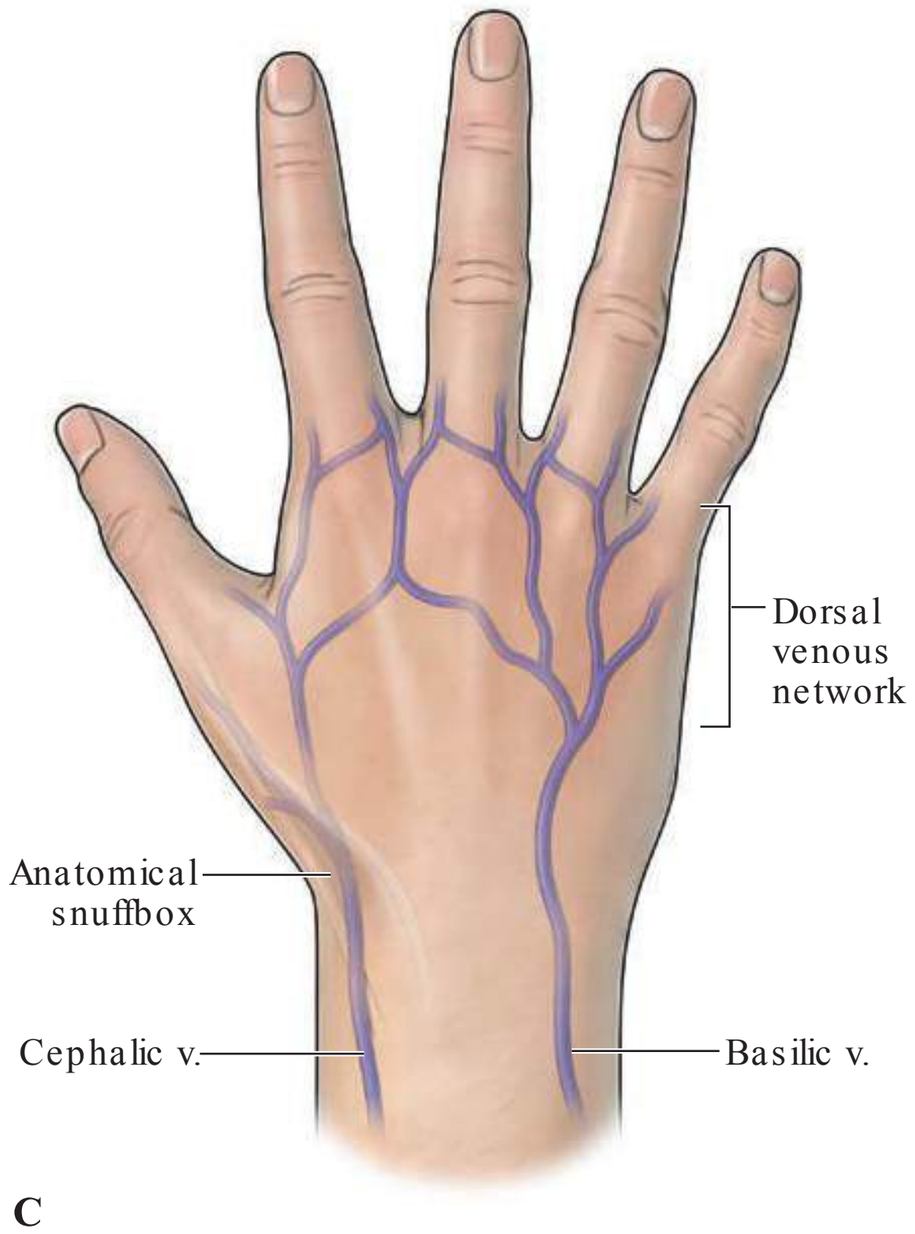


FIGURE 18-12 Nerves of the hand. (Reproduced, with permission, from Chapter 33. Hand. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

Radial Artery

The radial artery is formed from the lateral branch of the bifurcation of the brachial artery. The artery gives off branches in the proximal portion of the forearm that form an anastomosis around the elbow joint. It runs distally under the cover of the brachioradialis muscle. Just proximal to the wrist, it is located between the brachioradialis and the FCR tendons. A small branch called the superficial anterior (palmar) artery leaves the radial artery 5–8 mm proximal to the tip of the radial styloid, passes between the FCR and the brachioradialis, and continues distally to contribute to the superficial anterior (palmar) arch, which supplies the thenar mass. The radial artery has seven major carpal branches: three posterior (dorsal), three anterior (palmar), and a final branch that continues distally (see below).

Ulnar Artery

The ulnar artery originates as the medial branch of the bifurcation of the brachial artery. It too gives off branches in the proximal portion of the forearm that form an anastomosis around the elbow joint. The artery passes posterior (dorsal) to the ulnar head of the pronator teres and courses distally deep to the FDS, at which point it passes in the groove between the FCU and FDP, in the company of the ulnar nerve. In the proximal portion of the forearm, the artery gives off a common interosseous branch. The artery bifurcates, giving rise to the anterior and posterior interosseous arteries, which provide blood to structures in the deep anterior and posterior compartments of the forearm. The artery emerges at the wrist, just lateral to the tendon of the FCU. It then passes through the tunnel of Guyon and enters the superficial compartment of the hand. At the level of the carpus, the ulnar artery gives off a latticework of fine vessels that span the posterior (dorsal) and anterior (palmar) aspects of the medial carpals. Proximal to the end of the ulna, there are three branches: a branch to the posterior (dorsal) radiocarpal arch, one to the anterior (palmar) radiocarpal arch, and one to the proximal pole of the pisiform and to the anterior (palmar) aspect of the triquetrum.[41]

Vascular Arches of the Hand

Posterior (Dorsal) Arches. The posterior (dorsal) arches are connected longitudinally at their medial and lateral aspects by the ulnar and radial arteries. They are connected centrally by the posterior (dorsal) branch of the anterior interosseous artery. There are three posterior (dorsal) transverse arches: the radiocarpal, the intercarpal, and the basal metacarpal[41]:

- Posterior (dorsal) radiocarpal. The radiocarpal arch is supplied by branches of the radial and ulnar arteries and the posterior (dorsal) branch of the anterior interosseous artery.
- Posterior (dorsal) intercarpal. The posterior (dorsal) intercarpal arch has a variable supply, which can include the radial, ulnar, and anterior interosseous arteries.
- Basal metacarpal. The basal metacarpal arch is supplied by perforating arteries from the second, third, and fourth interosseous spaces. It contributes to the vascularity of the distal carpal row through anastomoses with the intercarpal arch.
- Anterior (palmar) arches. Similar to the posterior (dorsal) vascularity, the anterior (palmar) vascularity is composed of three transverse arches: the anterior (palmar) radiocarpal, the anterior (palmar) intercarpal, and the deep anterior (palmar) arch[41]:
  - Anterior (palmar) radiocarpal. This arch supplies the anterior (palmar) surface of the lunate and triquetrum.
  - Anterior (palmar) intercarpal. This arch is small and is not a major contributor of nutrient vessels to the carpals.
  - Deep anterior (palmar). This arch contributes to the radial and ulnar recurrent arteries and sends perforating branches to the posterior (dorsal) basal metacarpal arch and to the anterior (palmar) metacarpal arteries.

BIOMECHANICS

The wrist is the key joint of the hand and contains several segments whose combined movements create a total range of motion that is greater than the sum of its individual parts.[23] The osteokinematics of the wrist are limited to two degrees of freedom: flexion–extension and ulnar–radial deviation (Fig. 18-14). Wrist circumduction—a full circular motion made by the wrist—is a combination of these movements.[42] The apparent axial rotation of the palm—called pronation and supination—occurs at the proximal and DRUJs, with the hand moving with the radius, not separately from it.[42] The arthrokinematics that occur at the joints of the wrist and hand are summarized in Table 10-6.

Pronation and Supination

The true axis for pronation–supination at the wrist may be situated anywhere between the radial and ulnar styloid, resulting in not one, but many pronation–supination axes.[43,44]

- Approximately 75–90 degrees of forearm pronation is available. During pronation, the concave ulnar notch of the radius glides around the peripheral surface of the relatively fixed convex ulnar head. Pronation is limited by the bony impaction between the radius and the ulna.
- Approximately 85–90 degrees of forearm supination is available. Supination is limited by the interosseous membrane and the bony impaction between the ulnar notch of the radius and the ulnar styloid process.

Congruency of the DRUJ surfaces is maximal at the midrange of motion, although the joint is not considered to be truly locked in this position.[6] At this position, the TFCC is maximally stretched, and the interosseous membrane is relatively lax.

At the joint surfaces, the concave radius slides in the same direction as the physiological motion so that it slides anteriorly with pronation and posteriorly with supination. The proximal and DRUJs are intimately related biomechanically, with the function and stability of both joints dependent on the configuration of, and the distance between, the two bones. This configuration and distance maintain ligament and muscle tension.[45] A change in the length of the ulna of as little

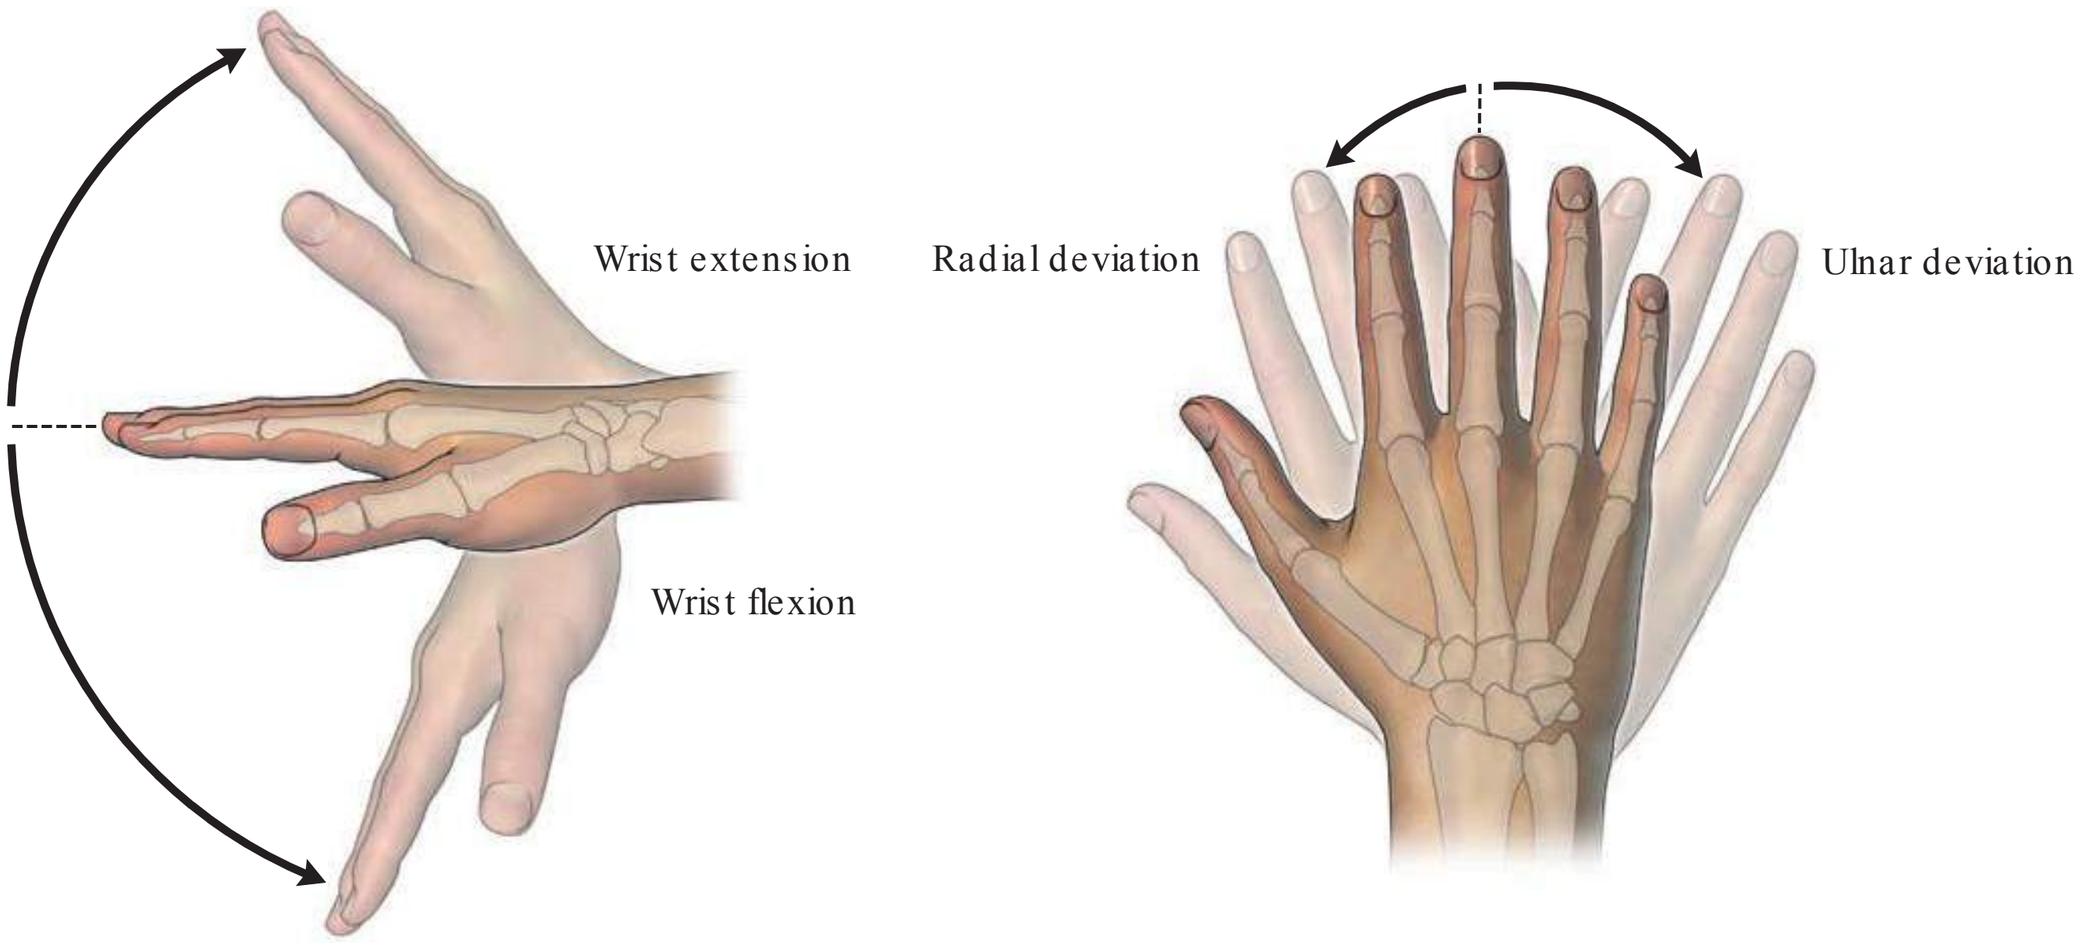

FIGURE 18-14 Movements of the wrist. (Reproduced, with permission, from Chapter 32. Forearm. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

as 2 mm results in a change in the transmission of forces of 5–40%.[46]

Movement of the Hand on the Forearm

Due to the morphology of the wrist, movement at this joint complex involves a coordinated interaction between a number of articulations. These include the radiocarpal joint, the proximal row of carpals, and the distal row of carpals. All of these joints permit the motion to occur around two axes: anterior–posterior in flexion–extension, and transverse in radial and ulnar deviation. Wrist extension is accompanied by a slight radial deviation and pronation of the forearm. Wrist flexion is accompanied by a slight ulnar deviation and supination of the forearm.

A number of concepts have been proposed over the years to explain the biomechanics of wrist motion.[47–60] The essential kinematics of the sagittal plane involve the mechanism of the carpal bone motions related to the central column of the wrist formed by the series of articulations among the radius, lunate, capitate, and third metacarpal bone.[42] Within this concept:

- the radiocarpal joint is represented by the articulation between the radius and lunate composed of the radius, scaphoid, trapezoid, trapezium, and the column of the thumb;
- the CMC joint is assumed to be a rigid articulation between the capitate and the base of the third metacarpal;
- The ulnar or medial compartment of the midcarpal joint is represented by the articulation between the lunate and capitate. This column strongly supports the movements in the central column, while simultaneously anchoring the wrist to the radius.[48]

Under the column concept, the radial and ulnar columns are proposed to move with the central column due to mutual displacements between the proximal facets of the scaphoid and lunate. In addition, the proximal carpals are considered to move at the radiocarpal and midcarpal levels.[23,49]

Flexion and Extension Movements of the Wrist

The movements of flexion and extension of the wrist are shared between the radiocarpal articulation and the intercarpal articulation in varying proportions.[19] The arthrokinematics are based on synchronous convex-on-concave rotations at the radiocarpal and midcarpal joints.[42]

- During wrist extension, most of the motion occurs at the radiocarpal joint (66.5% or 40 degrees vs. 33.5% or 20 degrees at the midcarpal joint) and is accompanied with slight radial deviation and pronation of the forearm.[19]
- During wrist flexion, most of the motion occurs in the midcarpal joint (60% or 40 degrees, vs. 40% or 30 degrees at the radiocarpal joint) and is accompanied by slight ulnar deviation and supination of the forearm.[19]

Extension

At the radiocarpal joint, extension occurs as the convex surfaces of the scaphoid and lunate roll posteriorly (dorsally) on the radius and simultaneously slide anteriorly (palmarly).[42] Rotation directs the lunate's distal surface in an extended, posterior (dorsal) direction. At the midcarpal joint, the convex head of the capitate rolls posteriorly (dorsally) on the concave lunate and simultaneously slides in an anterior (palmar) direction.[42] When the wrist is extended, the radiolunotriquetral and radiocapitate ligaments are stretched, and tension develops within the wrist and finger flexor muscles. Tension within the structures stabilizes the wrist in its close-packed position of extension.[42,61,62]

Loss of active extension in the wrist constitutes a considerable functional impairment, including the following[23]:

- A reduction in grip strength.
- Changes in muscle length–tension relationships, which has serious implications when considering the action of the extrinsic muscles of the hand. For example, the strength of the thumb and finger flexors requires normal motion and function of wrist extension.

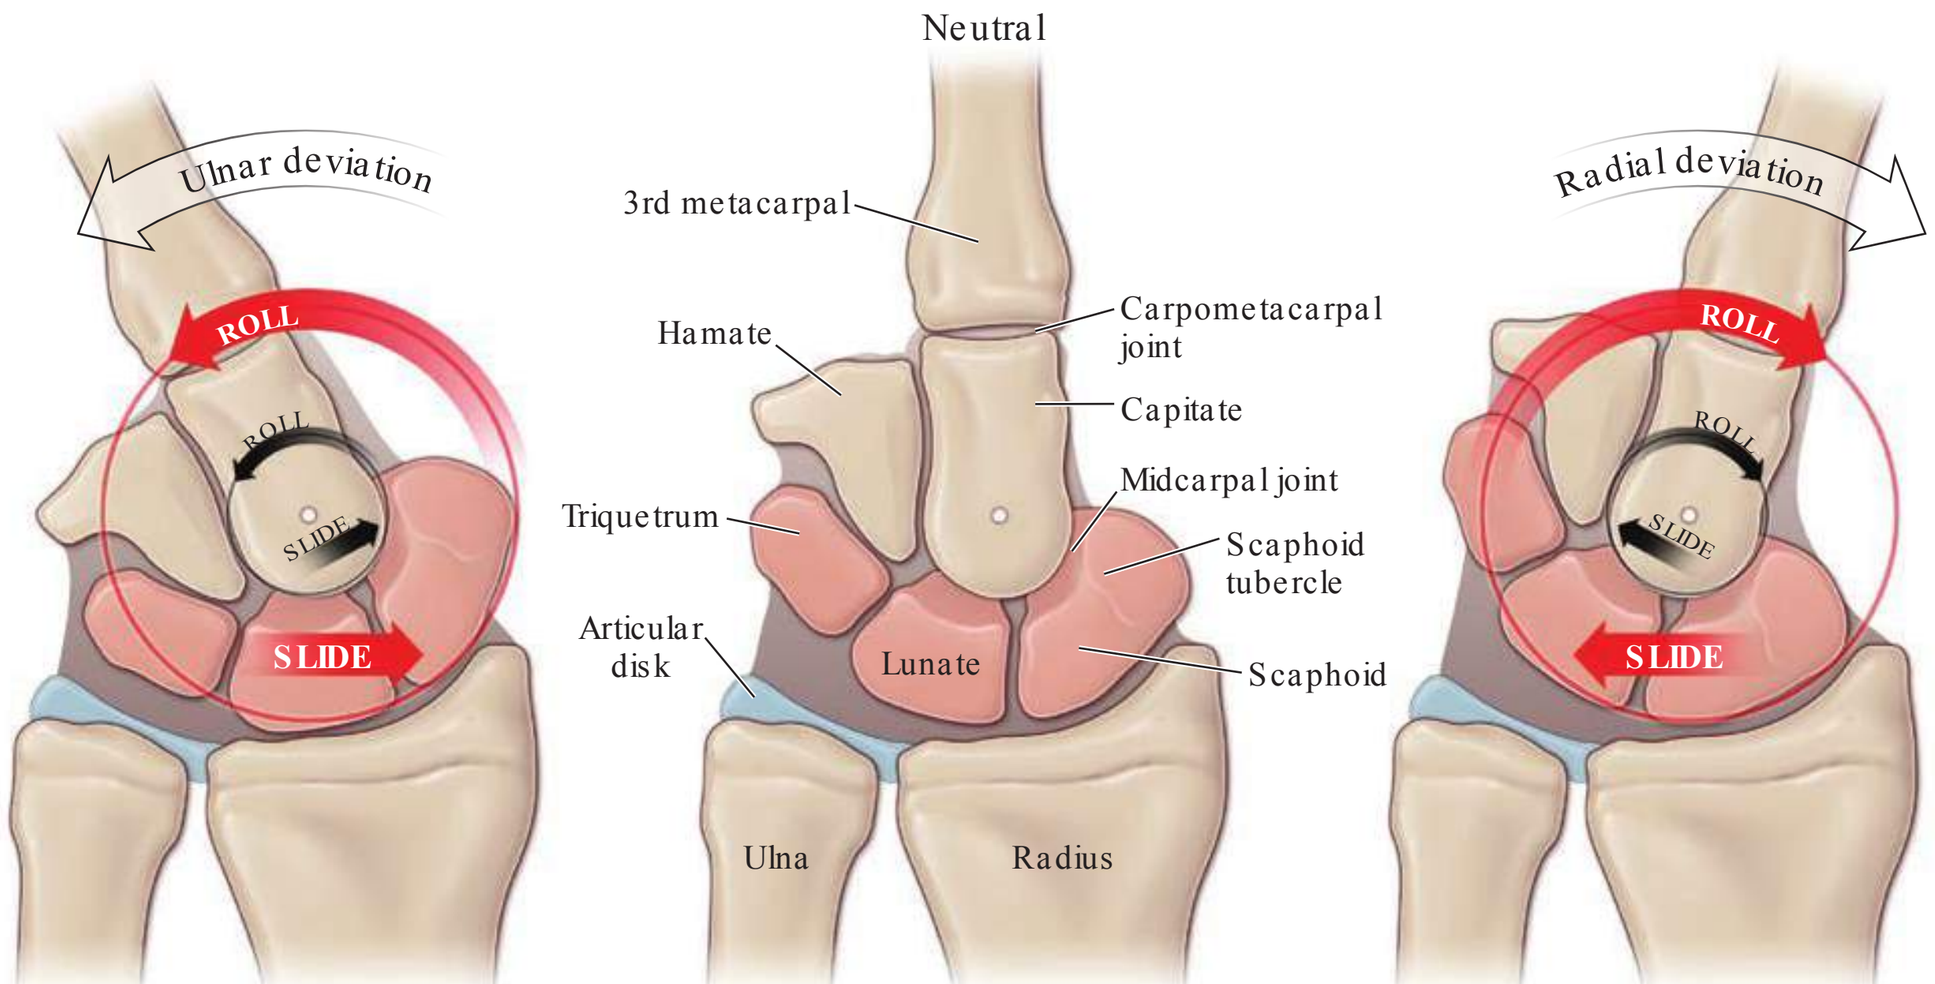

FIGURE 18-15 A model of the central column of the right wrist showing ulnar and radial deviation.

Flexion

The arthrokinematics of wrist flexion are similar to those described in extension but occur in a reverse fashion.

Frontal Lateral Movements of the Wrist

Like flexion and extension, the movements of ulna and radial deviation of the wrist are shared between the radiocarpal articulation and the intercarpal articulation in varying proportions (Fig. 18-15).[19] The amount of deviation is approximately 40 degrees of ulnar deviation and 15 degrees of radial deviation. There is a physiological ulnar deviation at rest, which is easily demonstrated clinically and radiographically.

Ulnar Deviation

Ulnar deviation occurs primarily at the radiocarpal joint.[62] During ulnar deviation, the radiocarpal and midcarpal joints contribute fairly equally to the overall motion (Fig. 18-15).[42] At the radiocarpal joint, the scaphoid, lunate, and triquetrum roll ulnarly and slide a significant distance radially.[42] Ulnar deviation of the midcarpal joint occurs primarily from the capitate rolling ulnarly and sliding slightly radially.[42] Ulnar deviation is limited by the radial collateral ligament.[62] Although ulnar deviation brings the triquetrum into contact with the TFCC, the lack of direct ulnar-triquetral articulation permits a greater range of ulnar deviation. The muscle with the best biomechanical advantage to produce ulnar deviation of the wrist in pronation is the ECU.[23]

Radial Deviation

Radial deviation at the wrist occurs through similar arthrokinematics as described for ulnar deviation (Fig. 18-15).[42] Radial deviation occurs primarily between the proximal and the distal rows of the carpal bones. The motion of radial deviation is limited by the impact of the scaphoid onto the radial styloid and the UCL. The APL and EPB are best suited to produce radial deviation of the wrist.[23]

CLINICAL PEARL

Extension of the wrist is accompanied by radial deviation, and flexion of the wrist is accompanied by ulnar deviation. The wrist also allows relatively extensive traction and gliding accessory movement.

A number of studies have examined the necessary range of motion at the wrist to perform functional activities. These studies report that at least 5 degrees of wrist flexion, 35 degrees of wrist extension, 10 degrees of radial deviation, and 15 degrees of ulnar deviation are needed to perform common personal care activities comfortably.[63,64] Less motion is required for 90% of personal care activities: 5 degrees of flexion, 6 degrees of extension, 7 degrees of radial deviation, and 6 degrees of ulnar deviation.[65]

Wrist Movements and the Digits

The position of the wrist in flexion or extension influences the tension of the long or "extrinsic" muscles of the digits. The position of the wrist also has important repercussions on the position of the thumb and fingers. Neither the flexors nor the extensors of the fingers are long enough to allow a maximal range of motion at the wrist and the fingers simultaneously.[23] In fact, due to the restraining action of the long antagonistic muscles, complete flexion of the fingers is possible only if the wrist is in approximately 20 degrees of extension, which corresponds to the optimal position for hand function.[23] Thus, the

movements of the wrist reinforce the action of the extrinsic muscles of the fingers and are synergistic with the more powerful digital flexors. As the wrist position changes, the functional lengths of the digital flexor tendons change, and the resultant forces in finger flexion vary. In order for grip to be effective and have maximal force, the wrist must be stable and positioned in slight extension and ulnar deviation.[23]

Articulations of the Fingers

There are notable differences between the IP and MCP articulations of the digits and even between the articulations at the same level for each digit.[23] These differences are produced by

- the shape of the articulations (the articulating surface at the distal end of each phalanx is convex while the articulating surface at the proximal end of each phalanx is concave);
- the orientation of the articular surface;
- the synovial insertion;
- the disposition of the collateral ligaments;
- the degree of play in the volar plate.

These elements determine the degree of mobility and stability of these articulations and the orientation of the distal segments. As the thumb pulp pronates in opposition, the pulps of the fingers supinate during external rotation when the MCP joints flex, or when the index finger moves radially. These variations in orientation allow for optimal use of the finger pulps for functional tasks of the hand (see Functional Position of the Hand).[23]

CLINICAL PEARL

The goal of functional restoration for the MCP joint flexion is 75 degrees for the index finger and middle finger, 80 degrees for the ring finger, and 85 degrees for the little finger.[23]

Thumb Movements

The first CMC joint is a saddle joint. The characteristic feature of a saddle joint is that each articular surface is concave in one diameter and convex in the other. Within the first CMC joint, the longitudinal diameter of the articular surface of the trapezium is generally concave from an anterior (palmar) to posterior (dorsal) direction, while the transverse diameter is generally convex along a medial to lateral direction. The proximal articular surface of the first metacarpal is reciprocally shaped to that of the trapezium. This articular relationship produces the following (Fig. 18-16):

- Thumb flexion and extension occur around an anterior–posterior axis in the frontal plane that is perpendicular to the sagittal plane of finger flexion and extension. In this plane, the metacarpal surface is concave, and the trapezium surface is convex. Flexion is accompanied by a conjunct rotation of internal rotation of the metacarpal. The extension is accompanied by a conjunct rotation of external rotation of the metacarpal. A total range of 50–70 degrees is available.
- Thumb abduction and adduction occur around a medial–lateral axis in the sagittal plane that is perpendicular to the frontal plane of finger abduction and adduction. During thumb abduction and adduction, the convex metacarpal surface moves on the concave trapezium. Abduction is accompanied by a conjunct rotation of internal rotation. Adduction is accompanied by a conjunct rotation of external rotation. A total range of 40–60 degrees is available.
- The opposition of the thumb involves a wide arc motion comprising sequential anterior (palmar) abduction and flexion from the anatomic position, accompanied by internal rotation of the thumb. Retroposition of the thumb returns the thumb to its anatomic position, a motion that incorporates the elements of adduction with extension and external rotation of the metacarpal.

Normal Ulnar Inclination of the Fingers

A normal ulnar inclination of the fingers occurs at the MCP joints due to a number of factors[23]:

- Asymmetry of the metacarpal heads and the collateral ligaments.
- Tendon factors: the extrinsic tendons, extensors, and flexors cross into the hand on the ulnar side of the longitudinal axis of the MCP joint.
- Muscle factors: the intrinsic muscles have a predominantly ulnar inclination and predominate over those with a radial inclination.
- The physiologic action of the thumb, which in lateral grip pushes the fingers in an ulnar direction.

The inclination is most marked in the index finger, less in the middle and little fingers, and almost nonexistent in the ring finger. The ulnar inclination is normally limited by the capsuloligamentous resistance at the MCP joints and by the action of the interosseous muscles, which act in a radial direction.[23] The

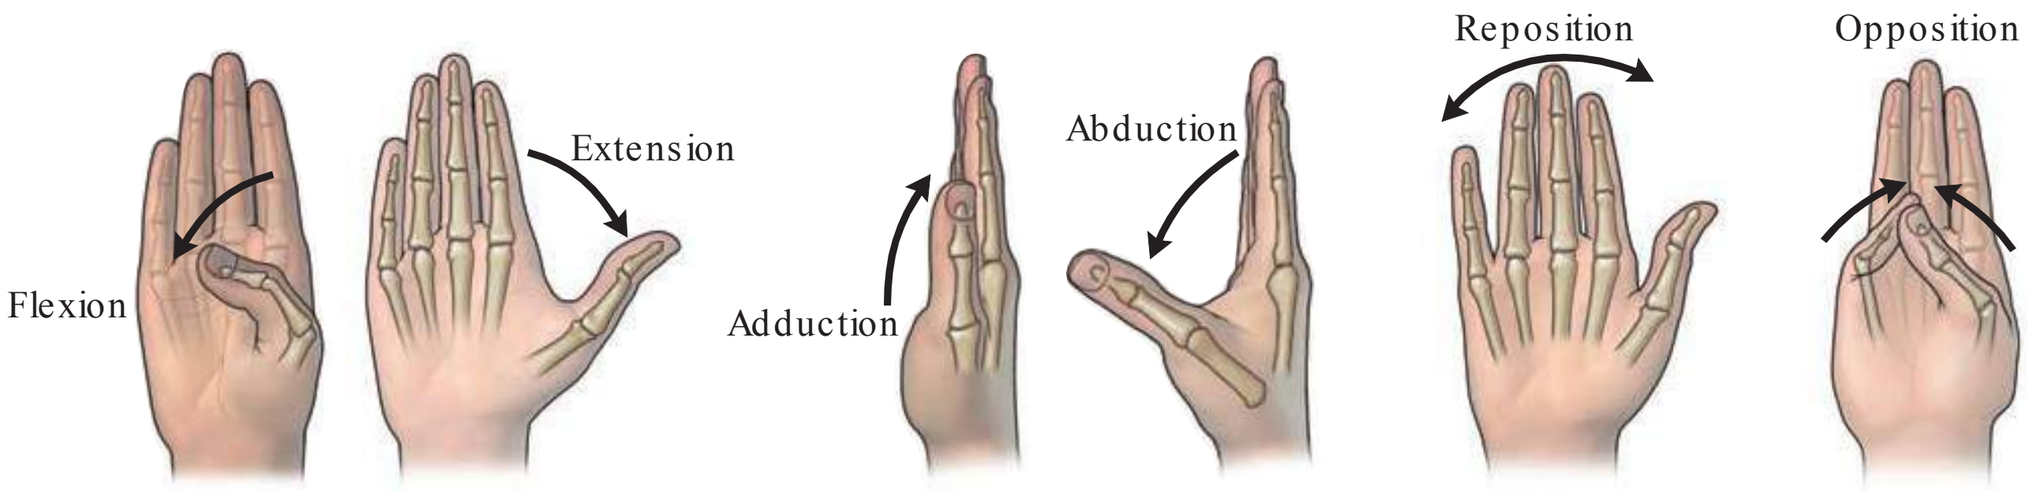

FIGURE 18-16 Thumb motions.

weakness of these stabilizing elements, particularly in rheumatoid arthritis (RA), allows the ulnar inclination to be accentuated, resulting in pathologic ulnar deviation.

Functional Position of the Hand

Grips

The grip is typically divided into the following stages[66,67]:

- Opening of the hand.
- Positioning and closing of the fingers to grasp an object and adapt to the object's shape.
- Controlled approach and purposeful closing of the fingers and/or palm. The amount of force exerted is determined by the weight, surface characteristics, and fragility of the object.[68]
- Maintenance and stabilization of the grip. This phase is not used in precision tasks.
- The release of the object.

Two major types of grips have been recognized: power grip and the precision or prehension grip.

Power Grip

The power grip involves the use of force to stabilize an object in the hand. The strength and power of a grip come from a combination of

- thumb adduction,
- isometric flexion,
- an approximation of the thenar and hypothenar eminences,
- intact function of the ulnar side of the hand.

The power grips include the following:

- Hook grasp. This grasp involves all or the second and third fingers (the IP joint only for the IP and MCP joints of the fingers) and is controlled by the forearm flexors and extensors (Fig. 18-17).
- Fist grasp. In this grasp, the hand moves around a narrow object (Fig. 18-18)

FIGURE 18-17 Hook grasp.

FIGURE 18-18 Fist grasp.

FIGURE 18-19 Cylindrical grasp.

FIGURE 18-20 Spherical grasp.

- Cylindrical grasp. In this grasp, the thumb is used, and the entire hand wraps around an object (Fig. 18-19)
- Spherical grasp. This grasp involves the hand moving around a spherical object as it moves into position (Fig.18-20)

FIGURE 18-21 Pulp-to-pulp pinch prehension.

Participation of the intrinsic muscles follows specific patterns in the various power grips. For example,

- the hook grip involves the fourth posterior (dorsal) interosseous, fourth lumbrical, and the ADM;
- the spherical grip involves all of the interossei (except the second), the ADM, and the fourth lumbrical.[69,70]

Precision Grip

In the precision grip, the muscles primarily function to provide exact control of finger and thumb position, so the position of the handled object can be changed either in space or about its own axis.[66,70] Due to the higher levels of sensory input required during these tasks, the areas with the most sensory receptors are used. A number of precision grips are recognized[23,62]:

- Pulp-to-pulp pinch, in which the pad of the thumb is opposed to the pad of one or more fingers (Fig. 18-21).
- Lateral prehension, where the anterior (palmar) aspect of the thumb presses against the radial aspect of the first phalanx of the index finger (Fig. 18-22).
- *T*ip prehension, in which the extreme tip of the thumb pad is opposed to the tip of the index or middle finger.
- T ree-*f*ingered pinch (thumb, index finger, and middle finger), as in sprinkling herbs, and multi-fingered pinch (Fig. 18-23).

FIGURE 18-22 Lateral prehension.

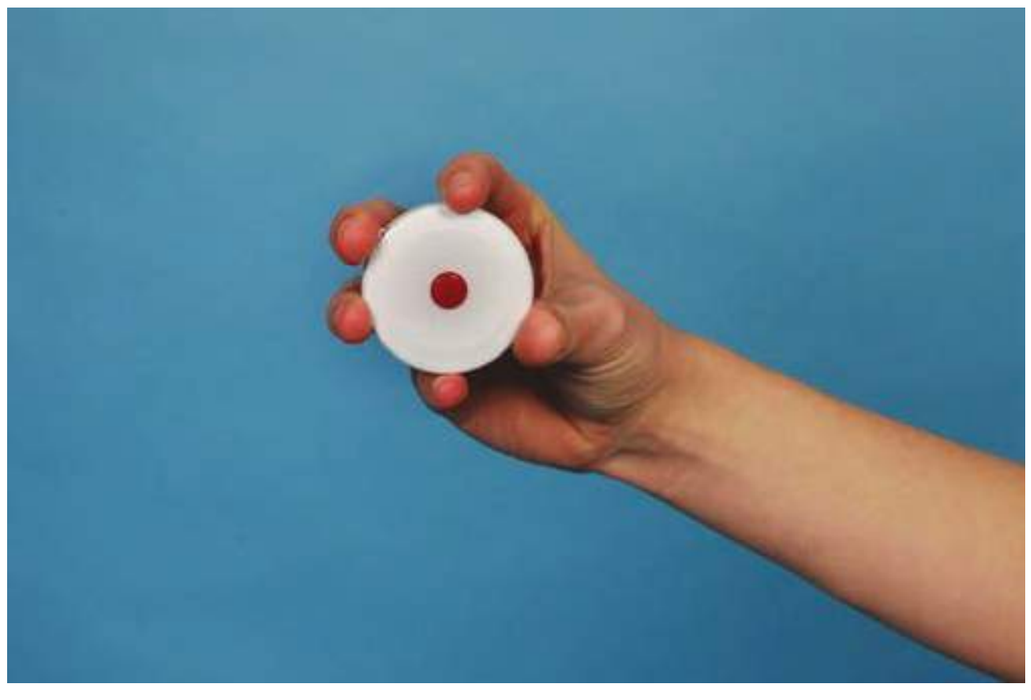

FIGURE 18-23 Multi-fingered pinch.

- Five-*f*ingered pinch, as in picking up a face towel (Fig. 18-24).

T e radial side of the hand and the MCP joints are involved more in the precision or prehensile types of grips.[23,62]

Different grip patterns are used regularly during daily functional activities (Table 18-3).[1,71]

EXAMINATION

Elucidating the cause of forearm, wrist, and hand pain can be challenging. T e examination must include all regions that may contribute to the symptoms of the forearm, wrist, and hand pain or numbness. T is requires a sound knowledge of differential diagnosis and often incorporates an examination of the entire upper kinetic chain, including the cervical and thoracic spine.

T e common pathologies for the forearm, wrist, and hand and their interventions are detailed after the "Examination" section. An understanding of both is obviously necessary. As mention of the various pathologies occurs with reference to the tests and measures and vice versa, the reader is encouraged to switch between the two.

History

T e assessment of the forearm, wrist, and the hand begins by recording a detailed history to help focus the examination. All

Data from McPhee SD. Functional hand evaluations: a review. Am J Occup Ther. 1987;41:158–163.

relevant information must be gathered about the site, nature, behavior, and the onset of the current symptoms. This should include information about the patient's age, hand dominance, avocational activities, and occupation.

CLINICAL PEARL

The nonneutral position of the hand are the extreme positions of extension, flexion, or ulnar deviation.[72,73] Sustained nonneutral positions of the hand and wrist subject nerves to prolonged stretch and periods of high pressure.[74] In addition, these positions place muscles in inefficient length–tension relationships,[73] resulting in decreased transmission of contractile forces[73,75] to the fingers.

In addition to those questions covered in Chapter 4, the following questions should be asked:

- When did the symptoms occur? The date of injury is particularly important, especially as simple traumatic arthritis of the wrist does not last more than a few days if the wrist is rested.
- Was there a mechanism of injury? If the problem is trauma related, the clinician should ascertain the following:
  - The forces applied. For example, a rotational force applied to the wrist region may lead to a fracture of the radius and dislocation of the distal end of the ulna (Galeazzi fracture).
  - Where and when the injury occurred.
  - The position of the wrist and hand at the time of the trauma. For example, a fall on the outstretched hand (FOOSH) injury can lead to a lunate dislocation, Colles fracture, or scaphoid fracture.
  - Whether the environmental conditions were clean or dirty (if a wound is present).
  - Whether there was an accompanying "pop" or "click."
  - Whether swelling occurred.

If the problem is nontrauma related, the onset of pain or sensory change, swelling, or contracture should be ascertained.

- Are there any local areas of tenderness? Localized tenderness may indicate a carpal fracture, particularly of the scaphoid. Scaphoid fractures are associated with a load applied to the radial side of the palm when the wrist is in extreme extension,[76] and can be ongoing sources of pain and dysfunction (refer to "Intervention Strategies"). Pain along the radial aspect of the wrist and forearm is a common symptom for several pathoanatomical diagnoses, including de Quervain disease, intersection syndrome, intercarpal instabilities, scaphoid fracture, superficial radial neuritis, C6 cervical radiculitis/radiculopathy, and arthrosis of the first CMC, intercarpal, or radiocarpal joints.[77]
- How does the patient rate his or her pain? The patient's perception of their pain can be measured using a visual analog scale.
- What is the behavior of the symptoms? The clinician should note the sequence of symptoms, the level of functional impairment, the progression of symptoms, the time of day the symptoms are worse, and whether the symptoms appear to be posture-related or work-related. Knowledge of the past behavior of previous wrist, hand, and finger disorders and their interventions can help in assessing the nature and prognosis of the patient's current problem.
- Which hand is the dominant hand (DH) of the patient? Dysfunction of the DH can be very disabling, so inquiries concerning the functional demands of the patient must be made.

Systems Review

A complete review of the medical history and general health of the patient should be included along with a review of systems, and the presence of other orthopaedic, neurologic, or cardiopulmonary conditions. An upper quarter scanning examination is performed to provide an overview of the upper extremity, the direction for a more detailed examination, and to rule out referral from the cervical, thoracic, shoulder girdle, and elbow joints.

The clinician should be able to determine the suitability of the patient for physical therapy. All inflammatory conditions, whether infectious or not, are accompanied by diffuse pain or tenderness with movement. RA often affects this region with more severity and frequency than elsewhere. Therefore, questions concerning other joint involvement and general debility must be asked. The presence of CTS, which is usually felt more at night, may also indicate RA.

If the clinician is concerned with any signs or symptoms of a visceral, vascular, neurogenic, psychogenic, spondylogenic, or systemic disorder that is out of the scope of physical therapy (see Chapter 5), the patient should be referred back to their physician.

Tests and Measures

Observation

The physical examination should begin with a general observation of the patient's posture—especially the cervical spine, the thoracic spine, and the position of the hand in relation to the body. For example, is the arm held against the chest in a protective manner, does the arm swing during the gait pattern, or does it just hang loosely? The patient's hands can be highly informative (Table 18-4). Although very subtle,

TABLE 18-4 Outline of Physical Findings of the Hand

I. Variations in size and shape of hand
- A. Large, blunt fingers (spade hand)
  1. Acromegaly
  2. Hurler disease (gargoylism)
- B. Gross irregularity of shape and size
  1. Paget disease of bone
  2. Maffucci syndrome
  3. Neurofibromatosis
- C. Spider fingers, slender palm (arachnodactyly)
  1. Hypopituitarism
  2. Eunuchism
  3. Ehlers–Danlos syndrome, pseudoxanthoma elasticum
  4. Tuberculosis
  5. Asthenic habitus
  6. Osteogenesis imperfecta
- D. Sausage-shaped phalanges
  1. Rickets (beading of joints)
  2. Granulomatous dactylitis (tuberculosis, syphilis)
- E. Spindliform joints (fingers)
  1. Early rheumatoid arthritis
  2. Systemic lupus erythematosus
  3. Psoriasis
  4. Rubella
  5. Boeck sarcoidosis
  6. Osteoarthritis
- F. Cone-shaped fingers
  1. Pituitary obesity
  2. Frohlich dystrophy
- G. Unilateral enlargement of hand
  1. Arteriovenous aneurysm
  2. Maffucci syndrome
- H. Square, dry hands
  1. Congenital hypothyroidism
  2. Myxedema
- I. Single, widened, flattened distal phalanx
  1. Sarcoidosis
- J. Shortened fourth and fifth metacarpals (bradymetacarpalism)
- K. Shortened, incurved fifth finger (symptom of DuBois)
  1. Down syndrome
  2. Behavioral problem
  3. Gargoylism (broad, short, thick-skinned hand)
- L. Malposition and abduction, fifth finger
  1. Turner syndrome (gonadal dysgenesis, webbed neck, etc.)
- M. Syndactylism
  1. Congenital malformations of the heart, great vessels
  2. Multiple congenital deformities
  3. Laurence–Moon–Biedl syndrome
  4. In normal individuals as an inherited trait
- N. Clubbed fingers
  1. Subacute bacterial endocarditis
  2. Pulmonary causes
     a. Tuberculosis
     b. Pulmonary arteriovenous fistula
     c. Pulmonic abscess
     d. Pulmonic cysts
     e. Bullous emphysema
     f. Pulmonary hypertrophic osteoarthropathy
     g. Bronchogenic carcinoma
  3. Alveolocapillary block
     a. Interstitial pulmonary fibrosis
     b. Sarcoidosis
     c. Beryllium poisoning
     d. Sclerodermatous lung
     e. Asbestosis
     f. Miliary tuberculosis
     g. Alveolar cell carcinoma
  4. Cardiovascular causes
     a. Patent ductus arteriosus
     b. Tetralogy of Fallot
     c. Taussig–Bing complex
     d. Pulmonic stenosis
     e. Ventricular septal defect
  5. Diarrheal states
     a. Ulcerative colitis
     b. Tuberculous enteritis
     c. Sprue
     d. Amebic dysentery
     e. Bacillary dysentery
     f. Parasitic infestation (gastrointestinal tract)
  6. Hepatic cirrhosis
  7. Myxedema
  8. Polycythemia
  9. Chronic urinary tract infections (upper and lower)
     a. Chronic nephritis
  10. Hyperparathyroidism (telescopy of distal phalanx)
  11. Pachydermoperiostosis (syndrome of Touraine, Solente, and Gole)
- O. Joint disturbances
  1. Arthritides
     a. Osteoarthritis
     b. Rheumatoid arthritis
     c. Systemic lupus erythematosus
     d. Gout
     e. Psoriasis
     f. Sarcoidosis
     g. Endocrinopathy (acromegaly)
     h. Rheumatic fever
     i. Reiter syndrome
     j. Dermatomyositis
  2. Anaphylactic reaction-serum sickness
  3. Scleroderma

II. Edema of the hand
- A. Cardiac disease (congestive heart failure)
- B. Hepatic disease
- C. Renal disease
  1. Nephritis
  2. Nephrosis
- A. Hemiplegic hand
- B. Syringomyelia
- C. Superior vena caval syndrome
  1. Superior thoracic outlet tumor
  2. Mediastinal tumor or inflammation
  3. Pulmonary apex tumor
  4. Aneurysm
- A. Generalized anasarca, hypoproteinemia
- B. Postoperative lymphedema (radical breast amputation)
- C. Ischemic paralysis (cold, blue, swollen, numb)
- D. Lymphatic obstruction
  1. Lymphomatous masses in axilla
- A. Axillary mass
  1. Metastatic tumor, abscess, leukemia, Hodgkin disease
- A. Aneurysm of ascending or transverse aorta or of axillary artery
- B. Pressure on innominate or subclavian vessels
- C. Raynaud disease
- D. Myositis
- E. Cervical rib
- F. Trichiniasis
- G. Scalenus anticus syndrome

III. Neuromuscular effects
- A. Atrophy
  1. Painless
     a. Amyotrophic lateral sclerosis
     b. Charcot–Marie–Tooth peroneal atrophy
     c. Syringomyelia (loss of heat, cold, and pain sensation)
     d. Neural leprosy
  2. Painful
     a. Peripheral nerve disease
  3. Radial nerve (wrist drop)
     a. Lead poisoning, alcoholism, polyneuritis, trauma
     b. Diphtheria, polyarteritis, neurosyphilis, anterior poliomyelitis
  4. Ulnar nerve (benediction palsy)
     a. Polyneuritis, trauma
  5. Median nerve (claw hand)
     a. Carpal tunnel syndrome
  6. Rheumatoid arthritis
  7. Tenosynovitis at wrist
  8. Amyloidosis
  9. Gout
  10. Plasmacytoma
  11. Anaphylactic reaction
  12. Menopause syndrome
  13. Myxedema
- B. Extrinsic pressure on the nerve (cervical, axillary, supraclavicular, or brachial)
  1. Pancoast tumor (pulmonary apex)
  2. Aneurysms of subclavian arteries, axillary vessels, or thoracic aorta

1. Myocardial infarction
2. Pancoast tumor
3. Brain tumor
4. Intrathoracic neoplasms
5. Discogenic disease
6. Cervical spondylosis
7. Febrile panniculitis
8. Senility
9. Vascular occlusion
10. Hemiplegia
11. Osteoarthritis
12. Herpes zoster

D. Ischemic contractures (sensory loss in fingers)
1. Tight plaster cast applications

E. Polyarteritis nodosa

F. Polyneuritis
1. Carcinoma of lung
2. Hodgkin disease
3. Pregnancy
4. Gastric carcinoma
5. Reticuloses
6. Diabetes mellitus
7. Chemical neuritis
   a. Antimony, benzene, bismuth, carbon tetrachloride, heavy metals, alcohol, arsenic lead, gold, emetine
8. Ischemic neuropathy
9. Vitamin B deficiency
10. Atheromata
11. Arteriosclerosis
12. Embolic

G. Carpodigital (carpopedal spasm) tetany
1. Hypoparathyroidism
2. Hyperventilation
3. Uremia
4. Nephritis
5. Nephrosis
6. Rickets
7. Sprue
8. Malabsorption syndrome
9. Pregnancy
10. Lactation
11. Osteomalacia
12. Protracted vomiting
13. Pyloric obstruction
14. Alkali poisoning
15. Chemical toxicity
    a. Morphine, lead, alcohol

H. Tremor
1. Parkinsonism
2. Familial disorder
3. Hypoglycemia
4. Hyperthyroidism
5. Wilson disease (hepatolenticular degeneration)
6. Anxiety
7. Ataxia
8. Athetosis
9. Alcoholism, narcotic addiction
10. Multiple sclerosis
11. Chorea (Sydenham, Huntington)

Data from Berry TJ. The Hand as a Mirror of Systemic Disease. Philadelphia, PA: FA Davis Co; 1963; Juddge RD, Zuidema GD, Fitzgerald FT. General appearance. In: Judge RD, Zuidema GD, Fitzgerald FT, eds. Clinical Diagnosis. 4th ed. Boston, MA: Little, Brown and Company; 1982:29–47.

the DH tends to be larger than the nondominant hand. The posture and alignment of the involved wrist and hand are examined. Wrist angulation into ulnar deviation increases shearing in the first posterior (dorsal) compartment. This angulation can predispose the patient to de Quervain syndrome (see "Intervention Strategies").[78] A prominence of the distal ulna may indicate DRUJ instability.[79] The clinician should observe how the patient appears to relate to the involved hand and if or how the patient attempts to use the hand.[11] The contour of the anterior (palmar) surface, including the arches, should be examined. If a finger is involved, its attitude should be observed. Digital deformities are the hallmark of RA.[80]

A visual inspection of the involved wrist and hand is made and is compared with the uninvolved side. The clinician inspects for lacerations, surgical scars, masses, swelling, or erythema.

- Scars should be examined for degree of adherence, the degree of maturation, hypertrophy (excess collagen within the boundary of the wound), and keloid (excess collagen that no longer conforms to wound boundaries).
- The location and type of edema should be noted. Edema, the accumulation of fluid in the intercellular spaces, is a common consequence of surgery or injury to the hand. A determination is made as to whether the swelling is generalized or localized, hard or soft. Anterior effusion over the flexor tendons at the wrist may indicate rheumatoid tendovaginitis. Swelling that persists more than a few days following a trauma probably suggests a carpal fracture. Localized swelling accompanied by redness and tenderness may indicate an infection. Measuring edema is an important part of the physical examination of individuals with conditions affecting the wrist and hand. Volumetry, a clinical application of Archimedes principle of water displacement as a measure of volume, is considered the gold standard for measuring hand size.[81] This method involves lowering the limb into a water-filled Plexiglass or metal tank (the volumeter) and measuring the amount of water displaced.[82] The reliability and validity of volumetric measurements are well established.[81] However, this method is time consuming and requires specialized equipment. An alternative method of measuring is the figure-of-eight method. Compared to the volumetric method, the figure-of-eight method is more practical for clinical use as the procedure takes less time to perform and requires equipment that is less expensive and is readily available in most clinical settings.[81] The correct application of the tape is described in Table 18-5. Leard et al.[81] reported the figure-of-eight method to be a reliable and valid measure of hand size in individuals with conditions affecting the hand.

CLINICAL PEARL

The normal physiologic angles for relaxed hand posture are 14–15 degrees of ulnar deviation for the index finger, 13 degrees for the middle finger, 4 degrees for the ring finger, and 7–8 degrees for the little finger.

The swan-neck deformity is one of the most frequently encountered deformities of the fingers (see "Intervention

TABLE 18-5 Figure-of-Eight Taping Method

Step	Description
1	The starting point for the tape measure is the outermost aspect (medial surface using anatomical position as a reference) of the most distal aspect of the ulna styloid process
2	The tape measure is drawn across the anterior (ventral) surface of the wrist to the most distal aspect of the radial styloid process
3	The tape measure is placed diagonally across the posterior (dorsal) aspect of the hand with the proximal surface of the tape measure placed over the fifth metacarpophalangeal (MCP) joint line
4	The tape measure is then brought across the anterior (ventral) surface of the MCP joints and the proximal surface of the tape measure is positioned over the second MCP joint line
5	The tape measure is wrapped diagonally across the dorsum of the hand back to the starting point

Data from Leard JS, Breglio L, Fraga L, et al. Reliability and concurrent validity of the figure-of-Eight method of measuring hand size in patients with hand pathology. J Orthop Sports Phys Ther. 2004;34:335–340.

Strategies").[80] When it occurs in the thumb it is referred to as a zigzag deformity. Any other finger deformities such as mallet finger and boutonniere (see "Rheumatoid Arthritis") are noted (Table 18-6). Other hand deformities include the following:

- Ulnar drift. The classic deformity of ulnar drift and ulnar deviation is associated with RA (although it can occur in other conditions) and the MCP joints. The deformity occurs due to the cumulative effects of various factors. Initially, the MCP joint capsule and ligamentous structures are stretched by the proliferation of the synovium, which loosens the collateral ligaments and decreases joint stability (see "Rheumatoid Arthritis").
- Extensor plus. This is deformity results from either shortening of the extensor communis tendon or adherence of the tendon to the first part of the proximal phalanx at the extensor hood. It results in the inability to flex the PIP and MCP joints simultaneously, although each joint can be flexed normally individually.
- Myelopathy hand. This is deformity, which is characterized by a loss of power in abduction and extension of the ulnar fingers, is caused by cervical spinal cord pathology in conjunction with cervical spondylosis.[83] Confirmation of this finding is made when lower motor neuron findings are seen at the level of the lesion while upper motor neuron findings are seen below the level of the lesion.

The nails should be inspected to see if they are healthy and pink (Table 18-7). Local trauma to the nails seldom involves more than one or two digits. The nails should be checked for hangnail infection or whether they appear ridged, which could indicate an RA dysfunction. Clubbed nails are an indication of hypertrophy of underlying structures. The presence of a paronychia or a pale paronychia should prompt the clinician to probe the axilla and neck lymph nodes for tenderness and swelling. Beau lines are transverse furrows that begin at the lunula and progress distally as the nail grows. They result from a temporary arrest of growth of the nail matrix occasioned by trauma or systemic stress.[84] With the knowledge that nails grow about 0.1 mm/day, by measuring the distance between the Beau lines and the cuticle, one may be able to approximately determine the date of the stress. For example, if the distance is 5 mm, the stress event occurred approximately 50 days before. Spoon nails (koilonychias) may occur in a form of iron deficiency anemia (Plummer–Vinson syndrome), coronary disease, and with the use of strong detergents.[84] Clubbing of the nails, characterized by a bulbous enlargement of the distal portion of the digits, may occur in association with cardiovascular disease, subacute endocarditis, advanced cor pulmonale, and pulmonary disease.[84]

Finger color should be observed. Fingers that are white in appearance might indicate Raynaud disease (see Chapter 5). Blotchy or red fingers might indicate liver disease. Blue fingers may indicate a circulatory problem.

Intrinsic muscle fibrosis is characterized by stiffness of the IP joints. On flexion of the MCP joint, extension of the fingers becomes tight and flexion is restricted. On extension of the MCP joint, flexion of the IP joints is possible.

- Adhesions proximal to the MCP joint allow the lumbrical action (i.e., MCP flexion and PIP and DIP joint extension).
- Adhesions distal to the MCP joints result in the ability to extend the MCP and flex the PIP and DIP joints, but there is no extension possible in the fingers.

Palpation

Palpation of the wrist and hand is an integral component of the physical examination. Palpation may be performed separately or with the range-of-motion tests. Fortunately, most of the structures are superficial (Fig. 18-25), so a sound knowledge of surface anatomy is essential. The findings from palpation can often be confirmed using a specific special test (see "Special Tests"). Palpation of the following muscles, tendon, insertions, ligaments, capsules, and bones should occur as indicated and be compared with the uninvolved side for tenderness and/or swelling.

Trapezium

The trapezium is located immediately proximal to the base of the first metacarpal bone, just distal to the scaphoid. The tubercle of the trapezium lies anteriorly at the base of the thenar eminence. It can be made more prominent by opposing the thumb to the little finger and ulnarly deviating the wrist. Tenderness over this carpal may indicate scaphotrapezial arthritis secondary to scaphoid instability.[13]

Thumb CMC Joint

To examine the thumb CMC joint, the clinician palpates carefully along the shaft of the thumb metacarpal down to its proximal flare. Just proximal to this flare is a small depression where the CMC joint is located. By applying direct radial

TABLE 18-6 Hand and Finger Deformities and Their Possible Causes

Deformity	Possible Cause
MCP joint flexion	Rupture of the extensor tendon just proximal to the MCP joint
Hyperextension of the MCP joint	Paralysis of the interossei
Deepening of the anterior (palmar) gutter and an inability to fully stretch out the palm	Tightness of the anterior (palmar) aponeurosis
Wasting of the hypothenar eminence and a clawed hand with flexion of the fourth and fifth digits (hand of benediction)	Ulnar nerve palsy
Wrist drop with increased flexion of the wrist, flexion of the MCP joint, and extension of the DIP joints	Radial nerve lesion
Isolated thenar atrophy	Arthritis of the CMC joint Median nerve lesion C8 or T1 nerve root lesion
Ape-hand deformity with a wasting of the thenar eminence and an inability to oppose or flex the thumb or abduct it in its own plane[83]	Median nerve palsy
Z-deformity of the wrist	Pattern of deformity in the rheumatoid hand[84]
Atrophy of the hand intrinsics	Pancoast tumor
Claw-hand deformity	Loss of ulnar nerve motor innervation to the hand, with resultant paralysis of the interosseous muscles, and muscle atrophy of the hypothenar eminence; this deformity is more severe in lesions distal to innervation of the FDP muscle, as this muscle adds to the flexion force upon the IP joints[6]
PIP hyperextension and slight flexion of the DIP	Rupture or paralysis of the FDS
A fixed flexion deformity of the MCP and PIP joints, especially in the ring or little finger	Dupuytren contracture
A hook-like contracture of the flexor muscles, which is worse with wrist extension as compared to flexion	Volkmann ischemic contracture

DIP, distal interphalangeal; FDP, flexor digitorum profundus; MCP, metacarpophalangeal; PIP, proximal interphalangeal.

and ulnar stresses to the joint, the clinician can determine the overall stability of the joint as compared to the other thumb. Tenderness here is usually indicative of degenerative arthritis.

EPB, APL, and FCR Tendons

The EPB and APL tendons make up the first extensor compartment on the dorsum of the wrist and together form the radial border of the anatomic snuffbox. The APL is the first prominent tendon medially. The prominence of these tendons can be enhanced by extending and radially abducting the thumb. Tenderness over these tendons may indicate de Quervain tenosynovitis. Just medial to the APL is the radial artery with the FCR tendon, which inserts on the second metacarpal, situated medially.

Flexor Retinaculum

The flexor retinaculum, which can be palpated just medial to the FCR, transforms the carpal arch into the carpal tunnel. It is attached medially to the pisiform and hook of the hamate and laterally to the tubercle of the scaphoid and tubercle of the trapezium. Its proximal edge is at the distal crease of the wrist. The retinaculum can be the location for a retinacular cyst which, because of its firmness, is frequently mistaken for a bony spur.

Hamate

The hook of the hamate is palpated just distal and radial (in the direction of the thumb web space) to the pisiform on the anterior (palmar) aspect. Locating the hamate can be made easier if the clinician places the middle of the distal phalanx of the thumb on the pisiform, with the thumb pointing between the web space between the index and long finger. The clinician flexes the IP joint of the thumb and presses into the hypothenar eminence to feel the firm hook. The hook of the hamate is concave laterally, and the ulnar nerve's superficial division, which is just lateral and proximal to the hook, can be rolled on it. Tenderness over this carpal is common, and so the clinician should compare findings with the other side. Severe tenderness could indicate a fracture of the hamate, especially if associated with a FOOSH injury or a missed hit swing of a racket or bat.[85] The FCU tendon surrounds the hamate as it inserts on the pisiform.

TABLE 18-7 Glossary of Nail Pathology

Condition	Description	Occurrence
Beau lines	Transverse lines or ridges marking repeated disturbances of nail growth	Systemic diseases, toxic or nutritional deficiency states of many types, trauma (from manicuring)
Defluvium unguium (onychomadesis)	Complete loss of nails	Certain systemic diseases, such as scarlet fever, syphilis, leprosy, alopecia areata, and exfoliative dermatitis; dermatoses such as nail infection, psoriasis, eczema; arsenic poisoning.
Diffusion of lunula unguis	Spreading of lunula	Dystrophies of the extremities
Eggshell nails	Nail plate thin, semitransparent bluish-white, with a tendency to curve upward at the distal edge	Syphilis
Fragilitas unguium	Friable or brittle nails	Dietary deficiency, local trauma
Hapalonychia	Nails very soft, split easily	Following contact with strong alkalis; endocrine disturbances, malnutrition, syphilis, chronic arthritis
Hippocratic nails	Watch-glass nails associated with drumstick fingers	Chronic respiratory and circulatory diseases, especially pulmonary tuberculosis; hepatic cirrhosis
Koilonychia	"Spoon nails"; nails are concave on the outer surface	Dysendocrinisms (acromegaly), trauma, dermatoses, syphilis, nutritional deficiencies, hypothyroidism
Leukonychia	White spots or striations or rarely the whole nail may turn white (congenital type)	Local trauma, hepatic cirrhosis, nutritional deficiencies, and many systemic diseases
Mees lines	Transverse white bands	Hodgkin granuloma, arsenic and thallium toxicity, high fevers, local nutritional derangement
Moniliasis of nails	Infections (usually paronychial) caused by yeast forms (Candida albicans)	Occupational (common in food handlers, dentists, dishwashers, and gardeners)
Onychatrophia	Atrophy or failure of development of nails	Trauma, infection, dysendocrinism, gonadal aplasia, and many systemic disorders.
Onychauxis	Nail plate is greatly thickened	Mild persistent trauma, systemic diseases, such as peripheral stasis, peripheral neuritis, syphilis, leprosy, hemiplegia, or at times may be congenital
Onychia	Inflammation of the nail matrix causing deformity of the nail plate	Trauma, infection, many systemic diseases
Onychodystrophy	Any deformity of the nail plate, nail bed, or nail matrix	Many diseases, trauma, or chemical agents (poisoning, allergy)
Onychogryposis	"Claw nails"; extreme degree of hypertrophy, sometimes with horny projections arising from the nail surface	May be congenital or related to many chronic systemic diseases (see "Onychauxis")
Onycholysis	Loosening of the nail plate beginning at the distal or free edge	Trauma, injury by chemical agents, many systemic diseases
Onychomadesis	See defluvium unguium.	
Onychophagia	Nail biting	Neurosis
Onychorrhexis	Longitudinal ridging and splitting of the nails	Dermatoses, nail infections, many systemic diseases, senility, injury by chemical agents, hyperthyroidism
Onychoschizia	Lamination and scaling away of nails in thin layers	Dermatoses, syphilis, injury by chemical agents

TABLE 18-7	Glossary of Nail Pathology (Continued)	
Condition	**Description**	**Occurrence**
Onychotillomania	Alteration of the nail structures caused by persistent neurotic picking of the nails	Neurosis
Pachyonychia	Extreme thickening of all the nails; the nails are more solid and more regular than in onychogryposis	Usually congenital and associated with hyperkeratosis of the palms and soles
Pterygium unguis	Thinning of the nail fold and spreading of the cuticle over the nail plate	Associated with vasopastic conditions, such as Raynaud phenomenon and occasionally with hypothyroidism

Data from Berry TJ. The Hand as a Mirror of Systemic Disease. Philadelphia, PA: FA Davis Co; 1963; Judge RD, Zuidema GD, Fitzgerald FT. General appearance. In: Judge RD, Zuidema GD, Fitzgerald FT, eds. Clinical Diagnosis. 4th ed. Boston, MA: Little, Brown and Company; 1982:29–47.

Pisiform

The pisiform is located on the flexor aspect of the palm, on top of the triquetrum, at the distal crease. Tenderness of this structure may indicate pisotriquetral arthritis or inflammation of the FCU tendon.[4] The pisiform may be fractured from a direct fall or blow to the hypothenar aspect of the hand.

Triangular Fibrocartilage Complex

The TFCC is located distal to the ulnar styloid and proximal to the pisiform. Tenderness over this structure indicates an injury to the TFCC.[4]

Ulnar Head and Styloid Process

The ulnar head forms a rounded prominence on the ulnar side of the wrist, which is easily palpated on the posterior aspect of the hand with the forearm in pronation.[79] The ulnar styloid process is ulnar and distal to the head of the ulna. It is best located with the forearm in supination.

Radial Styloid Process

The radial styloid process is larger and rounder than the ulnar styloid process. It is best palpated at the most proximal point of the anatomic snuffbox (see below), during radial abduction of the thumb. With simultaneous radial deviation of the wrist, this prominence becomes visible. Tenderness over the styloid, especially with radial deviation, may indicate contusion, fracture, or radioscaphoid arthritis.[86]

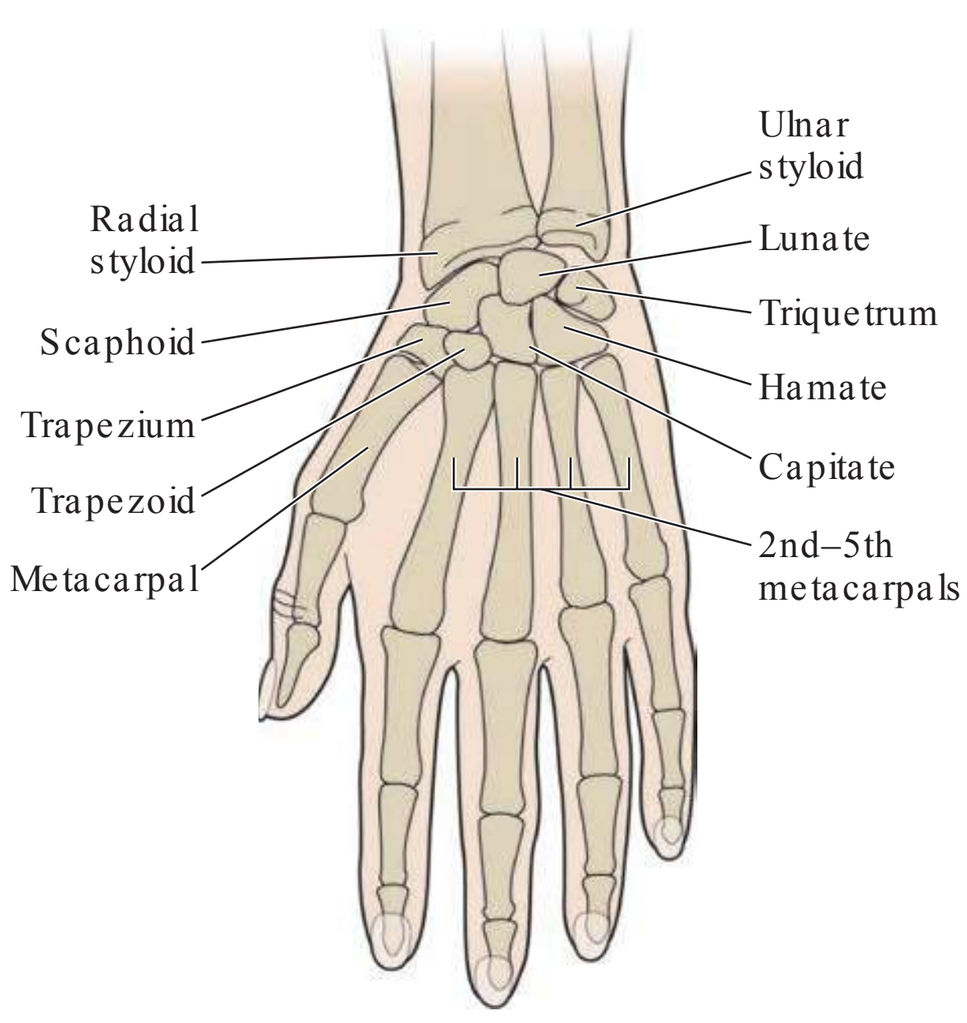

FIGURE 18-25 Bony structures of the hand.

Lister Tubercle

This is a small bony prominence on the posterior (dorsal) and distal end of the radius. It is found by sliding a finger proximally from a point between the index and the middle fingers. Just distal to Lister tubercle is the joint line of the scaphoid and radius. The ECRL and ECRB tendons travel radial to Lister tubercle and insert on the base of the second and third metacarpals. The extensor digitorum communis (EDC) tendon travels ulnarly to Lister tubercle. Radial to Lister tubercle and proceeding further radially are the tendons of the ECRB, ECRL, EPB, and APL.

Scaphoid

The scaphoid is palpated just distal to the radial styloid in the anatomic snuffbox. The neck of the scaphoid is located on the floor of the anatomic snuffbox. Palpation can be made easier by positioning the wrist in ulnar deviation. The scaphoid may be grasped and moved passively by firm pressure between an opposed index finger and thumb applied to the anterior (palmar) surface and anatomic snuffbox simultaneously. In most individuals, the scaphoid is mildly tender to palpation, but those with a scaphoid fracture, nonunion, or scaphoid instability have severe discomfort (see "Special Tests").[2,87]

Lunate

The lunate is located just distal and ulnar to Lister tubercle with the wrist flexed and is immediately proximal to and in line with, the capitate. The mobile lunate can be felt to glide posteriorly (dorsally) with extension. It is the most commonly dislocated carpal, and the scapholunate articulation is the most common area for carpal instability. Scapholunate synovitis [posterior (dorsal) wrist syndrome] or a scapholunate ligament injury presents with tenderness or fullness in this region.[2] Tenderness specific to the lunate can indicate Kienböck disease or osteonecrosis of the lunate.[88,89]

Capitate

The capitate is localized by palpating proximally over the posterior (dorsal) aspect of the third metacarpal until a small depression is felt. While palpating in this depression, as the

wrist is flexed, the clinician should feel the capitate, the central bone of the carpals, move posteriorly (dorsally). Tenderness in this depression may indicate scapholunate or lunotriquetral instability or capitolunate degenerative joint disease.

Second and Third Metacarpals

The base of the second and third metacarpals and the CMC joints are localized by palpating proximally along the posterior (dorsal) surfaces of the index and long metacarpals to their respective bases.[79] A bony prominence found at the base of the second or third metacarpal may be a carpal boss, a variation found in some individuals due to hypertrophic changes of traumatic origin.[79]

Triquetrum

The triquetrum is located by radially deviating the wrist while palpating just distal to the ulnar styloid. With ulnar deviation, the triquetrum articulates with the TFCC, which functions as a buffer between the styloid and the triquetrum. Tenderness and swelling in the triquetral hamate region are often present with midcarpal instability, which occurs when the anterior (palmar) triquetral–hamate–capitate ligament is ruptured or sprained.[90]

Tunnel of Guyon

The tunnel of Guyon is located in the space between the hamate and the pisiform.[6]

Carpal Tunnel

The distal wrist crease marks the proximal edge of the carpal tunnel. The boundaries of the carpal tunnel are as follows:

- Radial: scaphoid tubercle and trapezium.
- Ulnar: pisiform and hamate.
- Posterior (dorsal): the carpal bones.
- Anterior (palmar): transverse carpal ligament.
- Proximal: antebrachial fascia.
- Distal: distal edge of the retinaculum at the CMC level, FCR, and scaphoid tubercle.

PIP Joints

Palpation of the PIP joint offers important information. Palpation of the joint over four planes [posterior (dorsal), anterior (palmar), medial, and lateral] allows assessment of point tenderness over ligamentous origins and insertions that is highly suggestive of underlying soft-tissue disruption.[22] In cases in which the joint is grossly swollen and tender, this part of the examination may provide more accurate information several days after the injury.[22]

Active Range of Motion (AROM), then Passive Range or Motion with Overpressure

The gross motions of the wrist, hand, finger, and thumb flexion, extension, and radial and ulnar deviations are tested (Fig. 18-14), first actively and then passively (Table 18-8). Horger[91] conducted a reliability study to determine (a) the intrarater and interrater reliability of goniometric measurement of active and passive wrist motions under clinical conditions and (b) the effect of a physical therapist's specialization on the reliability of measurement. The results indicated that measurement of wrist motion by individual therapists is highly reliable and that intrarater reliability is higher than interrater reliability for all active and passive motions.[91] Interrater reliability was generally higher among specialized therapists for reasons not immediately apparent from this study.[91] With the exception of pain, identified sources of error were found to have surprisingly little effect on the reliability of measurement.[91]

TABLE 18-8 Active Range-of-Motion Norms for the Forearm, Wrist, and Hand

Motion	Degrees
Forearm pronation	85–90
Forearm supination	85–90
Radial deviation	15
Ulnar deviation	30–45
Wrist flexion	80–90
Wrist extension	70–90
Finger flexion	MCP: 85–90; PIP: 100–115; DIP: 65–80
Finger extension	MCP: 30–45; PIP: 0; DIP: 20
Finger abduction	20–30
Finger adduction	0
Thumb flexion	CMC: 45–50; MCP: 50–55; IP: 85–90
Thumb extension	MCP: 0; IP: 0–5
Thumb adduction	30
Thumb abduction	60–70

CMC, carpometacarpal; DIP, distal interphalangeal; IP, interphalangeal; MCP, metacarpophalangeal; PIP, proximal interphalangeal.

Any loss of motion compared with the contralateral, asymptomatic wrist and hand should be noted.

During the measurement of motion, one must be aware that finger joint positions may affect wrist joint ranges (and vice versa) due to the constant length of the extrinsic tendons that cross multiple joints. Forearm pronation and supination can have a similar impact on joint ranges. For example,

- greater wrist flexion occurs with finger extension than with finger flexion because the ED tendons are not stretched maximally;
- less deviation range of motion is available when the wrist is fully extended or flexed.

Thus during the examination, the clinician should maintain all joints in a consistent position (usually neutral), except the one being measured. In addition, the clinician should identify wrist and finger joint position when measuring the strength of related muscles.

Somatic dysfunction of the wrist permits motion toward the dysfunction; motion away from the dysfunction will be restricted.

Fanning and folding of the hand is performed by palpating the anterior (palmar) surface of the pisiform, scaphoid, hamate, and trapezium with the index and middle fingers and the posterior (dorsal) surface of the capitate with the thumbs as the hand is alternately fanned and folded. During these

motions, the clinician should note the quantity and quality of the conjunct rotations. An absence of the conjunct rotations may indicate an intercarpal dysfunction.

The uninvolved joint should always be examined first. This allows for a determination of the normal function, allays the patient's anxiety, and allows for a true comparison of function.[4] During palpation, the clinician should be on the alert for any thickening over tendons, tenderness, or areas of fluctuation.[4] During active and passive testing, the presence of crepitus must be determined. The presence of crepitus with motion may indicate a tendon sheath synovitis or vaginitis.

CLINICAL PEARL

Crepitus usually accompanies a particularly acute tendinopathy.

Pronation and Supination

Pronation and supination of the wrist on the forearm will provisionally test the TFCC and the proximal and DRUJs. Full forced pronation–supination without evoking pain eliminates the DRUJ and the TFCC as potential sources of the patient's complaints.[2] Normal ranges for pronation and supination are approximately 85–90 degrees with approximately 75 degrees occurring in the forearm articulations and the remaining 15 degrees the result of wrist action. The normal end feel for these motions is tissue stretch, although, in cachexic patients, the end feel of pronation may be bone to bone.

Radial and Ulnar Deviation

The normal radial deviation is approximately 15 degrees while normal ulnar deviation is between 30 and 45 degrees. The normal end feel for these motions is bone to bone.

Wrist Flexion

The normal range of motion of wrist flexion is 80–90 degrees with an end feel of tissue stretch. According to Watson,[2] any loss of passive wrist flexion is a sign of underlying organic carpal pathology. To determine whether painful wrist flexion is due to a problem between the scaphoid and radius, or the scaphoid and the trapezium and trapezoid, the wrist is placed in full flexion, with the posterior (dorsal) surface of the hand resting on the treatment table. The clinician pushes on the scaphoid and second metacarpal in a posterior (dorsal) direction. An increase in pain with this maneuver may indicate a problem at the scaphoid–radius articulation.

If there is no increase in pain with this maneuver, the wrist is placed in a neutral position with regard to flexion and extension. The clinician stabilizes the trapezium and trapezoid and pushes the scaphoid posteriorly (dorsally). An increase in pain with this maneuver may indicate a problem at the trapezium/trapezoid–scaphoid articulation.

To determine whether the painful wrist flexion is due to a problem between the capitate and the lunate or the lunate and the radius, the wrist is placed in full flexion. The clinician pushes the lunate in an anterior (palmar) direction. An increase in pain with this maneuver may indicate a problem at the capitate–lunate articulation. If the pain is not increased with this maneuver, the wrist is placed in full flexion, and the clinician pushes the lunate in a posterior (dorsal) direction. An increase in pain with this maneuver may indicate a problem at the lunate–radius articulation. A decrease in pain with this maneuver may indicate a problem at the capitate–lunate articulation.

Wrist Extension

The normal range of motion for wrist extension is 70–90 degrees with an end feel of the tissue stretch. According to Watson,[2] any loss of passive wrist extension is a sign of underlying organic carpal pathology. To determine whether the pain with wrist extension is due to a problem between the scaphoid and the radius or the scaphoid and the trapezium/trapezoid, the wrist is positioned in full extension with the palm positioned on the table. The clinician pushes on the radius in an anterior (palmar) direction, thus increasing the amount of wrist extension. An increase in pain with this maneuver may indicate a problem at the scaphoid–radius articulation. If this maneuver does not increase pain, the wrist is positioned as before. The clinician now pushes on the radius in a posterior (dorsal) direction. A decrease in pain with this maneuver may indicate a problem at the scaphoid–radius articulation. An increase in pain with this maneuver may indicate a problem at the scaphoid and trapezium/trapezoid articulation.

This is confirmed by placing the wrist as before in full extension and pushing on the scaphoid in a posterior (dorsal) direction. A decrease in pain with this maneuver indicates a problem between the scaphoid and the radius, whereas an increase in pain with this maneuver indicates the problem is between the scaphoid and the trapezium/trapezoid.

The clinician fixes the scaphoid and pushes the trapezium/trapezoid in an anterior (palmar) direction. A decrease in pain with this maneuver may indicate a problem at the scaphoid–trapezium/trapezoid articulation. If the pain remains unchanged with this maneuver, the problem is likely to be at the scaphoid–radius articulation. To confirm this hypothesis, the scaphoid can be pushed in an anterior (palmar) direction while the wrist is maintained in the position of full extension. This should increase the pain if the hypothesis is correct.

To determine whether the pain is due to a problem between the capitate and lunate or the lunate and radius, the wrist is positioned in full extension, with the palm of the hand on the table. The clinician pushes on the radius in an anterior (palmar) direction. An increase in pain with this maneuver indicates a problem at the capitate–lunate articulation.

If the pain is increased by pushing the lunate and capitate in an anterior (palmar) direction, this may indicate a problem at the lunate–radius articulation.

If fixing the lunate and pushing the capitate in an anterior (palmar) direction (a relative motion of the lunate posteriorly [dorsally] in relation to the capitate) increases the pain, the problem is likely at the capitate–lunate articulation.

Thumb

The following motions are tested in varying degrees of wrist flexion and extension:

- CMC abduction, adduction, flexion, extension, and opposition (Fig. 18-16). During opposition, the clinician

should observe for the conjunct rotation component of the motion.

- MCP and IP flexion and extension.

Fingers

It should never be assumed that lack of full active flexion or extension of the PIP is merely secondary to joint pain or fusion, because closed rupture of the middle slip of the extensor hood is easily missed until the appearance of a boutonniere deformity.[22] During flexion of the fingers, the overall area of the fingers should converge to a point on the wrist corresponding to the radial pulse. T is can only occur if the index finger flexes in a sagittal plane and all the others in an increasingly oblique plane. A skyline view of the knuckles is made. In full flexion, a posteriorly (dorsally) subluxed capitate may be seen as a local swelling on the back and middle of the flexed wrist.

Total active motion of the fingers is the sum of all angles formed by the MCP, PIP, and DIP joints in simultaneous maximum active flexion, minus the total extension deficit at the MCP, PIP, and DIP joints (including hyperextension at the IP joints) in maximum active extension.

A normal value for total AROM in the absence of a normal contralateral digit for comparison is 260 degrees, based on 85 degrees of MCP flexion, 110 degrees of PIP motion, and 65 degrees of DIP motion.[92]

A comparison of active and passive motion indicates the efficiency of flexor and extensor excursion and/or degree of muscle strength within the available PROM.[92] Instances of greater passive than active motion may indicate a limited tendon glide due to adherence of the tendon to surrounding structures or relative lengthening of the tendon due to injury or surgery, weakness, or pain.[92]

Due to the multitude of joints and multiarticular muscles found in the hand, the clinician may need to differentiate between various structures in order to determine the cause of a motion restriction (see "Special Tests).[92] For example, adherence of the extrinsic flexors is tested by passively maintaining the fingers and thumb in full extension while passively extending the wrist. In the presence of flexor tightness, the increasing flexor tension that develops as the wrist is passively extended will pull the fingers into flexion. Adherence of the extensor tendons is simply a reverse process. T e digits are passively maintained in full flexion while the wrist is passively flexed. If there is a tension, detected by the clinician's hand as the wrist is brought into flexion, that is pulling the fingers into extension, extrinsic extensor tightness exists.

Strength Testing

Isometric tests are carried out in the extreme range, and if positive, in the neutral range. T ese isometric tests must include the interossei and lumbricals. T e straight plane motions of wrist flexion, extension, and ulnar and radial deviation are tested initially. Pain with any of these tests requires a more thorough examination of the individual muscles. T e clinician should be able to extrapolate hand placements for these tests by noting the anatomy of these muscles from the figures. T e muscles that control wrist extension (see Chapter 17), wrist flexion (see Chapter 17), radial deviation, and ulnar deviation are tested first. Further details on manual muscle testing can be found in Chapter 12.

Wrist

FCR/FCU. During the testing of these muscles, substitution by the finger flexors should be avoided by not allowing the patient to make a fist. T e clinician applies the resistive force into extension and radial deviation for the FCU, and extension and ulnar deviation for the FCR.

ECRL/ECRB. Any action of the EDC should be ruled out by having the patient make a fist while extending the wrist. T e clinician applies the resistive force on the dorsum of the second and third metacarpals, with the force directed into flexion and ulnar deviation.

Extensor Carpi Ulnaris. T e ECU is tested by having the patient make a fist in wrist extension, while the clinician applies resistance on the ulnar dorsum of the hand, with the force directed into flexion and radial deviation.

Thumb

APL/APB. T e forearm is positioned midway between pronation and supination, or in maximal supination. T e MCP and IP joints are positioned in flexion. T e muscles are tested with an anterior (palmar) abduction of the thumb in the frontal plane for the longus and in the sagittal plane for the brevis.

Opponens Pollicis. T e forearm is positioned in supination, and the posterior (dorsal) aspect of the hand rests on the table. T e patient is asked to touch the finger pads of the thumb and little finger together. Using one hand, the clinician stabilizes the first and fifth metacarpals and the palm of the hand. With the other hand, the clinician applies a force to the distal end of the first metacarpal in the opposite direction of opposition (retroposition).

FPL/FPB. T e forearm is positioned in supination and supported by the table, and the hand is positioned so that the posterior (dorsal) aspect rests on the table. T e thumb is adducted. T e longus is tested by resistance applied to the distal phalanx, whereas both heads of the brevis are tested by resistance applied to the proximal phalanx.

Adductor Pollicis. T is muscle is tested by having the patient hold a piece of paper between the thumb and radial aspect of the index finger's proximal phalanx while the clinician attempts to remove it. If weak or nonfunctioning, the IP joint of the thumb flexes during this maneuver due to substitution by the FDP (Froment sign).

Extensor Pollicis Longus/EPB. Both of these muscles can be tested with the patient's hand flat on the table, palm down, and asking the patient to lift only the thumb off the table. To test each individually, resistance is applied to the posterior (dorsal) aspect of the distal phalanx for the EPL while stabilizing the proximal phalanx and metacarpal and to the posterior (dorsal) aspect of the proximal phalanx for the EPB while stabilizing the first metacarpal.

Intrinsics

Lumbricals. T e four lumbricals are tested by applying resistance to the posterior (dorsal) surface of the middle and

distal phalanges while stabilizing under the proximal phalanx of the finger being tested. The anterior (palmar) and posterior (dorsal) interossei act with the lumbricals to achieve MCP flexion coupled with PIP and DIP extension.

Anterior (palmar) Interossei. The three anterior (palmar) interossei adduct the second, fourth, and fifth fingers to the midline. Resistance is applied by the clinician to the radial aspect of the distal end of the proximal phalanx of the second, fourth, and fifth fingers, after first stabilizing the hand and fingers not being tested.

Posterior (Dorsal) Interossei/ADM. The four posterior (dorsal) interossei abduct the second, third, and fourth fingers from the midline. The ADM abducts the fifth finger from the midline.

The intrinsic muscles are tested in the frontal plane to avoid substitution by the extrinsic flexors and extensors. Resistance is applied by the clinician to the ulnar aspect of the distal end of the proximal phalanx of each of the four fingers, after first stabilizing the hand and fingers not being tested.

Fingers

Flexor Digitorum Profundus. This muscle is tested with DIP flexion of each digit while the MCP and PIP are stabilized in extension and wrist neutral. Due to the variability of nerve innervation for this muscle group, each of the fingers can be tested to determine whether a peripheral nerve lesion is present. The index finger is served by the anterior interosseous nerve, the middle finger by the main branch of the median nerve, and the ring and little finger by the ulnar nerve.

Flexor Digitorum Superficialis. There is normally one muscle tendon unit for each finger; however, an absent FDS to the little finger is common. The clinician should only allow the finger to be tested to flex by firmly blocking all joints of the nontested fingers, with the wrist in neutral.

ED/Extensor Indicis Proprius. There is only one muscle belly for this four-tendon unit. These three muscles are the sole MCP joint extensors. With the wrist in neutral, the strength is tested with the metacarpals in extension and the PIP/DIP flexed. The extensor indicis proprius can be isolated by positioning the index finger and hand in the "number one" position—the index finger in extension with other fingers clenched in a fist. The EDM muscle is tested with a resistance of little finger extension with the other fingers maintained in a fist.

To isolate intrinsic muscle function, the patient is asked to actively extend the MCP joint and then to attempt to actively extend the PIP joint. Because the ED, EI, and EDM tendons are "anchored" at the MCP joint by active extension, only the intrinsic muscles can now extend the PIP joint.[17] To test the terminal extensor tendon function, the clinician stabilizes the middle phalanx and asks the patient to extend the DIP joint.[11]

Flexor Digiti Minimi. The forearm is positioned in supination, and the posterior (dorsal) aspect of the hand rests on the table. The clinician stabilizes the fifth metacarpal and the palm with one hand and then applies resistance to the anterior (palmar) surface of the proximal phalanx of the fifth digit with the other hand.

Opponens Digiti Minimi. The forearm is positioned in supination, and the posterior (dorsal) aspect of the hand rests on the table. The patient is asked to touch the finger pads of the thumb and little finger together. Using one hand, the clinician stabilizes the first and fifth metacarpals and palm of the hand. With the other hand, the clinician applies a force to the distal end of the fifth metacarpal in the opposite direction of opposition (retroposition).

FIGURE 18-26 Grip strength.

Grip Strength

A loss of grip or pinch is a measurable factor used in the determination of permanent disability by compensation boards in some states.[93]

The assessment of grip strength (Fig. 18-26) and pinch strength (Fig. 18-27) is used to assess the function of the hand, using a dynamometer. The average values for grip strength are given in Table 18-9. Normal grip strength, which provides a

FIGURE 18-27 Pinch meter.

TABLE 18-9 Grip Strength in Normal Men and Women of Various Ages for the Dominant Hand (DH) in Kilopounds per Square Centimeter (kp/cm^2) and the Ratio-dominant Hand/Nondominant Hand (DH/NDH), Based on 25 Determinations

statistical analysis of males versus females.[94] The mean value for the nondominant hand can be calculated from the values of the DH and the ratio.

A number of protocols using a sealed hydraulic dynamometer, such as the Jamar dynamometer (Fig. 18-26) (Asimow Engineering Co., Santa Monica, CA), have been shown to be accurate, reliable, and valid for measuring grip strength.[95,96] These dynamometers register force in pounds per square inch, or kilopounds per square centimeter, and have adjustable handles to accommodate any sized hand, or any hand that may have a limitation of finger joint motion.[97]

Studies have demonstrated that the second handle setting of the Jamar dynamometer allows for the maximum grip strength from the patient.[97,98] The widest grip uses mostly the profundus muscles. At the narrowest grip, the profundus and superficialis muscle excursion are fully used, preventing much in the way of their contribution to the overall grip strength.[93,97]

Unfortunately, these tests are not purely objective, as they rely on the sincerity of effort from the patient.[99] Thus a number of tests have been introduced in an attempt to aid in the detection of insincerity of effort:

- The *five*-position grip strength test.[93] This test uses the Jamar dynamometer and uses the five handle settings to measure grip strength at the five different grip widths. In normal and motivated patients, maximum grip strength occurs at the second or third grip width. The maximum grip strength, recorded at the first or fifth width setting, is supposed to be indicative of an insincerity of effort, although the reliability of the five-position grip strength test has been questioned.[98,100]
- The rapid exchange grip test, rapid simultaneous grip strength tests. The first test was developed by Lister.[101] Both of these tests use the Jamar dynamometer and compare the maximum grip strength during a five-position static grip strength test, with the maximum grip strength recorded when gripping the dynamometer repeatedly at a fast rate (80 times per minute).[102,103] In normal and motivated patients, the static measure of grip strength of grip strength should be approximately 15% greater than the dynamic measure, while in patients demonstrating insincerity of effort, the dynamic measure is equal to or greater than the initial static measure.[103] The rapid exchange and the rapid simultaneous grip strength tests are time consuming and frequently performed erroneously in the clinical setting.[99]
- The rapid repeat test. The patient is seated with their arm by their side, the elbow in 90 degrees of flexion, and the forearm and wrist in neutral. The dynamometer, set at the second handle setting, is supported by the clinician and the patient alternately grips with both right and left hands on ten occasions, or until the patient has to stop due to fatigue or discomfort. This test has been found to be an unreliable discriminator of true and faked hand weakness.[99]

It is probably wise to combine the results of different grip strength tests before making any decisions.[104]

Functional Assessment

The hand serves many important functions that allow us to interact with others and the environment. In addition to providing a wealth of sensory information, the hand functions to grasp objects.

Hand functions have been further categorized by adding the terms grasp and prehension. These terms are used to describe functions of power or precision.[20,21]

The *functional* position of the wrist is the position in which optimal function is likely to occur. This position involves

wrist extension of between 20 and 35 degrees, ulnar deviation of 10–15 degrees, slight flexion of all of the finger joints, midrange thumb opposition, and slight flexion of the thumb MCP and IP joints.[62] In this position, which minimizes the restraining action of the long extensor tendons, the pulps of the index finger and thumb are in contact.

A number of motions can be used to quickly assess hand function, including the following:

- The opposition of the thumb and little finger.
- Pad to pad mobility of the thumb and other fingers. The majority of the functional activities of the hand requires at least 5 cm of opening of the fingers and thumb.[105]
- The ability to make three different fists:
  - The hook fist (placing fingertips onto MCP joints).
  - Standard fist.
  - Straight fist (placing fingertips on the thenar and hypothenar eminences). The ability to flex the fingers to within 1–2 cm of the distal anterior (palmar) crease is an indication of functional range of motion for many hand activities.[105]

The *functional* range *of* motion for the hand is the range in which the hand can perform most of its grip and other functional activities (Table 18-10).

The percentage losses of digital function are as follows: thumb, 40–50%; index finger, 20%; long finger, 20%; ring finger, 10%; little finger, 5%. Loss of the hand is 90% of the upper extremity and 54% of the whole person.

The function of the digits is related to nerve distribution. Flexion and sensation of the radial digits, important in precision grips, are controlled mainly by the median nerve, whereas flexion and sensation of the ulnar digits, important to the power grip, are controlled by the ulnar nerve. The muscles of the thumb, used in all forms of gripping, are controlled by both the median and the ulnar nerves. The release of a grip or opening of the hand is controlled by the radial nerve. A loss of the relationship between the thumb and the index finger results in an inability to perform fine motor skills that involve pulp-to-pulp pinch, as well as functions that require power.

TABLE 18-10 Functional Range of Motion of the Hand and Wrist

Joint Motion	Functional Range of Motion (Degrees)
Wrist flexion	5–40
Wrist extension	30–40
Radial deviation	10–20
Ulnar deviation	15–20
MCP flexion	60
PIP flexion	60
DIP flexion	40
Thumb MCP flexion	20

DIP, distal interphalangeal; MCP, metacarpophalangeal; PIP, proximal interphalangeal.

J Hand Surg Am. 1985:10:39–46; Ryu J, Cooney WP, Askew LJ, et al. Functional ranges of motion of the wrist joint. J Hand Surg Am. 1991;16:409–420.

Hand Disability Index[106]

The patient is asked to rate the following seven questions on a scale of zero to three, with three being the most difficult.

Unable to perform task = 0

Able to complete task partially = 1

Able to complete task but with difficulty = 2

Able to perform task normally = 3

Are you able to do the following:

- Dress yourself, including tying shoelaces and doing buttons?
- Cut your meat?
- Lift a full cup or glass to your mouth?
- Prepare your own meal?
- Open car doors?
- Open jars that have previously been opened?
- Turn taps on and off?

A variety of evaluation tools have been devised for the hand, and they can be categorized into assessments of the neurovascular system, range of motion, sensibility, and function (Table 18-11).[105]

Dexterity tests include the following:

Minnesota Rate of Manipulation Test

This test, which primarily measures gross coordination and dexterity, consists of following five functions:

- Placing
- Turning
- Displacing
- One-hand turning and placing
- Two-hand turning and placing

The activities are timed and compared with the time taken by the other hand and then compared with normal values.[105,107]

Jebsen–Taylor Hand–Function Test[108]

This test, which requires the least amount of extremity coordination, measures prehension and manipulative skills, and consists of following seven subtests:

- Writing
- Card turning
- Picking up small objects
- Simulated feeding
- Stacking
- Picking up large, light objects
- Picking up large, heavy objects

The subtests are timed and compared with the time taken by the other hand. The results are also compared with normal values.[105,107]

TABLE 18-11 Functional Testing of the Wrist and Hand

Starting Position	Action	Functional Test
1. Forearm supinated, resting on table	Wrist flexion	Lift 0 lb: Nonfunctional Lift 1–2 lb: functionally poor Lift 3–4 lb: functionally fair Lift 5+ lb: functional
2. Forearm pronated, resting on table	Wrist extension lifting 1–2 lb	0 repetitions: nonfunctional 1–2 repetitions: functionally poor 3–4 repetitions: functionally fair 5+ repetitions: functional
3. Forearm between supination and pronation, resting on table	Radial deviation lifting 1–2 lb	0 repetitions: nonfunctional 1–2 repetitions: functionally poor 3–4 repetitions: functionally fair 5+ repetitions: functional
4. Forearm between supination and pronation, resting on table.	Thumb flexion with resistance from rubber band around thumb	0 repetitions: nonfunctional 1–2 repetitions: functionally poor 3–4 repetitions: functionally fair 5+ repetitions: functional
5. Forearm resting on table, rubber band around thumb and index finger	Thumb extension against resistance of rubber band	0 repetitions: nonfunctional 1–2 repetitions: functionally poor 3–4 repetitions: functionally fair 5+ repetitions: functional
6. Forearm resting on table, rubber band around thumb and index finger	Thumb abduction against resistance of rubber band	0 repetitions: nonfunctional 1–2 repetitions: functionally poor 3–4 repetitions: functionally fair 5+ repetitions: functional
7. Forearm resting on table	Thumb adduction, lateral pinch of piece of paper	Hold 0 s: nonfunctional Hold 1–2 s: functionally poor Hold 3–4 s: functionally fair Hold 5+ s: functional
8. Forearm resting on table	Thumb opposition, pulp-to-pulp pinch of piece of paper	Hold 0 s: nonfunctional Hold 1–2 s: functionally poor Hold 3–4 s: functionally fair Hold 5+ s: functional
9. Forearm resting on table	Finger flexion, patient grasps mug or glass using cylindrical grasp and lifts off table	0 repetitions: nonfunctional 1–2 repetitions: functionally poor 3–4 repetitions: functionally fair 5+ repetitions: functional
10. Forearm resting on table	Patient attempts to put on rubber glove keeping fingers straight	21+ s: nonfunctional 10–20 s: functionally poor 4–8 s: functionally fair 2–4 s: functional
11. Forearm resting on table	Patient attempts to pull fingers apart (finger abduction) against resistance of rubber band and holds	Hold 0 s: Nonfunctional Hold 1–2 s: functionally poor Hold 3–4 s: functionally fair Hold 5+ s: functional
12. Forearm resting on table	Patient holds piece of paper between fingers while clinician pulls on paper	Hold 0 s: nonfunctional Hold 1–2 s: functionally poor Hold 3–4 s: functionally fair Hold 5+ s: functional

Data from Palmer ML, Epler M. Clinical Assessment Procedures in Physical Therapy. Philadelphia, PA: JB Lippincott; 1990.

Nine-Hole Peg Test

This test was designed to assess finger dexterity of each hand.[109] The patient is asked to use one hand to place nine 3.2-cm (1.3-in) pegs in a 12.7 by 12.7 cm (5 by 5 in) board and is then asked to remove them. The task is timed and compared with the time taken by the other hand. The results are compared with normal values.[105,107]

Purdue Pegboard Test[110,111]

This test evaluates finer coordination, requiring prehension of small objects, with measurement categories divided into

- right hand
- left hand
- both hands
- right, left, and both hands
- assembly.

The subtests are timed and compared with normal values based on gender and occupation.[105,107]

Crawford Small Parts Dexterity Test[112]

This test involves the use of tweezers and a screwdriver and requires patients to control not only their hands but also small tools. This test correlates positively with vocational activities that demand fine coordination skills.[105]

The problem with most of these tests and others is that time is used as the critical measure of function, even though time is not an accurate measure of function.

Although not standardized, a few other simple tests can be used to assess hand dexterity. These include writing in a straight line, buttoning and unbuttoning different-sized buttons, and zipping and unzipping using a variety of zipper sizes. The following scale can be used to grade these activities:

Unable to perform the task = 0.

Able to complete the task partially = 1.

Able to complete the task but with difficulty = 2.

Able to perform the task normally = 3.

Passive Accessory Joint Mobility Tests

In the following tests, the patient is positioned in sitting or supine, with the arm resting comfortably. In each of the tests, the clinician notes the quantity of joint motion as well as the joint reaction. The tests are always repeated on, and compared to, the same joint in the opposite extremity.

Distal Radioulnar Joint

Anterior–Posterior Glide. The patient is positioned in sitting with the forearm resting on the table. Using a pinch grip with both hands, the clinician places both thumbs on the posterior (dorsal) aspects of the ulnar and radial styloid processes (Fig. 18-28). The distal radius is stabilized, and the distal ulna is moved posteriorly (dorsally) or anteriorly (palmarly) relative to the distal radius (Fig. 18-28). Alternatively, the distal ulna may be stabilized, and the distal radius moved. This technique is used to assess joint plane motions necessary for pronation (posterior glide) and supination (anterior glide), or

FIGURE 18-28 Mobility testing of the distal radioulnar joint.

in the case of joint mobilizations to increase the joint play necessary for these motions.

Radiocarpal Joint

The patient's hand rests on the table with the wrist supported with a towel. The radiocarpal and ulnocarpal joints are placed in the resting position.

Distraction

Using one hand, the clinician grasps the distal radius and ulna. Using the other hand, the clinician grips the proximal row of carpals. A perpendicular distraction force is applied to separate the proximal level of carpals from the distal radius and ulna (Fig. 18-29).

Posterior–Anterior Glide

Using one hand to stabilize the patient's distal forearm, the clinician grasps the patient's hand with the other hand using the styloid processes and pisiform for landmarks. The proximal row of carpals is then moved posteriorly (dorsally) and

FIGURE 18-29 Radiocarpal distraction.

FIGURE 18-30 Anterior glide of the radiocarpal joint.

FIGURE 18-32 Assessment of joint mobility of distal carpals.

anteriorly (palmarly) (Fig. 18-30). The posterior glide tests the joint's ability to flex, whereas the anterior glide assesses the ability of the joint to extend.

Ulnar and Radial Glide

The patient's hand rests on the table with the wrist supported with a towel (Fig. 18-31). Using one hand to stabilize the patient's distal forearm, the clinician grasps the patient's hand with the other hand using the styloid processes and pisiform for landmarks. The proximal row of carpals is then moved posteriorly (dorsally) and anteriorly (palmarly). The ulnar (medial) glide tests the joint's ability to radially deviate, whereas the radial (lateral) glide assesses the ability of the joint to ulnarly deviate.

Intercarpal Joints

Distal Row. The patient's hand rests on the table or is held forward by the clinician. The clinician grasps the patient's hand with both hands, with the index fingers and thumbs of each hand used to pinch an individual carpal and the adjacent carpal (Fig. 18-32). One carpal is moved anteriorly relative to the other, and the clinician assesses the motion of the carpal in relation to the other. For example, the clinician assesses the motion of the capitate in relation to the hamate. An anterior glide of one carpal on another is a relative posterior glide of the other. For example, an anterior glide of the capitate on the hamate is a relative posterior glide of the hamate on the capitate.

Proximal Row. The same technique is used to assess the proximal row of carpals.

Midcarpal Joints

The articulation between the proximal row of carpals and the distal row of carpals can be assessed using distraction, anterior glide, posterior glide, radial glide, and ulnar glide (Fig. 18-33). While assessing the distraction and anterior and posterior glides provides little information, the assessment of the radial glide can provide information about the ability of the wrist joint to ulnarly deviate, and the assessment of the ulnar glide can provide information about the ability of the wrist joint to radially deviate.

CMC Joints

Using one hand, the clinician uses a pinch grip of the index finger and thumb to palpate and stabilize the carpal bone that articulates with the metacarpal bone being tested (Fig. 18-34). With a pinch grip of the index finger and thumb of the other hand, the clinician palpates the metacarpal (Fig. 18-34).

The carpal bone is stabilized, and the metacarpal is distracted (Fig. 18-35) and then glided posterior anteriorly along the plane of the CMC joint.

FIGURE 18-31 Ulnar glide of the radioulnar joint.

FIGURE 18-33 Assessment of joint mobility of intercarpals between distal and proximal rows.

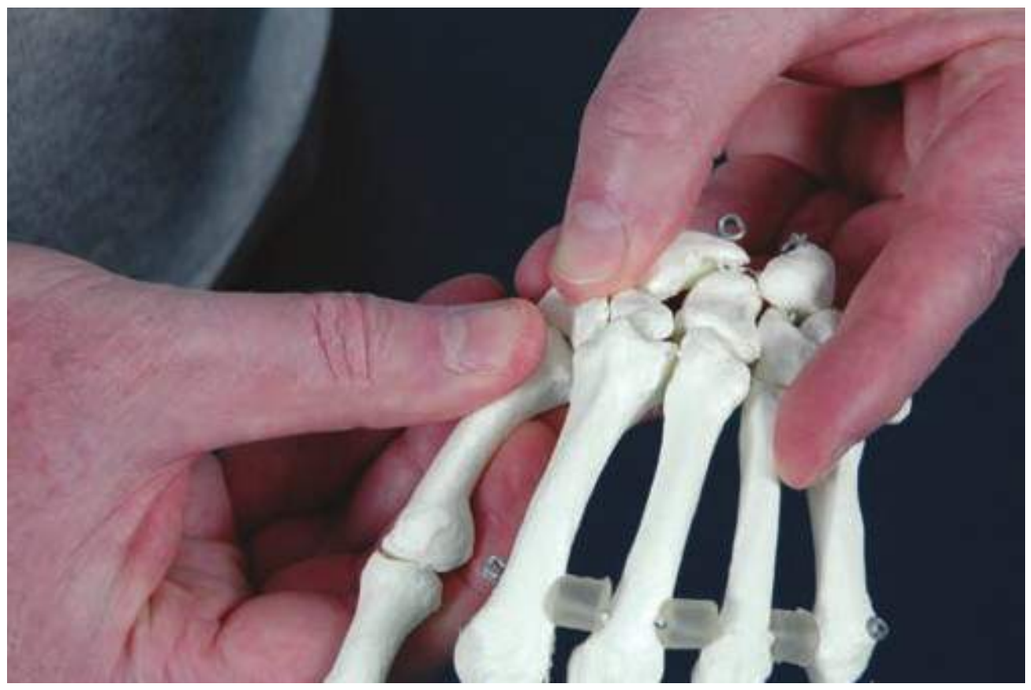

FIGURE 18-34 Carpometacarpal joint testing.

FIGURE 18-36 Ulnar glide of the first carpometacarpal joint.

First CMC (trapeziometacarpal) Joint

The patient is positioned in sitting or supine.

Ulnar (Medial) Glide. The clinician applies a glide in an ulnar direction through the thenar eminence toward the radial aspect of the patient's metacarpal (Fig. 18-36). The ulnar glide is used to assess trapeziometacarpal joint flexion.

Radial (lateral) glide. The clinician applies a glide in a radial direction through the thenar eminence toward the ulnar aspect of the patient's metacarpal. The radial glide is used to assess trapeziometacarpal joint extension.

Distraction. The distraction technique may be used to decrease pain and to stretch the joint capsule.

MCP/IP Joints

Using a pinch grip of the index finger and thumb of one hand, the clinician palpates and stabilizes the metacarpal/phalanx. With a pinch grip of the index finger and thumb of the other hand, the clinician palpates the adjacent phalanx.

Distraction. The clinician stabilizes the proximal bone and then applies a long axis distraction (Fig. 18-37).

Posterior–Anterior Glide. The clinician stabilizes the proximal bone and then glides the phalanx posteroanteriorly along the plane of the joint (Fig. 18-37).

Ulnar (Medial)–Radial (Lateral) Glide. The clinician stabilizes the proximal bone and then glides the phalanx mediolaterally along the plane of the joint (Fig. 18-37).

First Metacarpophalangeal Joint

Using a pinch grip of the index finger and thumb of one hand, the clinician stabilizes the trapezium on the radial and ulnar surfaces. With a pinch grip of the index finger and thumb of the other hand, the clinician grips the proximal metacarpal on the radial and ulnar surfaces. A radial–ulnar glide is then performed by the mobilizing hand. A radial glide is necessary for trapeziometacarpal extension, whereas the ulnar glide is necessary for trapeziometacarpal flexion.

Distal and PIP Joints

Using a pinch grip of the index finger and thumb of one hand, the clinician stabilizes the distal end of the most proximal phalanx. Using the other hand, the clinician grips the proximal end of the most distal phalanx. The PIP joint (Fig. 18-38) and DIP joint (Fig. 18-39) can then be distracted, or glided anteriorly or posteriorly. The anterior glide assesses the ability of the joint to move into flexion, whereas posterior glide assesses the ability of the joint to move into extension.

FIGURE 18-37 Long axis distraction of the MCP or IP joints.

FIGURE 18-38 Assessment of proximal interphalangeal joint.

FIGURE 18-40 Bunnell–Littler test.

Special Tests

The special tests for the wrist and hand can be subdivided on the basis of intent:

- Motion restriction
- Pain provocation
- Tendinous integrity
- Ligamentous stability
- Neurovascular status
- Sensibility testing
- Adverse neural tension.

Motion Restriction

- The Bunnell–Littler test is used to determine whether flexion restriction of the PIP is due to a tightness of the intrinsic muscles or due to a restriction of the MCP joint capsule. The MCP joint is held by the clinician in a few degrees of extension with one hand while the other hand attempts to flex the PIP joint. If the joint cannot flex, tightness of the intrinsics or a joint capsular contraction should be suspected.[113] From this position, the clinician now slightly flexes the MCP joint, thereby relaxing the intrinsics, and attempts to flex the PIP joint (Fig. 18-40). If the joint can now flex, the intrinsics are tight. If the joint still cannot flex, the restriction is probably due to a capsular contraction of the joint. This test is also called the intrinsic-plus test.[23]
- The Haines–Zancolli test is used to determine whether restricted flexion in the DIP joints is due to a restriction of the PIP joint capsule or tightness of the oblique retinacular ligament. The test for a contracture of this ligament is the same as the Bunnell–Littler test, only at the PIP and DIP joints. The clinician positions and holds the PIP joint in a neutral position with one hand and attempts to flex the DIP joint with the other hand (Fig. 18-41). If no flexion is possible, it can be due to either a tight retinacular ligament or capsular contraction. The PIP joint is then slightly flexed to relax the retinacular ligament. If the DIP can now flex, the restriction is due to tightness in the retinacular ligament. If the DIP cannot flex, then the restriction is due to a capsular contraction.

Pain Provocation Tests

Tests Thumb CMC Grind Test. The grind test is used to assess the integrity of the thumb CMC joint by axially loading the thumb metacarpal into the trapezium.[9,114] The clinician grasps the thumb metacarpal using the thumb and index finger of one hand and the proximal aspect of the thumb CMC joint with the other hand (Fig. 18-42). An axial compressive

FIGURE 18-39 Assessment of distal interphalangeal joint.

FIGURE 18-41 Haines–Zancolli test.

FIGURE 18-42 CMC grind test.

FIGURE 18-43 Lichtman test.

force, combined with rotation, is applied to the thumb CMC joint. Reproduction of the patient's pain and crepitus is a positive test for arthrosis and synovitis.

Lichtman Test. The Lichtman test is a provocative test for midcarpal instability.[9] The patient's forearm is positioned in pronation, and the hand is held relaxed and supported by the clinician. The clinician gently moves the patient's hand from radial to ulnar deviation while compressing the carpus into the radius (Fig. 18-43). A positive test is when the midcarpal row appears to jump or snap from an anteriorly (palmarly) subluxed position to the height of the proximal row.[9]

Linscheid Test. The Linscheid test is used to detect ligamentous injury and instability of the second and third CMC joints. The test is performed by supporting the metacarpal shafts and pressing distally on the metacarpal heads in anterior (palmar) (Fig. 18-44) and posterior (dorsal) directions.[79] A positive test produces pain localized to the CMC joints.[115]

Carpal Shake Test. This test is used if intercarpal synovitis is suspected.[9] The clinician grasps the patient's distal forearm (Fig. 18-45). The patient is asked to relax, and the clinician shakes the wrist (Fig. 18-45). Pain or resistance to this test indicates a positive test.

Wrist Flexion and Finger Extension Test. The patient is positioned in sitting with the elbow placed on the table. The clinician holds the patient's wrist in flexion and asks the patient to extend the fingers against manual resistance (Fig. 18-46). A positive test for scapholunate pathology is identified by pain over the scaphoid. No diagnostic accuracy studies have been performed to determine the sensitivity and specificity of this test.

FIGURE 18-44 Linscheid test.

FIGURE 18-45 Carpal shake test.

FIGURE 18-46 Wrist flexion and finger extension test.

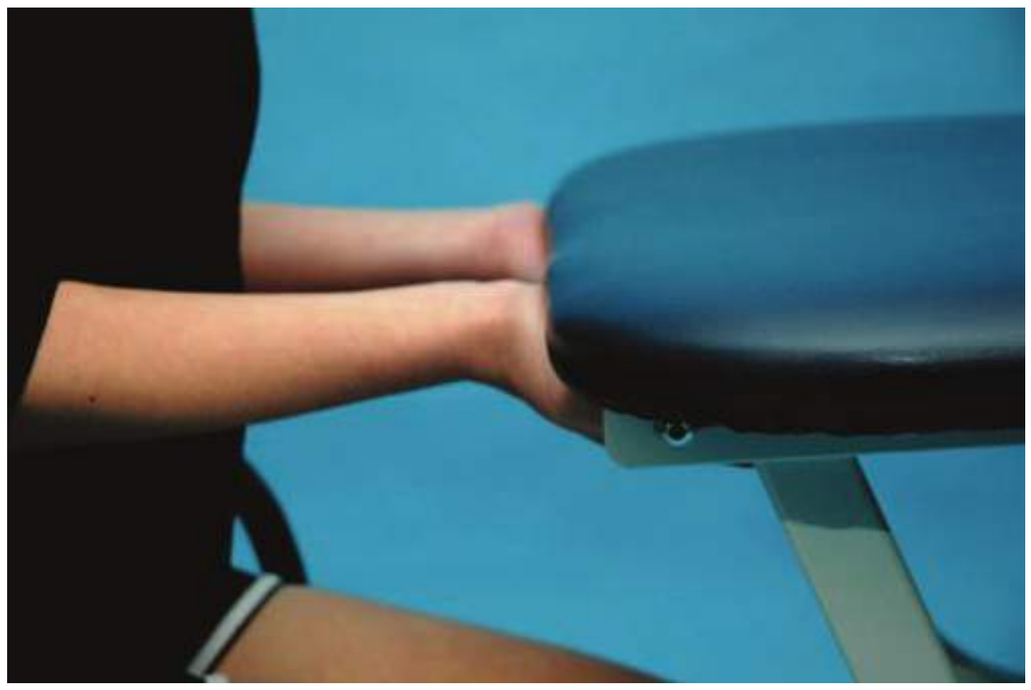

FIGURE 18-48 Supination lift test.

Press (Sit to Stand) Test. This test is used if a tear of the TFCC is suspected.[9] The patient is instructed to place both hands on the armrests of a chair and attempt to lift their body slightly off the chair (Fig. 18-47). Pain or resistance to this test indicates a positive test. Lester et al.[116] reported a sensitivity of 100% compared with arthroscopic surgery and a sensitivity of 79% when compared with magnetic resonance imaging (MRI) arthrogram. Specificity could not be determined on the basis of the methodology of this test design.

Supination Lift Test.[117] The patient is positioned in sitting with the elbows flexed to 90 degrees and the forearms supinated. The patient is asked to place the palms flat on the underside of the heavy table or against the clinician's hands. The patient is asked to lift the table or push up against the resisting clinician's hands (Fig. 18-48). A positive test for a TFCC tear is pain localized to the ulnar side of the wrist with difficulty applying force.

Ulnar Impaction Test. This test is used to assess the articulation between the ulnar carpus and the TFCC.[9] The patient is positioned in sitting, with the elbow flexed to about 90 degrees and the wrist positioned in ulnar deviation, and the fingers positioned in a slight fist. The clinician loads the wrist by applying a compressive force through the ring and small metacarpals (Fig. 18-49). Pain with this test indicates a possible tear of the TFCC or ulnar impaction syndrome (see "Intervention Strategies").

Finkelstein Test.[118] This test is used to detect stenosing tenosynovitis of the APL and EPB. The clinician grasps the patient's thumb, stabilizes the forearm with one hand, and then deviates the wrist to the ulnar side with the other hand (Fig. 18-50). No diagnostic accuracy studies have been performed to determine the sensitivity and specificity of this test, so the results of this test must be interpreted with caution,[119] as it may also be positive in Wartenberg syndrome (entrapment of the superficial radial sensory nerve),[120–122] basilar thumb arthrosis, EPB entrapment, or intersection syndrome (see "Intervention Strategies").[122] Deviating the wrist using pressure over the index metacarpal avoids confusion with thumb conditions.[123] A variation of Finkelstein test can be used to rule out an incomplete release of previous de Quervain disease.[124] If the usual Finkelstein test is positive, full abduction

FIGURE 18-47 Press (sit to stand) test.

FIGURE 18-49 Ulnar impaction test.

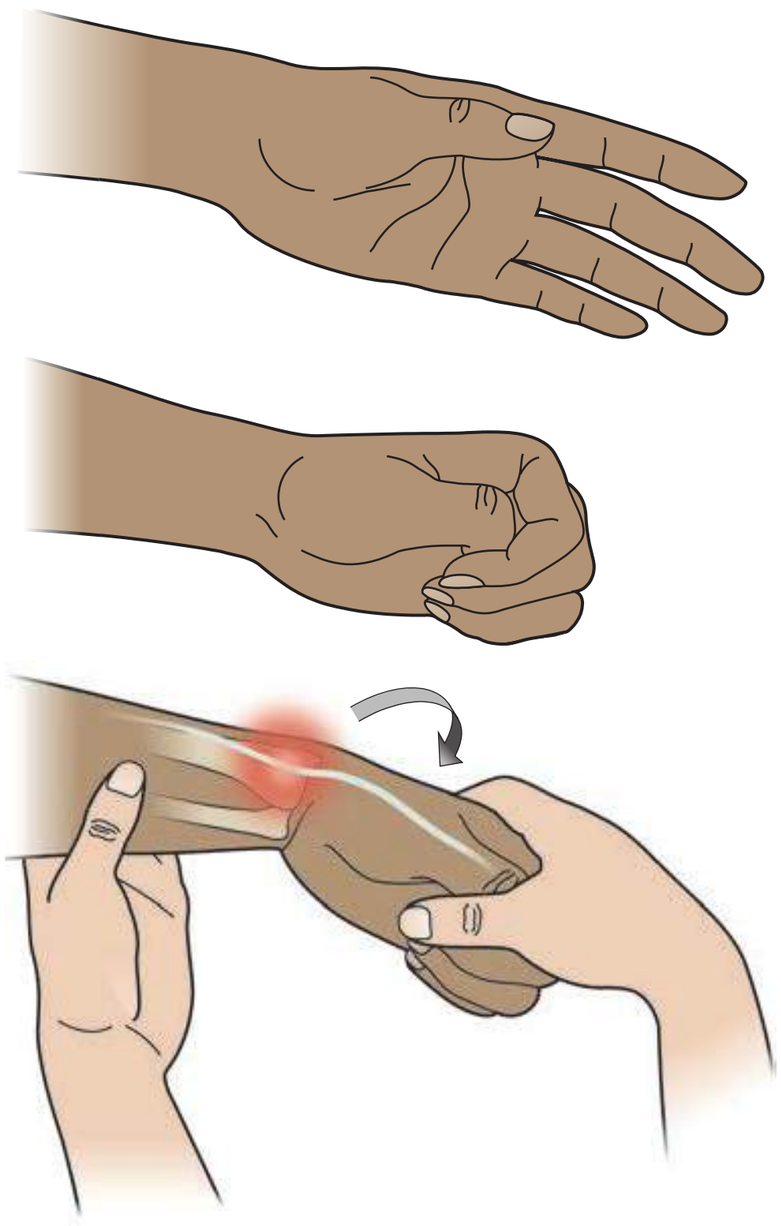

FIGURE 18-50 Finkelstein test.

FIGURE 18-51 Radioulnar ballottement test.

of the APL followed by flexion of the thumb's MCP joint will isolate the action of the EPB. Pain with this test will occur if the EPB lies in a separate sheath and was not released (EPB entrapment syndrome).[124] This test has been found to have a sensitivity of 81% and a specificity of 50%.[125]

Radioulnar Ballottement Test. The radioulnar ballottement test is used to assess DRUJ instability. The patient's elbow is flexed, and the clinician uses their thumb and index finger to stabilize the radius radially and the ulnar head ulnarly (Fig. 18-51). Stress is applied in an anterior–posterior direction. Normally there is no movement in the anterior or posterior direction in maximum supination or pronation. Pain or mobility with this test is suggestive of radioulnar instability.

Wartenberg Test. The Wartenberg test is used with patients who complain of pain over the distal radial forearm associated with paresthesias over the posterior (dorsal) radial hand (Wartenberg syndrome). These patients frequently report symptom magnification with wrist movement or when tightly pinching the thumb and index digit together. The Wartenberg test involves tapping the index finger over the superficial radial nerve (similar to the Tinel test for CTS) on the posterior and radial side of the wrist (Fig. 18-52). A positive test is indicated by local tenderness and paresthesia with this maneuver. Hyperpronation of the forearm can also cause a positive Tinel sign.

Finger Extension Test. This test is used to demonstrate posterior (dorsal) wrist syndrome, a localized scapholunate synovitis.[13] The clinician instructs the patient to fully flex the wrist and then actively extend the digits at both the IP and MCP joints. The clinician then applies pressure on the fingers into flexion at the MCP joints while the patient continues to actively extend (Fig. 18-53). A positive test occurs when there is production of central posterior (dorsal) wrist pain and indicates the possibility of Kienböck disease, carpal instability, joint degeneration, or synovitis (see "Intervention Strategies").[9]

FIGURE 18-52 Wartenberg test.

FIGURE 18-53 Finger extension test.

Scapholunate Shear Test. The patient is positioned in sitting with their forearm pronated. With one hand, the clinician grasps the scaphoid. With the other hand, the clinician grasps the lunate between the thumb and the index finger (Fig. 18-54). The lunate and scaphoid are then sheared in an anterior (palmar) and then posterior (dorsal) direction.[2] Laxity and reproduction of the patient's pain are positive signs for this test.[9]

Tendinous Integrity

FDS Test. This test is used to test the integrity of the FDS tendon. The clinician holds the patient's fingers in extension except for the finger being tested (this isolates the FDS tendon). The patient is instructed to flex the finger at the PIP joint (Fig. 18-55). If this is possible, the FDS tendon is intact. Since this tendon can act independently because of the position of the finger, it is the only functioning tendon at the PIP joint. The DIP joint, motored by the FDP, has no power of flexion when the other fingers are held in extension.

FDP Test. These tendons work only in unison. To test the FDP, the PIP joint and the MCP joints are stabilized in extension (Fig. 18-56). The patient is asked to flex this finger at the DIP joint. If flexion occurs, the FDP is intact. If no flexion is possible, the tendon is severed, or the muscle denervated.

FIGURE 18-55 Flexor digitorum superficialis (FDS) test.

The Integrity of the Central Slip (Extensor Hood Rupture).[126] The patient flexes the finger to 90 degrees at the PIP joint over the edge of the table. The patient is then asked to extend the PIP joint while the clinician palpates the middle phalanx (Fig. 18-57). The absence of extension force at the PIP joint, and fixed extension at the distal joint indicates complete rupture of the central slip.[22] No diagnostic accuracy studies have been performed to determine the sensitivity and the specificity of the clinical test.

Ligamentous Stability

A number of tests are available to evaluate the ligamentous stability of the forearm, wrist, hand, and finger joints. In the following tests, the patient is positioned in sitting, and the clinician is standing or sitting, facing the patient. The clinician must remember to perform these tests on the uninvolved side to provide a basis for comparison.

Piano Key Test. The piano key test evaluates the stability of the ulnomeniscotriquetral joint.[4] The clinician firmly stabilizes the distal radius with one hand and grasps the head of the ulna between the thumb and the index finger of the other hand. The ulnar head is depressed in an anterior direction (as in depressing a key on a piano) (Fig. 18-58).[9] The test is

FIGURE 18-54 Scapholunate shear test.

FIGURE 18-56 Flexor digitorum profundus test.

FIGURE 18-57 Integrity of the central slip (extensor hood rupture).

positive for a TFCC tear or triquetral instability if there is excessive movement in an anterior (palmar) direction or if upon release of the ulna, the bone springs back into its high posterior (dorsal) position. There may also be discomfort reported during the test.[79] La Stayo and Howell[127] found this test to have a sensitivity of 66% and a specificity of 64%.

Lunotriquetral Shear (Reagan) Test. This is test is designed to assess the integrity of the lunotriquetral ligament.[4] The clinician grasps the triquetrum between the thumb and the second finger of one hand and the lunate with the thumb and second finger of the other hand. The lunate is moved posteriorly (dorsally) with the thumb of one hand, while the triquetrum is pushed palmarly in the anteroposterior (AP) plane by the index finger of the other hand (Fig. 18-32). Crepitation, clicks, or discomfort in this area suggests injury to the ligament.[9,128] La Stayo and Howell[127] found this test to have a sensitivity of 64% and a specificity of 44% (LR+ 1.14; LR− 0.82).

FIGURE 18-58 Piano key test.

The Pisotriquetral Shear Test. The pisotriquetral shear test assesses the integrity of the pisotriquetral articulation.[9] The clinician stabilizes the wrist with the fingers posterior (dorsal) to the triquetrum and the thumb over the pisiform. The pisiform is rocked back and forth in a medial and lateral direction. A positive test is manifested with pain during this maneuver. No diagnostic accuracy studies have been performed to determine the sensitivity and specificity of this test.

Pivot Shift Test of the Midcarpal Joint. The patient is positioned in sitting with the elbow flexed to 90 degrees and the forearm supinated. The clinician uses one hand to stabilize the forearm while using the other hand to take the patient's hand into full ulnar deviation (Fig. 18-59). The patient's hand is then taken into full radial deviation. A positive test results if the capitate is felt to shift away from the lunate and indicates an injury to the anterior capsule and interosseous ligaments.[23] No diagnostic accuracy studies have been performed to determine the sensitivity and the specificity of this test.

Watson Test for Carpal Instability. The scaphoid shift maneuver examines the dynamic stability of the wrist, in particular, the integrity of the scapholunate ligament.[13] The patient is positioned in sitting with their elbow in approximately 90 degrees of flexion, the forearm slightly pronated, and the wrist ulnarly deviated. The clinician grasps the wrist from the radial side and stabilizes the scaphoid tubercle with the thumb and the posterior (dorsal) aspect of the scaphoid with the index finger. The clinician uses the other hand to grasp the metacarpals. Starting in ulnar deviation in slight extension, the wrist is moved into radial deviation and slight flexion. As the wrist is brought passively into radial deviation, the normal flexion of the proximal row forces the scaphoid tubercle into an anterior (palmar) direction (into the clinician's thumb). The clinician attempts to prevent the anterior (palmar) motion of the scaphoid. When the scaphoid is unstable, its proximal pole is forced to sublux posteriorly (dorsally.[9] Pain at the posterior (dorsal) wrist or a clunk suggests instability.[26,29] The results are compared with the other hand. The results from the scaphoid shift test, which has been found to have a sensitivity of 69% and a specificity of between

FIGURE 18-59 Pivot shift test of the midcarpal joint.

FIGURE 18-60 Gamekeeper's or skier's thumb.

FIGURE 18-61 Allen test.

64% and 68%,[127,129] should be used with caution, as the test can be positive in up to one-third of uninjured individuals.[14]

Scaphoid Shift Test. This is a slight modification of the Watson test. The patient positioning is similar to the Watson test except that the wrist is positioned in neutral to slight (0–10 degrees) radial deviation and neutral wrist flexion/extension. The clinician then quickly pushes the tubercle of the scaphoid in a posterior (dorsal) direction, noting a clunk, crepitus, or pain in comparison to the opposite wrist.[130] No diagnostic accuracy studies have been performed to determine the sensitivity and the specificity of this test.

Gamekeeper's or Skier's Thumb. The patient is positioned in sitting. The clinician stabilizes the patient's hand with one hand and takes the patient's thumb into extension with the other hand. While maintaining the thumb into extension, the clinician applies a valgus stress to the MCP joint of the thumb to stress the UCL (Fig. 18-60). A positive test is present if the valgus movement is greater than 30–35 degrees, indicating a complete tear of the UCL and the accessory collateral ligaments. Heymen et al.[131] reported a high sensitivity with this test (94%) and a 100% sensitivity and 46% specificity for detection of a palpable mass proximal to the MCP joint to indicate a complete tear of the UCL of the thumb.

Murphy Sign. The patient is asked to make a fist. If the head of the third metacarpal is level with the second and fourth metacarpals, the sign is positive for the presence of a lunate dislocation.[132]

Neurovascular Status

The assessment of sensibility and vasculature of the hand is an important component of every hand examination. Intact sensation is essential for precision movements and object manipulation. A number of tests can be used to document the neurovascular status of the wrist and hand.

Allen Test. The Allen test is used to determine the patency of the vessels supplying the hand. The clinician compresses both the radial and ulnar arteries at the wrist (Fig. 18-61), and then asks the patient to open and clench the fist three to four times to drain the venous blood from the hand. The patient is then asked to hold the hand open while the clinician releases the pressure on the ulnar artery and then the radial artery. The fingers and palm should be seen to regain their normal pink color. This procedure is repeated with the radial artery released and compression on the ulnar artery maintained. Normal filling time is usually less than 5 seconds. A distinct difference in the filling time suggests the dominance of one artery filling the hand.[128]

Tinel (Percussion) Test for CTS. The Tinel test is used to assist in the diagnosis of CTS. The area over the median nerve is tapped gently at the anterior (palmar) surface of the wrist (Fig. 18-62). If this produces tingling in the median nerve distribution, then the test is positive.[133] Variations exist among studies on the location and number of taps necessary to elicit a positive response, and in some studies the test is performed by tapping the median nerve in 20 degrees of wrist extension, while others tap along the path of the median nerve up to where the median nerve enters the carpal tunnel. The Tinel test has demonstrated a sensitivity of 60% and a specificity of 67%,[134] indicating that it is moderately acceptable for use in clinical practice.[135–138]

APB Weakness for CTS. The patient is positioned in sitting with their hand resting on the table. The clinician asked the patient to touch the pads of the thumb and small finger together. If this can be performed, the clinician then applies a strong force in order to resist thumb abduction (Fig. 18-63). A positive test is a weakness in some abduction with resisted testing as compared to the other hand. Studies performed to determine weakness in the APB are

FIGURE 18-62 Tinel test at the wrist.

FIGURE 18-63 Abductor pollicis brevis weakness.

FIGURE 18-65 Reverse Phalen test.

relatively consistent, demonstrating moderate diagnostic accuracy. For example, in a study by Gerr and Letz[139] the test was found to have a sensitivity of 63% and a specificity of 62%, compared to a Kuhlman and Hennessy study[140] that found the sensitivity to be 66% and the specificity to be 66%.

Phalen Test for CTS.[141,142] For the Phalen test, the patient sits comfortably with the wrists and elbows flexed (Fig. 18-64). The test is positive if the patient experiences numbness or tingling throughout the median nerve distribution of the hand within 45 seconds. For some patients, the performance of this test recreates their wrist, thumb, or forearm ache.[143] Some studies have varied this test to be performed by the patient with wrist in complete flexion and elbow extended, bilateral wrist flexion with the posterior aspect of the hand pressing against one another, or passive wrist flexion by the clinician. The original Phalen test has demonstrated a sensitivity of 75% and a specificity of 47%,[144] making it moderately acceptable for use in clinical practice.

Reverse Phalen Test for CTS. A reverse Phalen position is the same as the Phalen except the palms are placed together (Fig. 18-65). The patient is asked to keep both hands with the wrists in complete extension for 60 seconds (wrist and finger extension). A study by de Krom et al.[145] found the test to have a sensitivity of 41% and a specificity of 55% (LR+ 0.9; LR− 1.1). In another study, Werner et al.[146] showed that this maneuver results in a significantly higher intracarpal canal hydrostatic pressure as compared to a traditional Phalen or a modified Phalen maneuver and may add to the sensitivity of conventional screening methods.[133,147]

Hand Elevation Test for CTS. The patient is seated or standing and is asked to elevate both arms above the head (Fig. 18-66) and maintain them in this position until the patient feels paresthesia or numbness.[148] A positive test is the reproduction of symptoms, such as paresthesia and numbness in the median nerve distribution after raising the arms for no greater than 2 minutes. A study by Ahn[149] found this test to have a sensitivity of 76% and a specificity of 99% (LR+ 76; LR− 0.24). In another study[148], this test was found to be more specific than the Phalen and Tinel tests. Although this

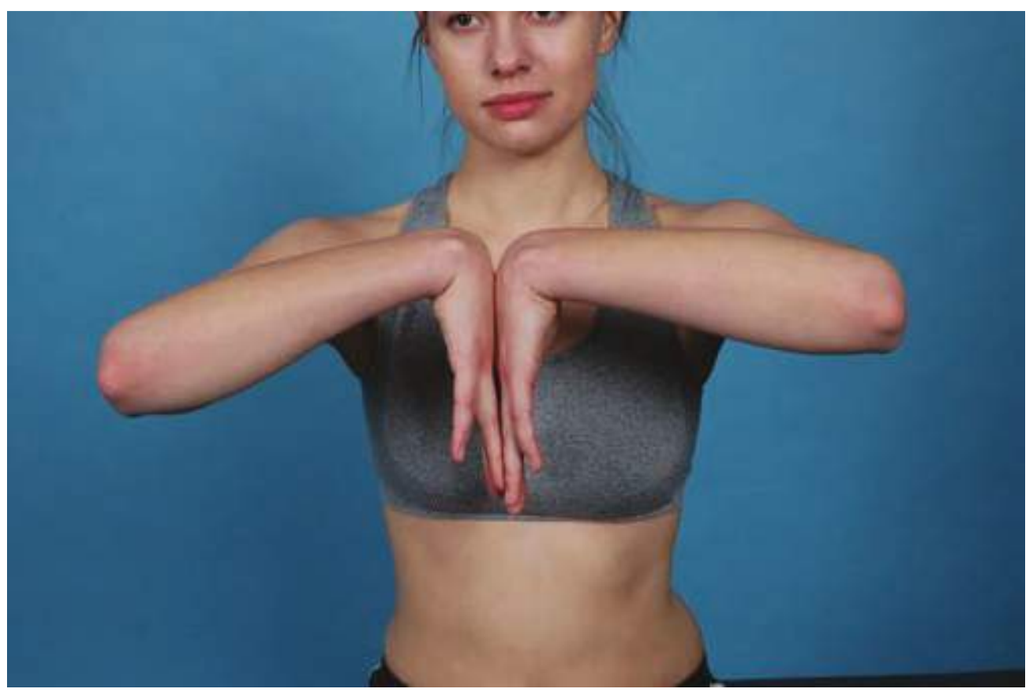

FIGURE 18-64 Phalen test.

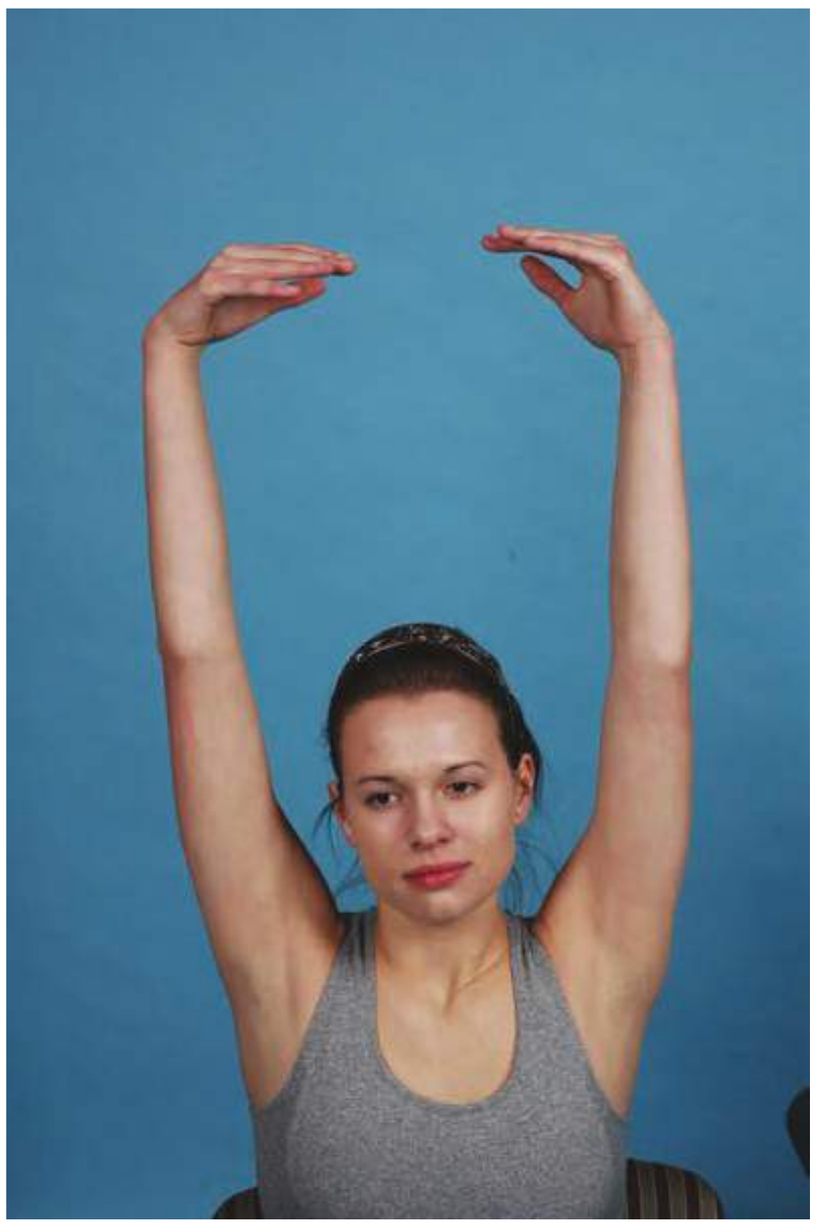

FIGURE 18-66 Hand elevation test.

clinical test has high diagnostic values, there are numerous procedural biases in both study designs. In addition, the test may be positive in patients with thoracic outlet syndrome.

Wrist Flexion and Median Nerve Compression. The patient is positioned in sitting with the elbow fully extended, the forearm in supination and the wrist flexed to 60 degrees. The clinician applies an even constant pressure over the median nerve at the carpal tunnel using the thumb. A positive test for CTS is the reproduction of symptoms along the median nerve distribution within 30 seconds. Tetro et al. found this test to have a sensitivity of 86% and a specificity of 95% (LR+ 17; LR− 0.1).[149]

Median Nerve Compression Test/Pressure Provocation Test

The clinician sits opposite to the patient and holds the patient's hand with the clinician's thumbs directly over the course of the median nerve as it passes under the flexor retinaculum between the FCR and the palmaris longus. The clinician places gentle sustained pressure with the thumbs for 15 seconds to 2 minutes. The clinician then removes the pressure and questions the patient on the relief of symptoms, which may take a few minutes. A positive test is the reproduction of pain, paresthesia, or numbness distal to the site of compression during the compression in the distribution of the median nerve. Williams et al.[150] found this test to have a sensitivity of 100% and a specificity of 97% (LR+ 33; LR− 0).

Flick Maneuver. The patient is positioned in sitting and is asked to vigorously shake his or her hands (Fig. 18-67). A positive test, indicating CTS, is the resolution of the paresthesia symptoms during or following administration of flicking the wrist. There appears to be some confusion as to what constitutes a flick. Some studies define a flick as a rapid, alternating movement up and down of the wrist, whereas others describe

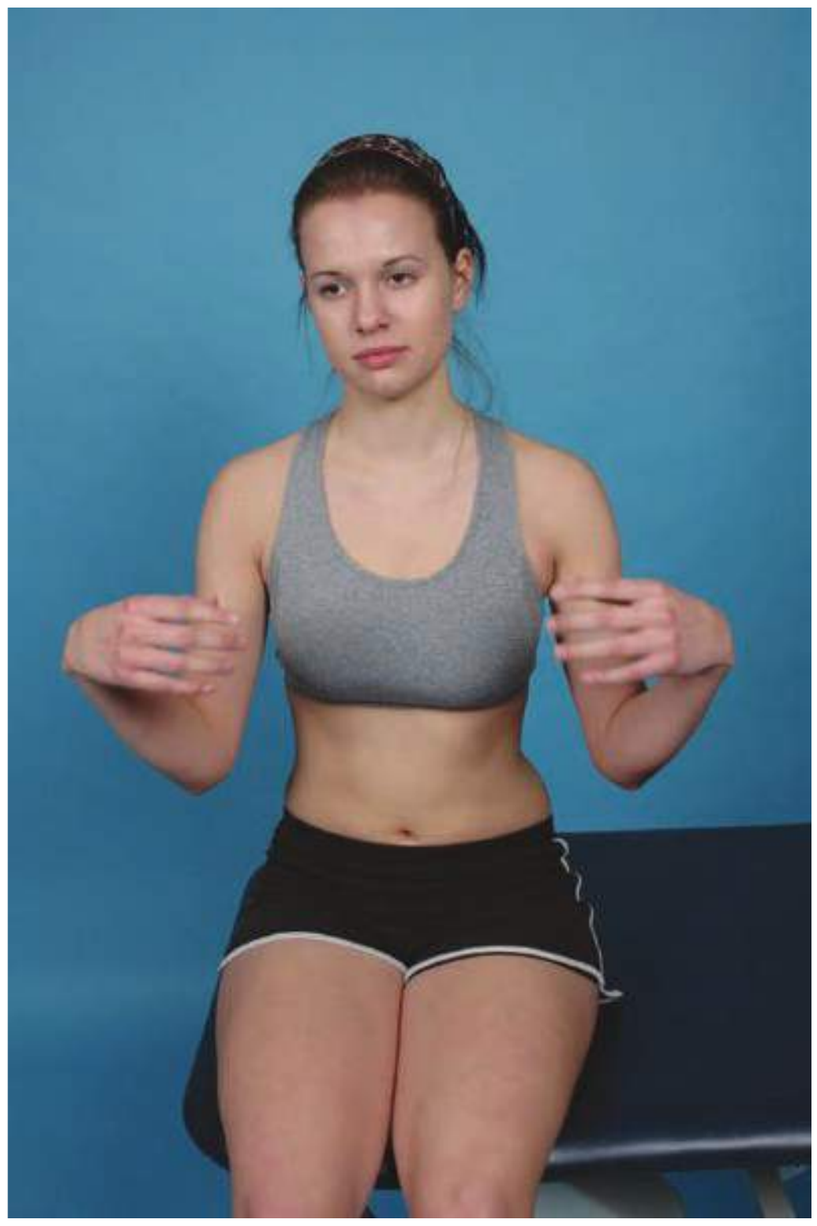

FIGURE 18-67 Flick maneuver.

the positive flick with as little movement as elbow extension. The diagnostic usefulness of this test is outlined in Table 18-12.

Semmes–Weinstein Monofilament Testing. The palm of the hand is divided into several areas, and only one point (usually in the center) is tested in each area.

- Between the fingertip and DIP joint.
- Between the DIP joint and PIP joint.

TABLE 18-12 The Diagnostic Usefulness of the Flick Maneuver

Study Description	Reliability	Sensitivity	Specificity	LR+	LR−	DOR	QUADAS Score
Hundred persons referred with suspected carpal tunnel syndrome underwent clinical and neurophysiological examinations blinded from each other. The gold standard for the CTS diagnosis was based on the results of these examinations but relief of CTS symptoms after surgery was also required[a]	NT	90	30	1.3	0.3	3.9	13
One hundred forty-two subjects referred for electrodiagnostic evaluation of possible CTS were first clinically evaluated with the flick, Phalen, and Tinel maneuvers before undergoing nerve conduction studies[b]	NT	37	74	1.4	0.9	1.7	11
The validity of 12 provocative tests for CTS in a random sample of 504 people from the general population was assessed[c]	NT	50	61	1.3	0.8	1.6	10

Red	4	4.56
Red/orange	300	6.65
Diagonal redline	No response	0

- Between the PIP joint and finger web.
- Between the finger web and the distal anterior (palmar) crease.
- Between the distal anterior (palmar) crease and the central palm.
- The base of the palm and wrist.
- Superficial radial nerve distribution (Fig. 18-68)

The clinician applies a monofilament perpendicular to the surface, and the pressure is increased until the monofilament begins to bend (Fig. 18-69). Filament 2.83 MN is considered the "Normal" filament and indicates normal light touch perception. A positive test for CTS is when the patient with eyes closed cannot report which digit is receiving pressure at 2.83 mg. Normal values are depicted in Table 18-13. The diagnostic usefulness of this test based on some of the studies is outlined in Table 18-14.

Weber (Moberg) Two-Point Discrimination Test. The two-point discrimination tests were first introduced by Weber in 1953 using calipers and by Moberg in 1958[151] using a paper clip.

Today it is recommended that a two-point aesthesiometer tool, such as a Disk-Criminator (Fig. 18-69) be used. The instrument is explained and demonstrated to the patient until an appreciation can be made between one and two points in an area of normal sensibility. The instrument is applied, in a perpendicular fashion, to all of the fingertips in a mixed series of two and one points for five consecutive applications. The patient should be able to recognize at least four out of the five or seven out of ten.[23] The clinician repeats the tests in an attempt to find the minimal distance at which the patient can distinguish between the two stimuli, decreasing or increasing the distance between the points depending on the response by the patient.[23] This distance is called the threshold for discrimination. Normal discrimination distance is less than 6 mm, although this can vary between individuals, and in the area of the hand, with normal fingertip scores between 2 and 5 mm and finger surface scores between 3 and 7 mm.[152] Studies investigating the sensitivity and the specificity of this test indicate that the test has a high specificity but low sensitivity. For example, Busch-Jaeger and Foucher[153] found the test to have a sensitivity of 6% and a specificity of 99%. Another study by Gelman et al.[135] found the sensitivity to be 33% and the specificity to be 100%. These findings suggest that the test is useful for ruling in CTS.

Froment Sign. This is more of a sign than a test and may present as a complaint from the patient who reports an inability to pinch between the index finger and the thumb without flexion occurring at the DIP joint (Fig. 18-70).[154] A positive Froment sign, which results from a weakness in the AP and short head of the FPB muscles, indicates an ulnar nerve entrapment at the elbow or at the wrist.

FIGURE 18-69 Disk-criminator.

FIGURE 18-70 Froment sign.

Wrist Ratio Index. Sliding calipers are used to measure the mediolateral wrist width and then the AP height in centimeters. The caliper jaws are aligned with the distal wrist crease for both measurements. The wrist ratio index is calculated by dividing the AP measurement by the mediolateral measurement. A positive test for CTS is a wrist ratio of greater than 0.67. When used in isolation, the wrist ratio index does not appear to have a strong diagnostic accuracy (Table 18-15).

The Katz Hand Diagram. Katz et al.[155] developed a hand symptom diagram rating system, which categorizes the distribution of current neuropathic hand symptoms using a key of numbness, tingling, pain, and decreased sensation. The diagram is designed to help diagnose those patients who have classic, probable, possible, and unlikely categories for CTS based on completion of the diagram. A number of studies have examined the diagnostic usefulness of the Katz Hand Diagram (Table 18-16).

The Wazir Sign[156]

The patient's wrist is rested in extension, supination, and a relaxed position supported by the clinician. Using a reflex hammer or finger tip, the clinician gently taps on the extended wrist around the palmaris longus tendon (Fig. 18-71). A positive sign, indicating cervical myelopathy, exaggerates the response of finger flexion, thumb flexion, and wrist flexion. The basis of this sign can be explained on the basis of disinhibition of tendon stretch reflex of the long flexor tendons of the fingers (C7 and C8), wrist flexors (C6 and C7), and/or with the involvement of pyramidal tracts.

Adverse Neural Tension

The Median Nerve. The patient is positioned in supine lying or sitting. The cervical spine is side bent and rotated to the opposite side. The shoulder girdle is positioned in retraction, depression, extension, and external rotation. The elbow is

positioned in extension, the forearm in supination, and the wrist in extension (Chapter 11). The fingers are positioned in extension. Nerve irritation is suspected if

- with the cervical spine in the resting position, the upper extremity position described above results in symptoms in the anterior (palmar)/radial side of the hand;
- if the symptoms increase with cervical side bending and rotation away from the tested extremity;
- if the symptoms decrease with side bending and rotation toward the tested extremity.

If adherence of the nerve is suspected at the wrist, the cervical spine is positioned in the resting position and the extremity is positioned as before. Neural involvement should be suspected if

- with wrist flexion the symptoms decrease but increase when the cervical spine is side bent and rotated away from the tested extremity;
- with wrist extension and the cervical spine side bent and rotated to the tested extremity, the symptoms decrease.

FIGURE 18-71 The Wazir sign.

Radial Nerve. The patient is positioned in a supine or sitting position, and the shoulder is positioned in retraction, depression, extension, and internal rotation. The elbow is positioned in extension, the forearm in pronation, the wrist in flexion and ulnar deviation, and the fingers in flexion (Chapter 11). If a nerve adhesion is suspected at the wrist, the procedure is as for the median nerve, except that the wrist is placed in extension and then taken back into flexion.

The posterior (dorsal) sensory nerve, which can become implicated (Wartenberg syndrome; see "Intervention strategies") in a variety of radial-sided injuries because of its superficial location, can be stretched with a combination of wrist flexion and ulnar deviation.

Ulnar Nerve. The shoulder girdle positioning used to describe the test for the median nerve is used. The elbow is flexed and supinated; the wrist is extended and radially deviated, and the fingers extended (Chapter 11). If a nerve adhesion at the wrist is suspected, the procedure is as for the median nerve.

Diagnostic Imaging

Diagnostic testing of the forearm, wrist, and hand is limited to plain radiographs for most patients (see Chapter 7). Bony tenderness with a history of trauma or a suspicion of bone or joint disruption indicates a need for radiographs. Standard projections for the wrist are the posteroanterior, lateral, and oblique. For the patient with a suspicion of a scaphoid injury, a scaphoid view should be added.[4] Wrist conditions rarely require computed tomography scans and MRI scans.[128]

The Evaluation

Following the examination, and once the clinical findings have been recorded, the clinician must determine a specific diagnosis or a working hypothesis, based on a summary of all of the findings. This diagnosis can be structure related (medical diagnosis) (Tables 18-17 and 18-18) or a diagnosis based on the preferred practice patterns as described in the Guide to Physical Therapist Practice.

INTERVENTION STRATEGIES

To restore the balance and beauty and power to a disabled hand is an adventure. The stakes are high. The rewards are exciting. The penalties *of f*ailure are grievous.

—Paul W. Brand (1914–2003)

Functional rehabilitation of the upper extremity emphasizes the restoration of functional use of the hand.[105] Hand functions can range from activities that require a strong gripping action to those that require fine precision and gentle touch. Stability of the wrist and hand is provided by a combination of muscular effort and ligamentous support. The motion of the hand and wrist is provided by a vast array of muscles and tendons and several articulated linkages. The hand and wrist can be involved in both open- and closed-kinetic chain activities.

Pain is perhaps the most common complaint with wrist and hand injuries, with stiffness following closely behind. Some conditions, such as peripheral nerve injury (as a result of fracture, dislocation, disease, etc.), diabetes mellitus, Raynaud, and complex regional pain syndrome (CRPS), are characterized by a loss of sensibility to varying degrees. Sensory recovery progresses in time and space according to the following successive stages:[157]

- Perception of pain and temperature—establishment of protective sensation
- Perception of low-frequency vibratory stimuli (30 Hz) as well as moving sense
- Per static tactile sense, at the same time as perception of high-frequency vibratory stimuli (256 Hz)
- Two-point discrimination—the last form of sensation to develop

Motor recovery is always slower than sensory recovery with the first sign of motor recovery being the regression of the atrophy in the territory normally supplied by the injured nerve.[157] Later, a weak contraction can be detected in the first muscle supplied by the nerve distal to the lesion, although this contraction is not powerful enough to produce joint movement or to overcome gravity.[157]

Physical therapy techniques that can be used to help with motor and sensory recovery include the following:

- Activities and techniques to increase tactile input, including electrical stimulation, high-frequency vibration, and tapping
- Contrast baths (for vasomotor disturbances)
- Protection through splinting
- Dexterity activities
- Weight-bearing activities through the affected extremity
- Neurodynamic mobilizations (Chapter 11)

These techniques to increase joint mobility and the techniques to increase soft-tissue extensibility are described in "Therapeutic Techniques".

Acute Phase

The goals of the acute phase include the following:

- Protection of the injury site to allow healing.
- Control pain and inflammation.
- Control and then eliminate edema.
- Restoration of a full pain-free range of motion in the entire kinetic chain.
- Improve patient comfort by decreasing pain and inflammation.
- Retard muscle atrophy.
- Minimize detrimental effects of immobilization and activity restriction.[158–163]
- Scar management if appropriate.
- Maintain general fitness.
- Patient to be independent with a home exercise program.

Pain and inflammation control is the major focus of the intervention program in the acute phase. This may be accomplished using the principles of PRICEMEM (protection, rest, ice, compression, elevation, manual therapy, early motion, and medication). Icing for 20–30 minutes, three to four times a day, concurrent with nonsteroidal anti-inflammatory drugs (NSAIDs), or aspirin can aid in reducing pain and swelling.

One of the most significant problems a clinician faces with a hand-injured patient is the control and the elimination of edema. Edema can increase the risk of infection, decrease motion, and inhibit arterial, venous, and lymphatic flow.[164] Methods to control edema include elevation of the upper extremity and hand above the level of the heart, cryotherapy, active exercise, retrograde massage, intermittent compression, continuous compression wrapping, and contrast baths.

Therapeutic exercises are performed with the goal of regaining adequate soft-tissue rebalancing of the wrist by restoring the alignment of the extensor and the flexor tendons as near to normal as possible, and to prevent scarring or soft-tissue contractures by influencing the physiologic process of collagen formation. Movement is necessary to maintain joint mobility and gliding tendon function. Range-of-motion exercises are introduced as early as tolerated. These may be passive, active assisted, or active, as appropriate. If protected motion is necessary, it can be provided with taping, bracing, or in extreme cases, casting.

PROM exercises are performed through the available range of motion to maintain joint and soft-tissue mobility, or a passive stretch can be applied to the end range of motion to lengthen pathologically shortened soft-tissue structures, thereby increasing motion. Depending on the focus of the intervention, the PROM exercises may include:

TABLE 18-18 Findings in Common Conditions of the Hand and Wrist

Condition	Findings
de Quervain stenosing tenosynovitis	Tenderness and swelling over the first posterior (dorsal) compartment at the radial styloid Finkelstein test aggravates pain
Dupuytren disease	Palpable nodules and pretendinous cords in anterior (palmar) aponeurosis, most commonly affecting the ring or the little finger Secondary flexion contracture of the MCP and, occasionally, PIP joints
Flexor tendon sheath infection	Cardinal signs of Kanavel present Finger held in flexed position at rest Swelling along the volar surface of the finger Tenderness on the volar surface of the finger along the course of the flexor tendon sheath Pain exacerbated by passive extension of the involved finger
Injury to the ulnar collateral ligament of the MCP joint of the thumb (skier's or gamekeeper's thumb)	Swelling and tenderness over the ulnar aspect of the thumb MCP joint Pain exacerbated by stress of the UCL Increased laxity of the thumb UCL (more severe injuries)
Scapholunate instability	Swelling over the radial wrist. X-rays show increased scapholunate gap on clenched fist view (>1 mm) Tenderness over the posterior (dorsal) wrist over the scapholunate ligament Scaphoid shift test produces abnormal popping and reproduces the patient's pain
Mallet finger	Flexed or dropped posture of the finger at the DIP joint History of jamming injury (impact of a thrown ball) Inability to actively extend or straighten the DIP joint
Jersey finger (FDP avulsion)	Mechanism is hyperextension stress applied to a flexed finger (e.g., grabbing a player's jersey) Patient lacks active flexion at the DIP joint (FDP function lost) Swollen finger often assumes a position of relative extension compared to the other more flexed fingers
Degenerative arthritis of the fingers	Heberden nodes (most common) Bouchard nodes (common) Mucous cysts (occasional) Decreased motion at involved IP joints Instability of involved joints (occasional)

Data from Mass DP, Reider B. Hand and wrist. In: Reider B, ed. The Orthopaedic Physical Examination. Philadelphia, PA: WB Saunders; 1999:99–158.

- MCP flexion and extension (Fig. 18-72).
- PIP and DIP flexion and extension (Fig. 18-73) and combined flexion and extension (Fig. 18-74).

AROM exercises should include specific and composite exercises. Composite exercises, which include fisting and thumb opposition to each digit in addition to exercises involving the wrist, elbow, and shoulder are designed to reproduce normal functional activities. Fast ballistic movements are discouraged if the goal is to restore mobility in the presence of increasing tissue resistance.[165] Examples of AROM exercises include the following:

- Active wrist and finger flexion and extension, wrist ulnar and radial deviation, finger adduction and abduction, and thumb opposition (Fig. 18-75), flexion, extension, abduction, and adduction. The wrist and hand muscles are usually exercised as a group if their strength is similar. Weaker muscles should be isolated in a similar fashion as that used when isolating the muscle for manual muscle testing. Protected range-of-motion exercises are performed to selectively mobilize joints and tendons while minimizing stress on repairing structures. As their name suggests, protected range-of-motion exercises are accomplished by placing the repaired structure in a

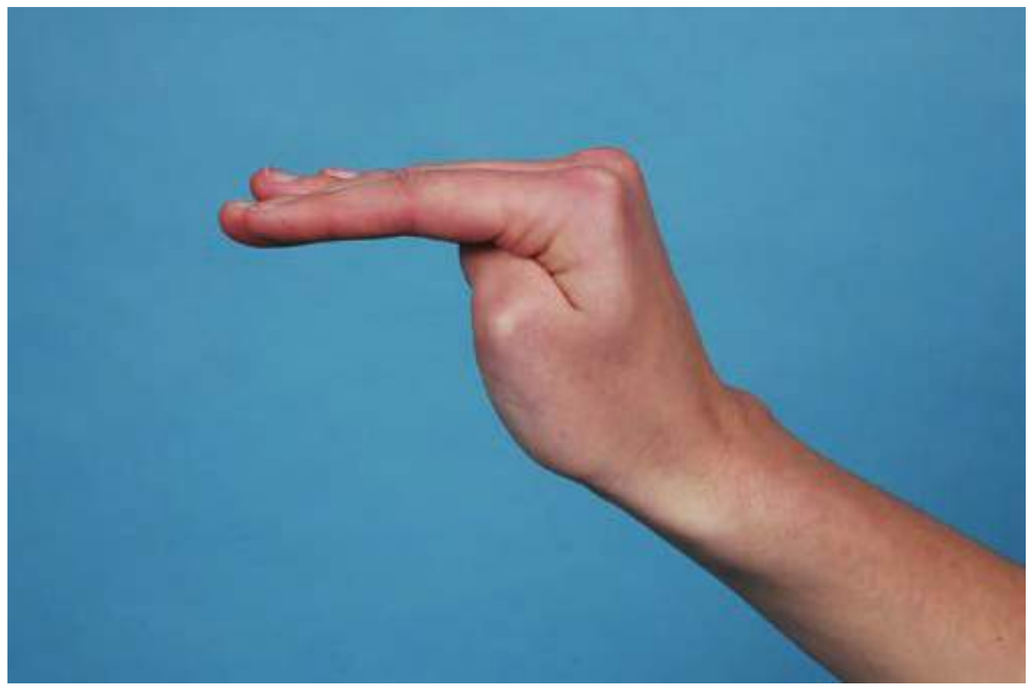

FIGURE 18-72 Isolated MCP flexion.

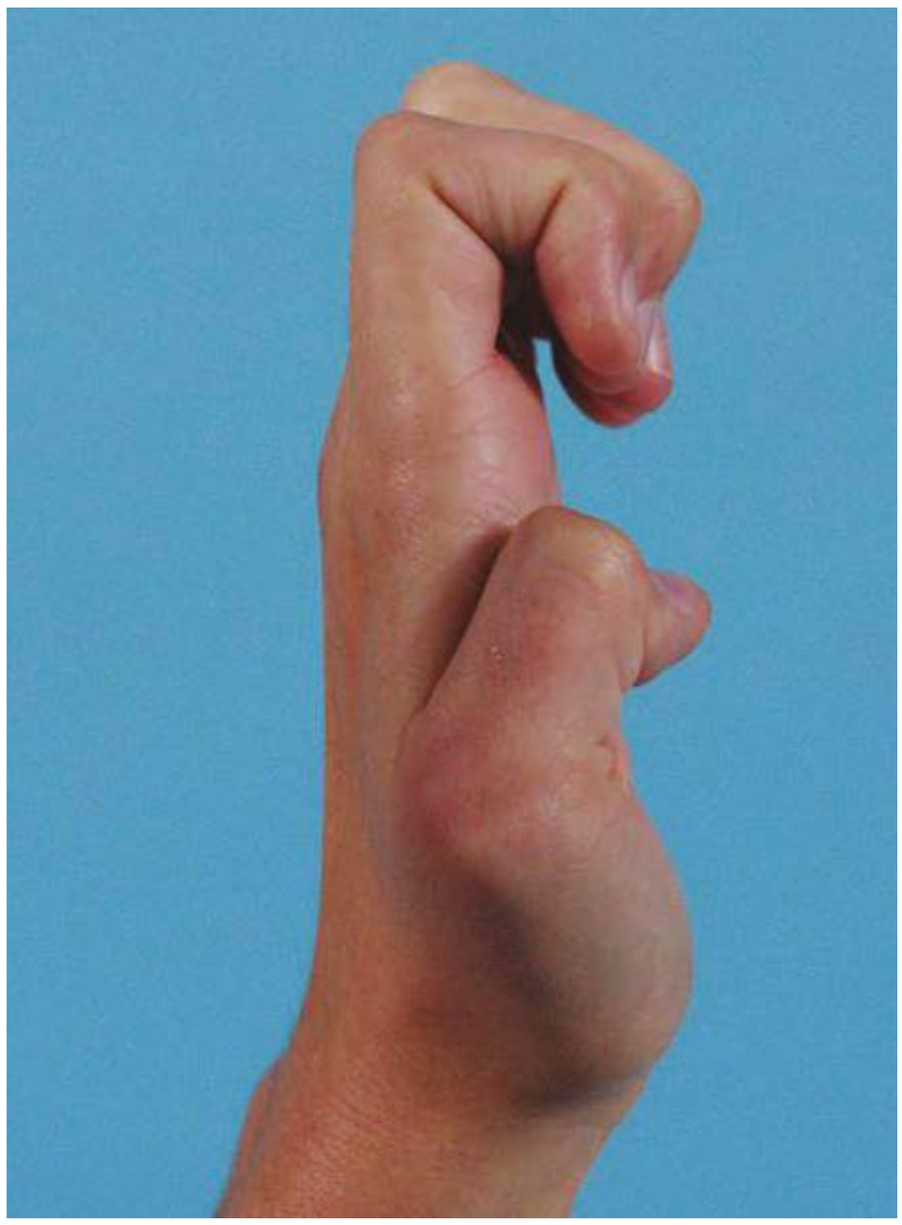

FIGURE 18-73 Isolated PIP and DIP flexion and extension.

protected position while adjacent tissues are carefully mobilized. An example of protective exercise can be seen following a radial nerve injury, where tendon transfers of the pronator teres, FCU, and FDS may be performed.[165] Following the surgery, the hand is immobilized with the wrist, MCP joints, and thumb in extension. At approximately 4 weeks, protective active motion exercises are introduced. These include MCP joint flexion and then PIP and DIP joint flexion with the MCP joint maintained in extension.[165]

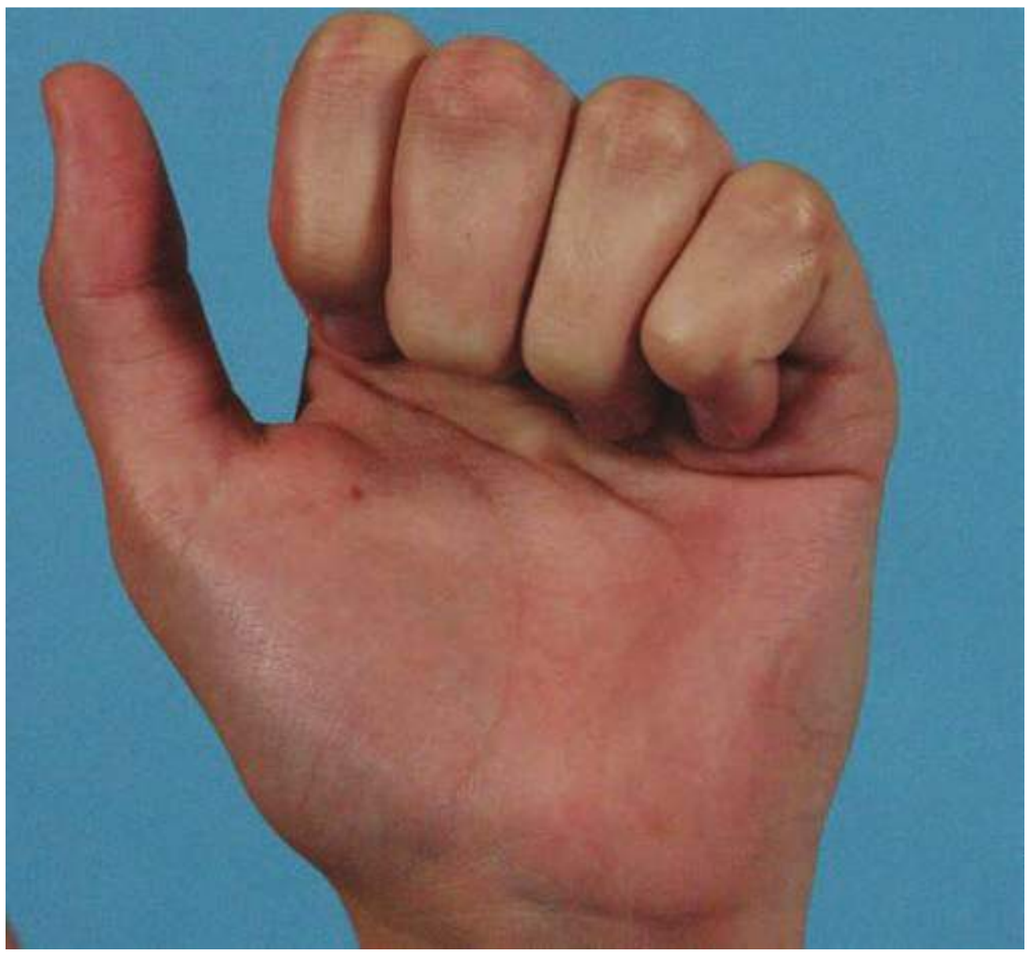

FIGURE 18-74 MCP, PIP, and DIP flexion and extension.

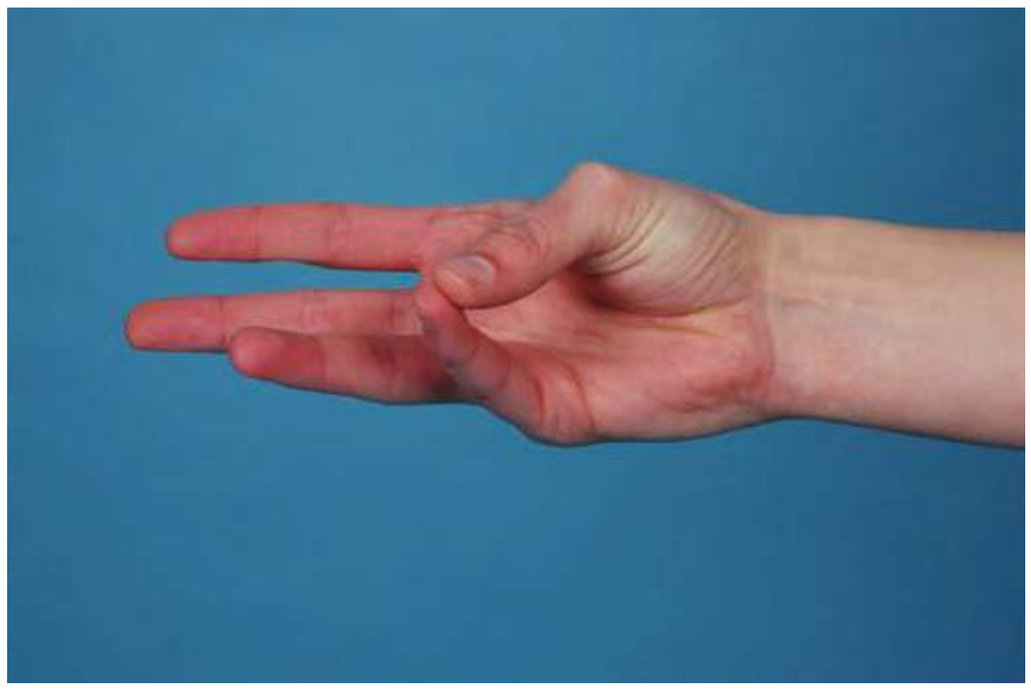

FIGURE 18-75 Thumb opposition.

- Active exercises of forearm pronation and supination.
- Active exercises of elbow flexion and extension

These AROM exercises are progressed to submaximal isometrics and muscle co-contractions. These early strengthening exercises are performed initially in the available pain-free ranges and, as the pain subsides, are gradually progressed so that they are performed throughout the entire range.

Scar tissue management focuses on the control of stresses placed on healing tissues. Early active and passive motion provides controlled stress, encouraging optimal remodeling of scar tissue.[164] Methods to control scarring include the use of thermal agents, transverse friction massage (TFM) (see Chapter 10), mechanical vibration, compressive techniques, and splinting.

Splinting of the wrist and hand may be necessary. It is not within the scope of this text to provide comprehensive detail with regard to splinting. Entire texts are devoted to the subject.[166–169] However, splinting can often be an integral part of the rehabilitation program, and creative splinting can provide a useful adjunct to exercise. The general purposes of a splint are as follows[170,171]:

- Prevent or correct deformity or dysfunction. Maintain or re-establish normal tissue length, balance, and excursion.
- Immobilize/stabilize. To stabilize a mobile joint so the corrective exercise force can be directed to the stiff joint or adherent tendon.[165]
- Protect. Static splints have no moveable parts and maintain joints in one position to promote healing and minimize stress.
- Control/modify scar formation.
- Substitute for a dysfunctional tissue.
- Provide exercise. Dynamic splints are used to provide active resistance in the direction opposite their line of pull to increase muscle strength, as well as to apply a corrective passive stretch to tendon adhesions and joint contractures.[165]Drop-out splints, which are commonly used with elbow flexion contractures, block joint motion in one direction but allow motion in another. Articulated splints contain at least two static components and are designed in such a way as to allow motion in one plane at a joint. Static-progressive splints involve the use of inelastic

components to allow progressive changes in joint position as PROM changes without changing the structure of the splint. Serial static splints differ from static progressive splints in that they require the clinician to remold the splint to accommodate changes in the range of motion.

Functional Phase

The functional phase of rehabilitation is usually initiated when normal wrist positions and co-contractions of the wrist flexors and extensors can be performed. The goals of the functional phase include the following:

- Attain full range of pain-free motion.
- Restore normal joint kinematics.
- Improve muscle strength to within normal limits.
- Improve neuromuscular control.
- Restore normal muscle force couple relationships.

The AROM exercises, initiated during the acute phase, are progressed until the patient demonstrates they have achieved the maximum range anticipated.

Normal joint kinematics are restored using joint mobilization techniques. Joint mobilization techniques refer to passive traction and/or gliding movements to joint surfaces that maintain or restore the joint play normally allowed by the capsule. The joint mobilization techniques for the forearm, wrist, and hand are described in "Therapeutic Techniques" at the end of this chapter.

Resistive exercises not only increase muscle strength and endurance but also improve the ability of the patient to actively mobilize stiff joints.[165] Resistance exercises for the hand and wrist can be classified as either static (isometric) or dynamic (concentric, eccentric, or isokinetic). Strengthening of the muscles of the wrist and hand begins with specific exercises and progress to exercises that involve the entire upper kinetic chain, including the trunk. Isometric exercises may be continued from the acute phase when the available range of motion remains restricted. Wherever possible, resistance exercises that strengthen functional muscle groups rather than individual muscles should be selected.[165] Specific exercises for the wrist and hand include the following:

- Resisted exercises into pronation (Fig. 18-76) and supination (Fig. 18-77).

FIGURE 18-77 Resisted supination.

- Hand and finger dexterity exercises, including the nine-peg board (Fig. 18-78) or stroking exercises.
- Manually resisted exercises (Fig. 18-79). These are performed by the clinician initially, before becoming part of the patient's home exercise routine (Fig. 18-80).
- Resisted exercises can be performed using gripping with light resistive putty (Fig. 18-81) or a hand exerciser (Fig. 18-82). Care must be taken with gripping or squeezing exercises because they typically restrict the use of the full range of motion.
- Resisted exercises can also be performed using elastic resistance (Fig. 18-83), dumbbells (Fig. 18-84), or using a device called the TheraBand™ FlexBar©, which is a flexible, durable resistance device with a ridged surface for enhanced grip during use that can be used to improve grip strength and upper extremity stabilization. The twisting techniques depicted in Figs. 17–72 through 17–75 can be used to include eccentric loading of the wrist extensors moving from a position of wrist extension to wrist flexion. Alternately, the techniques depicted Figures 17–76 to 17–79 include eccentric loading of the wrist flexors moving from a position of wrist flexion to wrist extension.
- Wrist extension should be done in pronation to work against gravity or in neutral forearm rotation to eliminate gravity. This exercise encourages the involvement of the ECRL, ECRB, and ECU. MCP flexion can be employed

FIGURE 18-76 Resisted pronation.

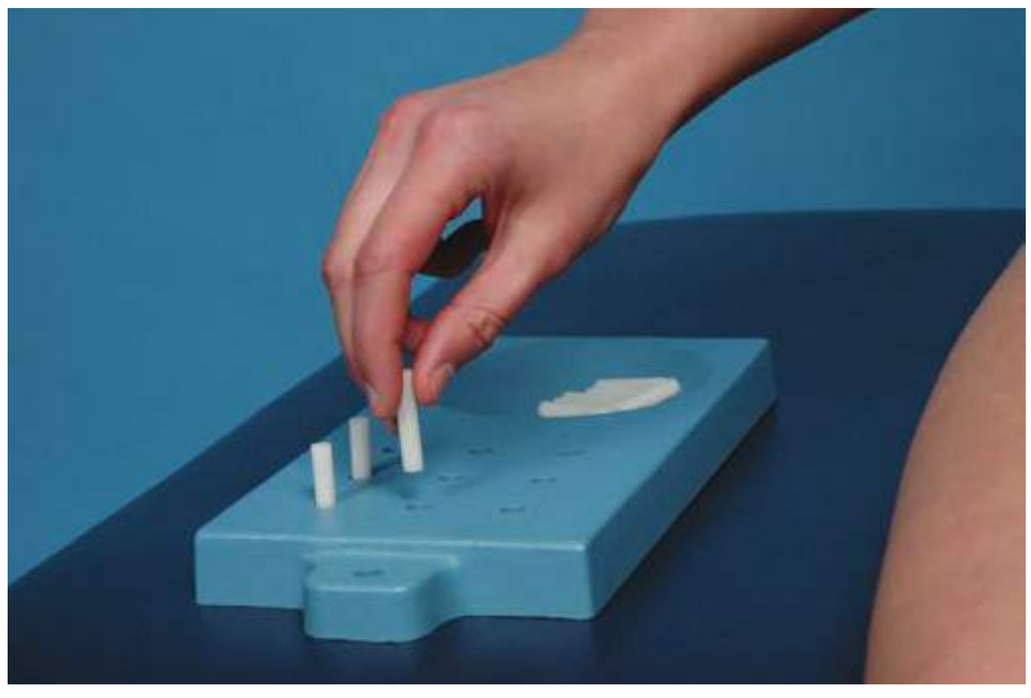

FIGURE 18-78 Nine-peg board.

FIGURE 18-79 Manually resisted exercises.

to eliminate any contribution from the ECU, thereby isolating the wrist musculature.

- Wrist flexion should be done in supination to work against gravity or in neutral forearm rotation to eliminate gravity. Wrist flexion works the FCU and FCR.

FIGURE 18-80 Resistance using elastic bands.

FIGURE 18-81 Putty exercises.

FIGURE 18-82 Hand exerciser.

FIGURE 18-83 Resisted wrist flexion with elastic resistance.

FIGURE 18-84 Resisted wrist extension with dumbbell.

- Proprioceptive neuromuscular facilitation patterns of the upper extremity are performed actively and then with resistance. These patterns incorporate the conjunct rotations involved with finger, hand, and wrist motions.
- Wall push-ups encourage full wrist extension, while full push-ups require full, or close to full, wrist extension.
- Wrist flexion ball flips. Holding a small weighted ball, the patient leans forward over a treatment table so that the forearm is resting on the table, but the hand and wrist are over the end, palm facing upward. The patient is asked to toss the ball into the air and then to catch it while keeping the elbow on the table.

The exercises for the other joints of the upper extremity are outlined in Chapters 16 and 17.

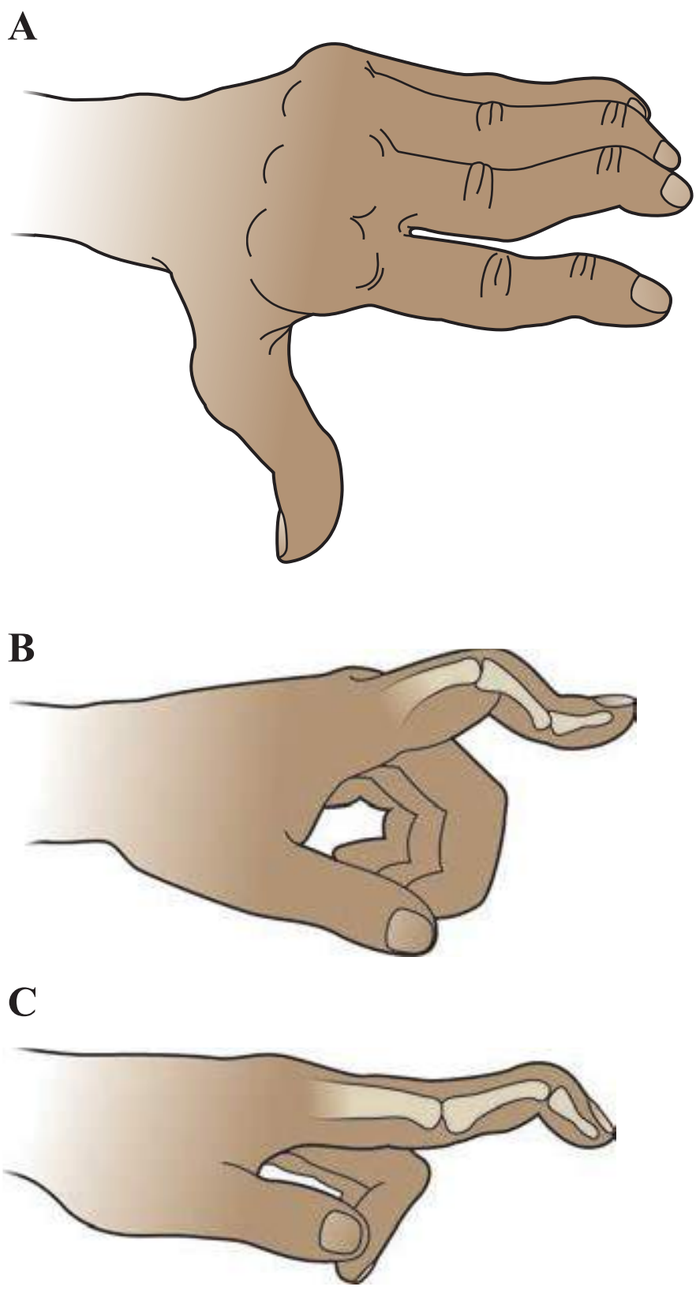

FIGURE 18-85 Finger deformities.

PRACTICE PATTERN 4D: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, RANGE OF MOTION ASSOCIATED WITH CONNECTIVE TISSUE DYSFUNCTION

Rheumatoid Arthritis

RA is a disease that affects the entire body and the whole person (see Chapter 5).[172] It is a lifelong disease, which in the majority of people is only modified somewhat by intervention.[173] The acute stage is characterized by pain, swelling, warmth, and limited motion from synovitis and tissue proliferation, most commonly in the MCP, PIP, and wrist joints bilaterally. The cycle of stretching, healing, and scarring that occurs as a result of the inflammatory process seen in patients with RA causes significant damage to the soft tissues and periarticular structures.[174] This damage includes progressive muscle weakness and imbalances in length and strength between agonists and antagonists and between intrinsic and extrinsic muscles. As a consequence, these events may lead to pain, stiffness, joint damage, instability, and ultimately deformity. In the advanced stages, there are joint instabilities, subluxations, and deformities. Many common hand and wrist deformities can be seen,[175] such as ulnar deviation of the MCP joints,[176] boutonnière deformity,[177] and swan-neck deformities of the digits.[179]

Ulnar Drift

The deformity of the ulnar drift and anterior (palmar) subluxation (Fig. 18-85A) is a result of a complex interaction of forces and damage to collateral ligaments and extensor mechanisms. Clinically, an ulnar drift of the MCP articulations often precedes the wrist deformities.[23] The ulnar drift results in an imbalance that has the resultant effect of pulling the fingers into ulnar deviation, pronation, and anterior (palmar) subluxation. The list of causes includes the following[175,178]:

- Subcollateral synovitis and weakening of the radial collateral ligament
- Distortion and attenuation of the sagittal fibers of the extensor hood
- A natural displacement of the extensor tendons to the ulnar side
- Radial deviation of the wrist
- Secondary contracture of the ulnar side intrinsic muscles
- Dysfunction of the radial side intrinsics
- Displacement of the flexor tendons to the ulnar side
- Appositional pinch (i.e., key pinch)
- Gravity
- The natural anatomic shape of the metacarpal head

Normally, in the flexed position, minimal lateral movement occurs at the MCP joint, but with increased laxity of the collateral ligaments, up to 45 degrees of lateral deviation occurs in this position.

Boutonnière Deformity

The boutonnière or buttonhole deformity (Fig. 18-85B) occurs when the common extensor tendon that inserts on the base of the middle phalanx is damaged. Damage to the central slip insertion requires extra effort to extend the joint, causing hyperextension at the DIP joint. The failure of the lateral bands to be connected to the central slip allows these bands to drift forward. Eventually, they pass the axis of rotation of the PIP joint, and instead of extending this joint, they act as flexors while still hyperextending the distal joint. Such destruction also results in the loss of the influence of

the interosseous muscles, ED longus, and lumbrical muscles on the PIP joints. Simultaneous with the loss of this muscle influence, the lateral bands of the extensor mechanism slide anteriorly. T e realignment of the extensor mechanism, coupled with the loss of certain muscle influence, produces a deformity of extension of the MCP and DIP joints and flexion of the PIP joint. T is is the classic boutonnière deformity.[179] T e causes, namely synovitis, central slip rupture, and displaced lateral bands are treatable by synovectomy,[180] repairs, or reconstruction of the central slip and relocation of the lateral bands.

Other causes of boutonnière deformity include injuries caused by division, rupture, avulsion, or closed trauma to the common extensor tendon. T e boutonnière deformity is the second most common closed tendon injury in sports.[26] In sports, the mechanism of injury is either a severe flexing force to the PIP joint or a direct blow to the posterior (dorsal) aspect of the PIP joint, which results in damage to the common extensor tendon. If traumatic in origin, this condition can be difficult to diagnose due to the degree of swelling, but if more than a 30-degree extension lag is present at the PIP joint, a boutonnière lesion should be suspected.[26]

T e presence of a mobile correctable deformity requires little more than immobilizing the PIP in full extension for 6–8 weeks, with the DIP and MCP joints, held free. Gentle AROM exercises can begin for flexion and extension of the PIP joint at 4–8 weeks, with the splint being reapplied between exercises. General strengthening usually begins at 10–12 weeks. For a return to competition, an additional 2 months is required.[26]

Swan-Neck (Recurvatum) Deformity

T e swan-neck deformity is characterized by a flexion deformity at the DIP and hyperextension of the PIP joint. T is deformity is the least functional of all of the deformities that exist within the hand. Destruction of the oblique retinacular ligament of the extensor mechanism leads to posterior (dorsal) displacement of the lateral bands of the extensor mechanism. T is rearrangement leads to an increased extensor force across the PIP joint with a resulting hyperextension of the PIP joint. T e extended position of the PIP joint stretches the FDS and FDP tendons. T e pull on the FDP tendon causes a passive flexion of the DIP joint. T e resultant loss of function includes an inability to bring the tips of the fingers into grasp. T e hypertrophy of rheumatoid synovitis displaces the tendon of the ECU forward. An alteration in posture at one joint leads to the reverse posture of the adjacent joint.[80] In addition to rheumatologic diseases, other etiologies include extensor terminal tendon injuries, spastic conditions, fractures to the middle phalanx that heal in hyperextension, and generalized ligamentous laxity.[180]

Clinical findings include a hyperextended PIP joint with a flexed DIP joint of the same digit (Fig. 18-85A).

T e intervention for swan-neck deformity depends on the etiological status of the PIP joint and its related anatomic structures. T e intervention for a swan-neck deformity with no loss of PIP joint flexion is usually conservative, with a Silver Ring splint used for the correction of the PIP hyperextension.[80]

Other Deformities Produced by RA

Radial Deviation of the CMC Block. T is deformity is the result of the predominant action of the radial tendons (i.e., the FCR and the extensors carpi radialis longus and brevis), which radially deviate the CMC block. T is deviation increases the angle between the radial border of the second metacarpal and the lower border of the distal radius, resulting in an important loss of muscular power in the flexors.[23,181]

T e deviation of the wrist can involve an opposite deviation of the MCP joint when the stabilizing elements of these joints (lateral ligament and volar plate) are weakened. T e radial deviation of the CMC block may produce an ulnar deviation of the MCP joints because of the interdependence of various articulations in the longitudinal chains.[23,182,183]

Effects of RA

T e end result of the above-mentioned deformities is a reduction in the function of the hand and upper limb. Although humans are capable of significant compromise and adaptation, the loss of function that occurs with RA progressively accumulates to a point at which simple tasks become more difficult. T e decreased excursion of tendons, weakness of muscles, and reduction of the range of motion in joints multiplies the overall effects. Even when the muscle power is available, it may not be applied in the most effective direction. Joint laxity, which has been precipitated by synovitis and recurrent effusion, is progressively aggravated. Eventually, the individual cannot cope with the resulting difficulties with doing activities of daily living. T is is the characteristic end point of this progressive disease.

Interventions for RA of the Hand and Wrist

Because pain and instability of the wrist prevent much of the power from the forearm muscles from being transmitted from the wrist to the hand, some stabilization at the wrist level is necessary. T e assessment of the thumb and finger problems involves careful evaluation of grasp and pinch. Based on the pathomechanics of the rheumatoid process, the following concepts form the foundation of any intervention to manage RA of the hand[184]:

- Control the inflammation.
- Focus on joint systems rather than isolated joints.
- Consider the status of all tissues in the hand.
- Consider the type of rheumatoid disease. T e intervention is related to the type of rheumatoid disease:
  - T e type in which scarring outweighs the articular damage. Patients with stiff joints because of scarring do poorly after soft-tissue surgery. Patients in this group require aggressive and sustained therapy, often for 3–4 months.
  - T e type in which joint laxity and tissue laxity become difficult to stabilize after soft-tissue procedures. T e patients in this group require careful intervention and control of the ROM and the direction of motion by the use of splints for many months after surgery.

T e components of the intervention for patients with RA of the hand include the following:

- Exercises. A combination of active exercises and isometric exercises are recommended to maintain muscle strength and improve range of motion. Range-of-motion exercises that encourage excursion of the long flexors are emphasized. T e hand intrinsics are stretched by placing the MCP joints in extension and radial deviation while simultaneously flexing the PIP and DIP joints. Resistive exercises need to be introduced carefully due to the inflammatory nature of RA. Gentle squeezing exercises using a sponge in a tub of warm water are recommended. Bony and soft-tissue surgery will be less than successful in restoring function if there is a residual severe imbalance in the forces acting across the joint.
- Joint protection/energy conservation. Joint protection is the process of reducing internal and external stresses on the joints during functional activity and to help prevent poor use and abuse of the hand and wrist. Joint protection techniques include the following:
  - Patient education to increase awareness of those activities that are stressful to the joints. In particular, tight and prolonged grasping should be avoided.
  - T e reduction of forces through the use of adaptive equipment and the avoidance of repetitive activities, positions of deformity, and the lifting of heavy weights. Many excellent self-help devices are available. Unless there is a reasonable use of the hand, any remaining imbalance will cause failure as shown in the secondary cycle of rheumatoid disease.
  - T e use of the larger/stronger and more proximal joints and muscles when available.
  - T e balance of rest and activity by planning ahead and using paced rests. Stress, rest, and sleep can have a significant effect on symptoms.
  - T e use of energy conservation techniques and labor-saving devices. Energy conservation involves sitting when able, organizing workspace and storage for accessibility, resting during activities when able, and using time savers such as prepared foods. Many different merchants offer adaptive equipment such as zipper pulls, kitchen utensils with enlarged handles, jar openers, and pens with a large grip.
  - Elimination of some activities.
  - Work simplification.
- Splinting. Static splinting can be used to immobilize painful joints and prevent further deformity through positioning.
- Pain management. T e clinician should encourage the patient to investigate alternatives to pain medication, such as relaxation techniques, yoga, adopting a positive outlook, and the use of thermo- or cryotherapy.

When surgery is warranted, either an arthrodesis of the wrist can be used, or an arthroplasty. Common indications for arthroplasty include severe pain, deformity and marked limitation of wrist motion, and subluxation or dislocation of the radiocarpal joint.

TFCC Lesions

Injuries to the TFCC typically occur following a fall on the supinated outstretched wrist or as the result of chronic repetitive rotational loading.

Patients with lesions of the TFCC complain of medial wrist pain just distal to the ulna, which is increased with end-range forearm pronation/supination and with forceful gripping. Often there is a painful click during wrist motions. Tenderness is clearly localized to the posterior (dorsal) anatomic depression, which is immediately distal to the ulnar head.[185] Passive mobilization of the carpal condyle against the head of the ulna, with the wrist in passive or active ulnar deviation, will frequently elicit a painful crepitus or roughness, or more rarely an actual snap (McMurray test for the wrist). Passive supination combined with ulnar deviation can also reproduce the pain.

Initial radiographs are usually negative but can provide information as to whether an ulna-plus variance coexists with the triangular fibrocartilage tear (ulnocarpal impingement syndrome).[185] T is condition is diagnosed on radiographs showing cystic or erosive changes in the ulnar head and along the proximal contour of the lunate.[186]

Injuries to the central, avascular portion of the disk are not amenable to spontaneous repair, whereas injuries to the vascularized periphery are.[185]

T e conservative invention for a TFCC injury typically includes a long-arm cast or splint fitted with the elbow in 90 degrees of flexion, and the forearm and wrist in ulnar deviation and extension for 6 weeks, if the TFCC is unstable.

While the wrist is in a cast or splint, the intervention should include proximal range-of-motion and strengthening exercises.

Active and active-assisted exercises are initiated to the wrist and forearm after cast removal, with emphasis on flexion and extension initially, followed by pronation/supination, and radial/ulnar deviation. Two weeks after cast removal, assuming the patient is asymptomatic, progressive strengthening is initiated to the hand and wrist, taking care to prevent torsional loads to the wrist.

Osteoarthritis

Osteoarthritis (OA) is the most common joint disease (see Chapter 2). T is condition can be primary or secondary, depending on the presence of a preexisting condition. While primary OA commonly involves the first CMC joint or sometimes the scaphotrapeziotrapezoid joint, it is uncommon in other parts of the joint.[185]

Secondary OA of the wrist attributable to an old trauma or infection is very common. In the case of malalignment of the scaphoid, degenerative arthritis will progress according to a very specific pattern that leads to an SLAC (scapholunate advanced collapse) wrist.[185] Degeneration occurs between the radius and the scaphoid and then between the lunate and the capitate. T e radiolunate joint is almost never involved. Finally, a scapholunate diastasis develops, and the capitate slides in between the lunate and the scaphoid.[187]

Patients with first CMC joint arthritis typically present with joint pain at the base of the thumb which is increased with use, restricted ROM in a capsular pattern, and joint crepitus.[185] First CMC arthritis is more common in women than men and is typically found in those 45 years and older.

Conservative intervention includes splinting, thermal modalities (moist heat or paraffin), and patient education.

Splinting

The splint should position the CMC joint in anterior (palmar) abduction to maximize the stability and anatomic alignment of the joint, with the IP joint free.[185]

Patient Education

The patient should be advised to

- minimize or avoid mechanical stresses, including sustained pinching;
- avoid sleeping on the hands as this forces the thumb into adduction;
- use self-help devices, such as jar lid openers and ergonomic scissors.

Gout

See Chapter 5.

Dupuytren Contracture (Palmar Fasciitis)

Population studies have shown that Dupuytren disease nearly always affects Caucasian races, particularly those of northern European descent.[188,189] The incidence increases with advancing age, and it is exceedingly rare in children.[190] Men are 7–15 times more likely to have a clinical presentation requiring surgery than women, who tend to develop a more benign form of the disease that appears later in life.[191,192]

The etiology of Dupuytren disease is thought to be multifactorial. There is a higher incidence in the alcoholic population, the diabetic population, and the epileptic population.[192–194] Because of the association between smoking and microvascular changes in the hand, some believe that tobacco may also play a role in this disease.[192] Although not usually related to hand trauma, Dupuytren disease occasionally develops after significant hand injuries, including surgery.[195]

Dupuytren disease is an active cellular process in the fascia of the hand, which is characterized by the development of nodules in the palmar and digital fascia, which occur in specific locations along longitudinal tension lines.[188,192] The pathologic changes in the normal fascia result in the formation of tendon-like cords.[196–198] The characteristic contracture, which behaves similarly to the contracture and maturation of wound healing is caused by a thickening and shortening of the fascia.[192] The contractures form mainly at the MCP and PIP joint, and occasionally at the DIP joint.[199] The most commonly involved digit is the little finger, which is involved in approximately 70% of patients.

The diagnosis of Dupuytren disease in its early stages may be difficult and is based on the palpable nodule, characteristic skin changes, changes in the fascia, and progressive joint contracture. The skin changes are caused by a retraction of the overlying skin, resulting in dimples or pits.

Dupuytren disease can be classified into three biologic stages[197]:

- First stage. This is proliferative stage is characterized by an intense production of myofibroblasts and the formation of nodules.
- Second stage. This is involutional stage is represented by the alignment of the myofibroblasts along lines of tension.
- Third stage. During this residual stage, the tissue becomes mostly acellular and devoid of myofibroblasts, and only thick bands of collagen remain.[200]

The disease, which is usually bilateral, tends to be more severe in one hand, although there appears to be no association with hand dominance. Up to three rays may be involved in the more severely affected hand.

To date, conservative interventions have not yet proven to be clinically useful in the treatment of established contractures.[201] Some surgeons feel that any amount of PIP joint contracture warrants surgery, whereas others feel that 15 degrees or greater is an indication.[188,202] Surgery is the intervention of choice when the MCP joint contracts to 30 degrees and the deformity becomes a functional problem.[202]

Studies have shown that 50% of operative results depend on the postoperative management of effective splinting and exercise.[192,203] The intervention should be directed toward promoting wound healing, which in turn minimizes scarring and maximizes scar mobility so that hand function can be restored.[192]

Scar management and splinting are an important part of the postoperative management. The initial splint is positioned to provide slight MCP joint flexion of 10–20 degrees with PIP joint extension to allow maximal elongation of the wound.[192]Active, active assisted, and passive exercises are usually initiated immediately.

Wrist Sprains

The most common wrist sprain results from a downward force to the wrist exceeding its normal range of motion.[204] This is forced movement of the joint is followed immediately by intense pain that subsides and then returns.[4] Swelling typically occurs within 1–2 hours of the injury, with the degree of joint swelling indicating the severity of the injury. With severe injuries, ecchymosis develops in 6–12 hours. Differential diagnosis includes a carpal fracture, particularly the scaphoid and lunate, traumatic instability, or a ligament tear.[205]

Conservative intervention depends on the severity of the sprain but likely includes some form of immobilization of the wrist to avoid exacerbating the injury. Custom splints, which cover the palm and extend to about midforearm, are designed to allow for proper hand and wrist contouring while and to allow the fingers to move freely.[4] Cocking the wrist up about 10 degrees places the wrist in a position of rest.

Slight sprains typically remain splinted for 3–5 days. The splint is worn at all times except for removal for hygiene and exercise. More severe sprains take longer to recover, but should still be removed from the splint in 3–5 days to avoid stiffness.[4] Icing for 20–30 minutes, three to four times a day, concurrent with NSAIDs or aspirin can aid in reducing pain and swelling.[4]

After splint removal, a rehabilitation program of AROM (wrist curls) should be started. Until the pain and swelling subside, wrist curls can be done in water to reduce muscle effort.[204] The clinician should consider taping the wrist to provide support and help decrease pain. The exercises are progressed to include a strengthening regime based on the hierarchy of strengthening exercises (see Chapter 12).

Perilunate Dislocation

A perilunate dislocation results from disruption of the scapholunate ligament, then extension of the injury to the capitolunate articulation and the lunotriquetral ligament.[206] Most carpal dislocations are of the perilunate variety with the lunate dislocating in an anterior (palmar) direction. T is is accompanied by damage to both of the interosseous ligaments of the proximal row and possible injury to the median nerve.[9]

T e usual mechanism of injury is a hyperextension of the wrist. Physical examination is often limited, revealing swelling and a deformity, and the injury may be confused with a distal radius fracture. If the median nerve is involved, paresthesias or numbness in the median nerve distribution may be present. T e dislocation is easily reduced if the intervention occurs soon after the injury. T e reduction involves placing the wrist in extension and putting pressure on the lunate, after which the wrist is moved into flexion and immobilized.

Kienböck Disease

Kienböck disease is an aseptic necrosis or osteonecrosis of the lunate. When the disease becomes advanced, carpal collapse, joint incongruity, and OA develop. T e choice of treatment for patients with symptomatic Kienböck disease depends largely on the severity of the disease. Surgical intervention can include excision arthroplasty, limited intercarpal arthrodesis, revascularization, arthrodesis between the radius and the lunate, and vascular bundle implantation.[207] Conservative management of Kienböck disease involves immobilization in a short arm cast. Upon cast removal at 6–10 weeks, AROM exercises are initiated for the wrist, forearm, and thumb. Within 1–2 weeks following cast removal, PROM exercises are initiated. A wrist and thumb static splint is fitted with the wrist in neutral, and the thumb midway between radial and anterior (palmar) abduction and is worn between exercise sessions and at night.

Intercarpal Instabilities

T e integrity of the carpal relationship depends on the stability provided by both the interosseous ligaments and the midcarpal ligaments.[9] T is relationship ensures that the carpal bones move as a unit. Conversely, disruption of this relationship allows abnormal independent motion of one or two carpal bones. Instability patterns are divided into those that are static and those that are dynamic. Static instability is the more severe of the two and usually involves a complete tear of one of the supporting ligaments or a fracture.[9] Dynamic instability patterns typically occur when the wrist is stressed. Carpal instability patterns that occur within the same row are classified as dissociative while those that occur across different rows are classified as nondissociative.

Dissociative

Two types of dissociative instability have been recognized[56]:

- Dorsal (posterior) intercalated segment instability (DISI). T e most common dissociated instability is the scapholunate dissociation, in which the scapholunate angle is greater than 70 degrees when viewed on the radiograph. Scapholunate instability usually follows a FOOSH injury where the primary forces are transferred through the wrist in extension and ulnar deviation. As the scaphoid and lunate become disassociated, the lunate no longer follows the scaphoid into flexion, instead migrating with the triquetrum into a dorsal (posterior) angulation.[9] T e patient with this type presents with difficulties and weakness with grasping and complains of chronic, vague wrist pain. T e examination reveals tenderness over the scaphoid and/or lunate, laxity between the scaphoid and lunate, and a positive scaphoid-shift test.
- Ventral intercalated segment instability (VISI). T e second most common dissociative instability is the lunatotriquetrum dissociation. Ventral refers to the ventral (anterior) tilt of the distal end of the lunate. T e signs and symptoms of this instability are similar to those of the scapholunate instability, except for the location. In this type, the lunate remains tethered to the scaphoid by the interosseous ligament but not necessarily to the triquetrum.[9] During wrist motions, the lunate follows the scaphoid into a flexed posture, but the triquetrum does not. A scapholunate angle of fewer than 30 degrees indicates a VISI lesion.

Nondissociative

T is is the most common dynamic instability of the wrist and usually results from an insufficiency of the posterior (dorsal) intercarpal ligaments. T e nondissociative instability may not be symptomatic, and the patient may be able to sublux and reduce the joint at will.[9] A clunk can be felt to occur as the distal row jumps back into place at the extreme of ulnar deviation.[208]

Conservative intervention for carpal instabilities usually involves a trial period of cast immobilization. Surgery is reserved for chronic cases.

UCL Sprain of the Thumb

UCL injuries, also known as gamekeeper's thumb, and skier's thumb, and breakdancer's thumb,[209] involve injury to the MCP joint of the thumb and are the most common ligament injury of the hand.[210]

T e patient typically complains of pain or tenderness on the ulnar aspect of the MCP joint.

For the purposes of planning the intervention, these injuries can be divided into two categories:

- Grade I and II sprains, in which the majority of the ligament remains intact. T e stability of the joint is tested in full extension and at 30 degrees of flexion, which stress the accessory collateral ligament and the UCL, respectively. An angulation of greater than 35 or 15 degrees greater than the uninvolved side indicates instability and the need for surgical intervention. Grade I and II tears are treated with immobilization in a thumb spica cast (a forearm-based splint fabricated from an anterior (palmar) or radial approach) for 3 weeks, with additional protective splinting for 2 weeks.

Thumb spica splints are designed to immobilize the wrist, CMC, and MCP joints of the thumb, thereby permitting the radial wrist extensors and the proximal thumb to rest. Thumb spicas can be used for the intervention of a number of conditions, including de Quervain disease and CMC arthritis.

When applying these splints, it is very important to ensure that the superficial radial nerve and the ulnar digital nerve of the thumb are not compromised. The splint is worn at all times except for removal for hygiene and exercise. AROM of flexion and extension begins at 3 weeks and progresses to strengthening exercises by 8 weeks, taking care not to apply any abduction stress to the MCP joint during the first 2–6 weeks.

- Grade III tears and displaced bony avulsions are treated with surgery and subsequent immobilization. If the ligament is completely torn, there is a concern for a Stener lesion, in which the torn UCL protrudes beneath the adductor aponeurosis.[211] Postsurgical rehabilitation involves wearing a thumb spica splint for 3–5 weeks, except during the active flexion and extension exercises. Otherwise, the exercise progression is the same as for the grade I and II sprains.
- Radial collateral sprains are classified and treated in a similar manner.

Ulnar Impaction Syndrome

The ulnar impaction syndrome can be defined as excessive impaction of the ulnar head against the TFCC and ulnar carpal bones. This results in a progressive degeneration of those structures.[212]

The patient with this syndrome typically presents with ulnar wrist pain and a limitation of motion. Upon physical examination, a combined motion of ulnar deviation and compression reproduces the pain (see "Special Tests").

The differential diagnosis includes ulnar impingement syndrome and arthrosis or incongruity of the DRUJ.[212]

It is important to remember that in the absence of obvious structural abnormalities, the ulnar impaction syndrome may result from daily activities that result in excessive intermittent loading of the ulnar carpal bones.

Conservative intervention includes the use of an ulnar gutter splint if there is evidence of wrist overloading.

Ganglia

Ganglia are thin-walled cysts containing mucoid hyaluronic acid that develop spontaneously over a joint capsule or tendon sheath. They are the most common soft-tissue tumor in the hand.[128,143] Common sites for ganglia are the anterior (volar) or posterior (dorsal) surfaces of the wrist and fingers.[4] Ganglia may not cause pain.[9] Frequently, as the ganglion begins to grow, the patient reports aching that is irritated by flexion and extension of the joint.[4]

At times, ganglia can occur in other parts of the wrist, causing compression of the ulnar or median nerve.[4] When compression occurs, associated sensory symptoms in the digits or intrinsic muscle weakness may develop.[143] Upon examination, a ganglion is smooth, round, or multilobulated and tender with applied pressure.

For symptom relief, immobilization of the wrist through splinting is effective. This may cause the ganglion to shrink temporarily, although it is uncommon for the immobilization to be effective in resolving the ganglion.[143] Needle aspiration can resolve the ganglion. Occasionally, surgical excision is indicated for the patient with significant pain or cosmetic irritation (Table 18-19).

TABLE 18-19 Rehabilitation Protocol After Excision of Wrist Ganglion

Time Frame (Weeks)	Intervention
2	Remove the short arm splint and sutures Initiate active and active-assisted wrist extension and flexion Continue interval splint wear during the day between exercises and at night
2–4	Advance ROM exercises to resistive and gradual strengthening exercises Discontinue the splint at 4 weeks
4–6	Allow normal activities to patient's tolerance
6	Allow full activity

Data from Brotzman SB, Calandruccio JH, Jupiter JB. Hand and wrist injuries. In: Brotzman SB, Wilk KE, eds. Clinical Orthopaedic Rehabilitation. Philadelphia, PA: Mosby; 2003:1–83.

Chondromalacia

Chondromalacia of the ulnar head is usually seen in young patients after a fall on the extended wrist with the impact predominantly hypothenar, or repeated episodes of stressful pronation and supination (work or leisure activity).[185] The pain is localized to the posterior (dorsal) distal radioulnar area, and manipulation of the ulnar head can elicit crepitation or a painful snap.[186]

Racquet Player's Pisiform

Racquet player's pisiform is a condition involving a minor subluxation of the pisiform, with occasional chondromalacia of the articular cartilage of the pisotriquetral joint.[16] The probable mechanism is a torsional stress upon the capsule of the pisotriquetral joint by the powerful and rapid pronation and supination movements at the wrist seen when wielding a racquet, particularly in badminton, racquetball, and squash players.

The typical clinical presentation is one of pain, disability, and swelling on the ulnar aspect of the wrist or proximal palm. The pain is reproduced with passive movement of the pisiform upon the triquetrum with the relaxed wrist flexed and ulnarly deviated.[16]

The typical intervention for this condition is surgical excision of the pisiform.[16]

PRACTICE PATTERN 4E: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, RANGE OF MOTION ASSOCIATED WITH LOCALIZED INFLAMMATION

Tendinopathy

Overuse syndromes are a common cause of tendinopathy, particularly in the "weekend warrior." As a rule, the tendons of the APL and EPB are involved. T ere are, however, some uncommon locations and types of tendinopathy. T ere has been a marked increase in reports of the so-called repetitive strain injury of the upper extremity.[185] One of the difficulties in evaluating this disorder is the establishment of a diagnosis in the absence of objective physical findings or confirmatory diagnostic images or laboratory data. T ese issues become more complicated when insurers and attorneys ask clinicians to establish a causal relation between the job and the complaints.[213,214]

Tenosynovitis is frequently seen in inflammatory rheumatic diseases, diabetes mellitus, or hypothyroid conditions (Table 18-20).

Conservative intervention includes nonsteroidal medications, splinting, patient education on the neutral rest position for the wrist, activity modification, and the avoidance of exacerbating activities (e.g., forceful gripping and heavy lifting). A stretching and icing regimen is recommended for the wrist flexors or extensors depending on the diagnosis. Occasionally, a series of steroid injections may be warranted. Patients are typically considered for surgery when a tenosynovitis has persisted for a period of 3 months of conservative treatment.

De Quervain Disease

De Quervain disease[215] is a progressive tenosynovitis or tendovaginitis, which involves the tendon sheaths of the first posterior (dorsal) compartment of the wrist, resulting in a thickening of the extensor retinaculum, a stenosing of the fibro-osseous canal, and an eventual entrapment and compression of the tendons.[216] Although originally thought of as an active inflammatory condition, recent histological studies have found the disorder to be characterized by degeneration and thickening of the tendon sheath.[217]

In most instances, the first posterior (dorsal) compartment is a single compartment, which contains the APL and the

TABLE 18-20 Clinical Findings in Common Forms of Tenosynovitis

Tenosynovitis	Findings	Dif erential Diagnosis
Intersection syndrome	Edema, swelling, and crepitation in the intersection area; pain over the dorsum of the wrist that is exacerbated by wrist flexion and extension, unlike the pain of de Quervain tenosynovitis, which is exacerbated by radial and ulnar deviation; pain extends less radially than it does in de Quervain tenosynovitis	Wartenberg syndrome, de Quervain tenosynovitis
De Quervain	Pain along the radial aspect of the wrist that worsens with radial and ulnar wrist deviation; pain on performing Finkelstein maneuver is pathognomonic	Arthritis of the first carpometacarpal joint, scaphoid fracture and nonunion, radiocarpal arthritis, Wartenberg syndrome, intersection syndrome
Sixth posterior (dorsal) compartment	Pain over the ulnar dorsum of the wrist that is worsened by ulnar deviation and wrist extension; other planes of motion may also be painful; tenderness over the sixth posterior (dorsal) compartment; instability of the extensor carpi ulnaris is shown by having the patient circumduct the wrist while rotating the forearm from pronation to supination	Extensor carpi ulnaris instability, triangular fibrocartilage complex tears, lunotriquetral ligament tears, ulnocarpal abutment syndrome, distal radioulnar joint arthritis, traumatic rupture of the subsheath that normally stabilizes this tendon to the distal ulna
Flexor carpi radialis tunnel syndrome	Pain, swelling, and erythema around the anterior (palmar) radial aspect of the wrist at the flexor carpi radialis tunnel; pain exacerbated by resisted wrist flexion	Retinacular ganglion, scaphotrapezial arthritis, first carpometacarpal arthritis, scaphoid fracture/ nonunion, radial carpal arthritis, injury to the anterior (palmar) cutaneous branch of the median nerve, Lindberg syndrome (tendon adhesions between the flexor pollicis longus and the flexor digitorum profundus)
Trigger finger	Pain on digital motion, with or without associated triggering or locking at the interphalangeal joint of the thumb or proximal interphalangeal joint of other fingers; may be crepitus or a nodular mass near the first annular pulley that moves with finger excursion	Connective tissue disease, partial tendon laceration, retained foreign body, retinacular ganglion, infection, extensor tendon subluxation

TFCC, triangular fibrocartilage complex; CMC, carpometacarpal; DRUJ, distal radioulnar joint; ECU, extensor carpi ulnaris
Data from Brotzman SB, Calandruccio JH, Jupiter JB. Hand and wrist injuries. In: Brotzman SB, Wilk KE, eds. Clinical Orthopaedic Rehabilitation. Philadelphia, PA: Mosby; 2003:1–83; Idler RS. Helping the patient who has wrist or hand tenosynovitis. J Musculoskel Med. 1997;14:62.

EPB tendons and their associated synovial sheaths. The APL and EPB tendons allow the thumb to flex, extend, and grip objects. Overuse, repetitive tasks which involve overexertion of the thumb, or radial and ulnar deviation of the wrist, and arthritis are the most common predisposing factors, as they cause the greatest stresses on the structures of the first posterior (dorsal) compartment.[78,118] Such activities include scraping wallpaper, painting, hammering, fly fishing, knitting, and cutting with scissors.[78,218–221]

Typically, patients report a gradual and insidious onset[78,118,222] of a dull ache over the radial aspect of the wrist made worse by such activities as turning doorknobs or keys.[4] Patients also may note a "creak" in the wrist as the tendon moves.

Examination of the wrist may reveal the following:

- A localized swelling and tenderness in the region of the radial styloid process[118,222] and wrist pain radiating proximally into the forearm and distally into the thumb.[118,222–224]
- Severe pain[118,222] with wrist ulnar deviation and thumb flexion and adduction.[120] A reproduction of the pain can also be reported with thumb extension and abduction.[225]
- Crepitus of the tendons moving through the extensor sheath.[120,266]
- Palpable thickening of the extensor sheath and of the tendons distal to the extensor tunnel.[227]
- A loss of abduction of the CMC joint of the thumb.
- A positive Finkelstein test (Fig. 18-50) (see "Special Tests").[118]

Although the diagnosis is mostly clinical, posteroanterior and lateral radiographs of the wrist can be obtained to rule out any bony pathology, such as a scaphoid fracture, radioscaphoid, or triscaphoid arthritis; and Kienböck disease.[4]

CLINICAL PEARL

Isolation of the EPB tendon in a separate compartment has been reported to contribute to the pathogenesis of de Quervain disease.[125]

The intervention can be conservative or surgical. Conservative intervention usually includes rest, modification of activities, splinting, and anti-inflammatory medication. In a study by Lane et al.[228] wrist splints and NSAIDs were found to be effective only in patients with minimal symptoms and no restrictions in daily activities. No added benefit has been found in using a combined injection and splinting approach.[229] If splinting is appropriate, a thumb spica splint is fabricated with the wrist in 15 degrees of extension, the thumb midway between anterior (palmar) and radial abduction, and the thumb MCP joint in 10 degrees of flexion. As the splint is supposed to be worn all day, when fitting the splint it is important that the thumb is able to oppose the index and long finger to aid with hand function. Following the removal of the splint after approximately 3–6 weeks, ROM exercises are prescribed, with a gradual progression to strengthening.

Three case reports have been published that describe manual physical therapy treatment for de Quervain disease. In the first report, Backstrom[230] reported the complete resolution of symptoms in a patient with a 2-month history of de Quervain tenosynovitis by incorporating Mulligan mobilization with movement (MWM) techniques (radial gliding of the proximal carpal row and ulnar gliding of the trapezium), capitate manipulation, CMC joint mobilizations, and TFM over the first posterior (dorsal) tunnel, into an overall treatment plan. The second case report, by Anderson and Tichenor[227] used an Australian (Maitland) approach consisting of central and unilateral cervical mobilizations, carpal bone mobilizations, cervical and upper extremity stretches, TFM to the APL and EPB tendon, and neural mobilizations. In this case report, the patient reported no wrist or hand pain following a 6-month treatment program. The third case report by Walker[77] used an impairment-based treatment approach for eight visits based on the examination findings of isolated radiocarpal, intercarpal, and CMC joint dysfunction. The treatments consisted of manual techniques and self-mobilizations applied to the radiocarpal, intercarpal, and CMC joints. At treatment completion, the patient achieved a pain-free state and nearly full function. These results were maintained at a long-term follow-up performed 10 months after treatment.[77]

The more invasive intervention begins with cortisone injections. If two to three injections do not give relief, surgical tendon sheath release is an option.[4]

Intersection Syndrome

Intersection syndrome is a tenosynovitis of the ECRL and ECRB (radial wrist extensors), where they cross under the APL and EPB.[123] Although similar to de Quervain, differentiation is made with the pain distribution. With the intersection syndrome, the pain is located in the distal forearm, 4–8 cm proximal to Lister tubercle, and is exacerbated by wrist flexion and extension, and by resisted wrist extension.[214] The condition is common in rowers, weightlifters, and canoeists due to repetitive wrist flexion and extension.[214]

Intervention, in addition to NSAIDs, involves[214,231]:

- splint immobilization of the wrist and thumb with the wrist in 15–20 degrees of extension;
- electrotherapeutic modalities, including iontophoresis/phonophoresis;
- manual techniques, including deep TFM followed by exercises for stretching and strengthening;
- patient education to emphasize the avoidance of any repetitive wrist flexion and extension in combination with a power grip.

EPL Tendinopathy

This condition is rare except in RA, but it occurs when the EPL muscle extends into a tight third compartment.[232] Overuse (drummer boy palsy), direct trauma, forced wrist extension, and distal radius fractures may cause EPL tendinopathy, which presents with the clinical signs and symptoms of decreased thumb flexion, pain, swelling, and crepitus at Lister tubercle.[214]

EIP Syndrome

An increase in muscle size of the extensor indicis, caused by swelling or hypertrophy from repetitive exercise, may cause

stenosis of the fourth posterior (dorsal) compartment and resultant tenosynovitis.[214]

A simple test of resistance applied to active index finger extension while holding the wrist in a flexed position is a reliable provocative test.[233]

ECU Tendinopathy

ECU tendinopathy, a tenosynovitis of the sixth posterior (dorsal) compartment, usually presents as chronic dorsoulnar wrist pain, which is aggravated with forearm supination and ulnar deviation, which causes the tendon to sublux palmarly.[214,234]

FCU Tendinopathy

T e FCU is the most common wrist flexor tendon to become inflamed and is often associated with repetitive trauma and racquet sports.[16] T e clinical signs and symptoms include pain and swelling localized just proximal to the pisiform, which is aggravated by wrist flexion and ulnar deviation.[214]

FCR Tendinopathy

FCR tendinopathy usually develops due to stenosis and tenosynovitis in the FCR fibro-osseous tunnel within the transverse metacarpal ligament. FCR tendinopathy usually produces localized pain and swelling and painful deviation of the wrist.[214] FCR tendinopathy frequently coexists with other conditions, including fracture or arthritis around the CMC joint of the thumb.[214]

Digital Flexor Tendinopathy and Trigger Digits

T is condition is typically characterized by painful snapping or triggering of the fingers and thumb due to a disproportion between the flexor tendon and its tendon sheath. T e condition invariably occurs at the metacarpal head level and at the A1 pulley (MCP joint pulley), with the result that the tendon is pulled through too narrow a canal.[214,235–237] T e condition is more common in the fibrous flexor sheath of the thumb, ring, or middle finger.[238,239]

T e etiology of this condition can be acquired or congenital, although it is more common in patients with diabetes, young children, rheumatic changes of the hand, and menopausal women.[240,241] T e base of the affected finger is often tender and is usually accompanied by the triggering phenomenon—pain on digital motion, with or without associated triggering or locking. As the condition progresses, it becomes very painful, and may result in limited or absent digital motion, especially in the PIP joint.[242] During excursion of the flexor tendon, the clinician may palpate crepitus or a moving nodular mass in the vicinity of, or slightly proximal to, the A1 pulley. T e presence of swelling is most consistent with tenosynovitis that occurs secondary to connective tissue disease.

Conservative intervention involves the fitting of a hand-based MCP flexion block splint in 0 degrees.[243] T ere is no consensus on the optimal orthotic regimen. T e purpose of this immobilization is to attempt to alter the mechanical forces on the proximal pulley system while encouraging maximal differential tendon gliding. Patient education plays an important role; the patient should be advised to eliminate any provocative movements, such as repetitive grasping or the use of tools that apply pressure over the area.

Medical intervention usually involves one or a series of 1–3 corticosteroid injections,[244] with open surgical release of the trigger finger reserved for those cases that do not respond to conservative measures.[244]

Tendon Ruptures

One of the main purposes of the hand is to grasp; therefore, the loss of flexor tendons imposes a catastrophic functional loss.[245] T e purpose of a flexor tendon repair is to restore maximum active flexor tendon gliding to ensure effective finger joint motion. Laceration or traumatic rupture of the extensor tendons are more common than in flexor tendons due to their superficial location and the fact they are substantially thinner than flexor tendons.[246]

Flexor Tendons

Most flexor tendon ruptures occur silently after prolonged inflammatory tenosynovitis, although the causes can also be traumatic. When all nine flexor tendons to the digits have ruptured, little can be done. Single tendon ruptures are more common, and the FPL tendon is the most vulnerable to attrition rupture where it crosses the scaphotrapezial joint and where local synovitis can create a sharp spike of bone that abrades against this spur and ruptures during use. T e FDP tendon to the index finger is also at risk from this bony spur.[247]

Flexor tendon injuries of the fingers, palm, wrist, and forearm are classified into five zones according to the level of injury. T e zone within which the tendon is repaired dictates to some extent the intervention.

- Zone 1. T is zone extends from the insertion of the FDP in the middle phalanx to that of the FDS in the base of the distal phalanx. Injuries at this level involve isolated lacerations of the FDS.
- Zone 2. T is is the region in which both flexor tendons travel within the fibro-osseous tunnel from the A1 pulley to the FDP insertion. Usually, both flexor tendons are injured at this level.
- Zone 3. T e area in the palm between the distal border of the carpal tunnel and the proximal border of the A1 pulley comprises zone 3. Common digital nerves and vessels, lumbrical muscles, and one or both flexor tendons may be injured in this region.
- Zone 4. T is zone consists of that segment of the flexor tendons covered by the transverse carpal ligament. Injuries at this level involve median or ulnar nerves and tendons.
- Zone 5. T e forearm from the musculotendinous junction of the extrinsic flexors to the proximal border of the transverse carpal ligament comprises zone 5. Interference with tendon gliding is less of a problem in this region.

Tendon injuries of the thumb are classified using three zones:

- Zone 1. T is is the region from the distal insertion of the FPL on the distal phalanx of the thumb to the neck of the proximal phalanx.

- Zone 2. This is the region from the proximal phalanx, across the MCP joint to the neck of the first metacarpal.
- Zone 3. This is the region from the first metacarpal to the proximal margin of the carpal ligament.

There are a number of different procedures and rehabilitation protocols for flexor tendon repairs. In brief, the retracted ends of the tendon are retrieved either by hand and wrist positioning or with a surgical instrument. Although it is not within the scope of this text to discuss suturing techniques, it is important to mention that several suturing methods have been found to withstand an early active mobilization (EAM) protocol, such as the one presented here. They include the Savage, Silfverskiold (modified Kirchmayer or modified Kessler),[248,249] Tang,[250] Robertson,[251] and cruciate[252] methods. In all of these methods, the anatomic relationship between the FDS and the FDP is maintained.

The rate of tendon healing following surgery depends on adequate nutrition (through vascular and synovial fluid perfusion), the part of the tendon affected, and the presence of the vinculum.

Early postoperative protected mobilization of repaired tendons has been popularly adopted as the postoperative treatment protocol after tendon repair.[253–259] Researchers have shown that early mobilization can prevent the formation of scar tissue without jeopardizing tendon healing. Several postsurgical protocols and modifications exist based on individual characteristics, the zone involved, the suture strength, and surgeon preferences. While it is not within the scope of this text to discuss all of the various types of protocols, it is important for the clinician to have an understanding of the concepts behind the two major types:[260]

- Early passive mobilization consists of passive flexion with active extension within the confines of a protective splint.[261]One of the original controlled motion protocols was developed by Kleinert et al., who used a posterior (dorsal) block splint with a rubber-band traction device and early active extension of the digit against the tension of the passive rubber-band flexion.[262] The block splint positioned the wrist in 40 degrees of flexion and the MCP joints in 40–60 degrees of flexion. In the 1970s, Duran and Houser[263] presented a controlled passive motion method that has become the basis for many of the early passive mobilization protocols used today. Various modified Duran protocols have since been developed. The Indianapolis protocol (Active Hold Program) is commonly used for a patient who is motivated and compliant. This protocol uses a modified Duran protocol for the first one to three weeks and then at four weeks the patient exercises 25 times every 2 hours without any splint.
- EAM consists of active flexion and extension of the involved finger within certain parameters of a protective splint.[261] In recent years, based on an improved understanding of connective tissue physiology and the success achieved with other types of surgical repairs, various active mobilization protocols have been attempted to obtain improved function of the repaired tendons.[256,257,264] It has been demonstrated that active mobilizations of the tendons are a more effective way to increase excursion and decrease adhesions of repaired tendons.[264–269] In addition, the tension added to the repaired tendon by active mobilization seems to help initiate proliferation of the tenocytes, (tendon forming cells) and increase the rate of collagen synthesis of the repaired tendon, thereby enhancing the tendon healing process.[270,271] Considering the resistance of the sheath during tendon gliding and a decrease in suture strength during the initial weeks after repair, most investigators believe that sufficient suture strength is vital to the performance of gentle or moderate active finger motion.[248,251,252] The typical EAM protocol allows active flexion and extension of the involved fingers within the first 3–5 days by incorporating a concept known as place and hold, in which the involved finger is passively flexed to a certain position and the patient is then asked to hold it there through active contraction of that muscle.[261] Another EAM protocol, referred to as the dynamic approach, uses dynamic, short arc, minimum muscle tension exercises to impose low-intensity stresses on the healing tendon in the initial stage.

CLINICAL PEARL

Surgical repairs and treatment protocols can vary greatly, necessitating a high level of communication between the surgeon and the clinician.

Extensor Tendons

Depending on the location and severity of injury to the extensor mechanism, surgery may or may not be indicated. The posterior surface of the fingers and wrist are divided into seven zones:

- Zone 1. DIP joint region.
- Zone 2. Middle phalanx.
- Zone 3. PIP joint region.
- Zone 4. Proximal phalanx
- Zone 5. Apex of the MCP joint region.
- Zone 6. Dorsum of the hand
- Zone 7. Wrist region/dorsal retinaculum.

The thumb tendons are divided into five zones

- Zone 1. IP joint region
- Zone 2. Proximal phalanx
- Zone 3. MCP joint region
- Zone 4. Metacarpal
- Zone 5. CMC joint region.

The mallet finger deformity, one of the most common extensor tendon injuries sustained by the athletic population, is a traumatic disruption of the terminal tendon. This condition is especially common in the baseball catcher and the football receiver and results in a loss of active extension of the DIP joint. The initial injury usually results from the delivery of a longitudinal force to the tip of the finger, which produces a sudden acute flexion force and a subsequent rupture of the extensor tendon just proximal to its insertion into the third phalanx or a fracture at the base of the distal phalanx.[26]

The physical examination reveals a flexion deformity of the DIP joint (Fig. 18-85C), which can be extended passively but not actively. This is due to the zero tension being provided by the EDC, in addition to the resulting increased tone in the FDP.

The primary goal of treatment is to maximize function and range of motion of the involved DIP joint. Mallet deformities with an associated large fracture fragment are typically treated with 6 weeks of immobilization following open reduction and internal fixation (ORIF), usually with K-wires.[26] Closed reduction is used for other types, followed by 6 weeks of continuous posterior (dorsal) splinting of the DIP in 0 degrees of extension to 15 degrees of hyperextension.[26] The PIP joint should be free to move. If splinted, the splint is removed once a day while simultaneously holding the DIP joint in extension to allow air to reach the anterior (palmar) aspect of the middle and distal phalanx. Following the period of immobilization, the splint or fixators are removed, and the terminal tendon is evaluated. If the tendon is unable to maintain the extension of the DIP joint, a splint is reapplied, and the tendon is retested periodically. Once the tendon has healed sufficiently to perform active extension of the DIP, AROM exercises to 20–35 degrees are initiated to the DIP joint. The clinician should continue to monitor for an extensor lag, and it is recommended that the patient continues to wear the splint between exercise sessions, at night, and when competing (as appropriate). Gentle progressive resistive exercises (PREs) using putty or a hand exerciser are initiated at week 8. Usually, the splint is discontinued at 9 weeks if the DIP extension remains at 0–5 degrees and there is no extensor lag. Unrestricted use usually occurs after 12 weeks.

Rupture of the Terminal Phalangeal Flexor (Jersey Finger)

A jersey finger rupture involves a rupture of the FDP tendon from its insertion in the distal phalanx. As there is no characteristic deformity associated with this type of rupture, this condition is often misdiagnosed as a sprained or "jammed" finger.[26]

The injury commonly occurs in football when the flexed finger is caught in a jersey while the athlete is attempting to make a tackle, hence the term jersey finger. However, any forceful passive extension that is applied while the FDP muscle is contracting can cause this type of rupture. Although this condition can occur in any finger, the most commonly injured is the ring finger.[272]

Three types are recognized:

- In Type I, the tendon retracts into the palm with or without a bony fragment.
- Type II is the most common. The tendon retracts to the PIP joint, and the long vinculum remains intact. As in type I, type II injuries may have a small bony avulsion.
- Type III injuries involve a large bony fragment.

To test the integrity of the tendon, the clinician isolates the FDP by holding the MCP and PIP joints of the affected finger in full extension and then asks the patient to attempt to flex the DIP. If the patient is able to flex the DIP, it is intact. If not, it is ruptured.

The intervention depends on the severity of the injury. If hand function is not seriously affected the condition is just monitored. However, if hand function is impacted, one option is surgical reattachment of the tendon, which requires a 12-week course of rehabilitation.

INTEGRATION OF PRACTICE PATTERNS 4F AND 5F

This includes conditions involving impaired joint mobility, motor function, muscle performance, and range of motion, or reflex integrity secondary to referred pain, spinal disorders, peripheral nerve entrapment, myofascial pain syndrome (MPS), and CRPS.

REFERRED PAIN

A number of structures can refer pain to the wrist and hand, and these include visceral structures, neurologic structures, and the more proximal joints (Chapter 5). The most common joints, which refer pain to the wrist and hand, include the cervical, thoracic, shoulder, and elbow joints.

TUMORS

See Chapter 5.

Peripheral Nerve Entrapment

Peripheral nerve entrapments are common in this region and are typically associated with a history of pain or vague sensory disturbances.[273] Due to the vagueness of the signs and symptoms, nerve injuries are frequently overlooked as a source of acute, or more commonly chronic, symptomatology.[185] An early indicator of peripheral compression neuropathy may be the loss of vibration sensibility.[147] Nerve conduction studies may be performed, focusing on the sites of interest. Diabetes, with its associated neuropathies or cheiroarthropathy, may be an underlying cause of chronic wrist pain.[185]

Radial Nerve

The posterior interosseous nerve can be compressed as it enters the posterior (dorsal) wrist capsule by repetitive wrist extension maneuvers, inciting symptomatic inflammation.[274]

The major disability associated with radial nerve injury is weak wrist and finger extension, with the wrist and fingers adopting a position termed "wrist drop." The hand grip is weakened as a result of poor stabilization of the wrist and finger joints, and the patient typically demonstrates an inability to extend the thumb, proximal phalanges, wrist, and elbow, depending on the level. Supination of the forearm and adduction of the thumb are also affected. There is also decreased or impaired sensation on the posterior (dorsal) surface of the first interosseous space.

Wartenberg Syndrome

Wartenberg syndrome is a compression of the superficial sensory radial nerve. Inflammation of the tendons of the first posterior (dorsal) compartment can result in superficial radial neuritis. T is results in pain, paresthesias, and numbness of the radial aspects of the hand and wrist.[275] In addition, the tendons of the brachioradialis and ECRL muscles can press on the nerve in a scissor-like fashion when the forearm is pronated, causing a proximal tethering on the distal segment of the nerve at the wrist.[276]

Wartenberg sign is described wherein the patient is asked to extend the fingers, and abduction or clawing of the little finger occurs.[154]

Median Nerve Compression at the Wrist

Median nerve compression at the wrist is referred to as CTS, a cause of a cluster of symptoms, including chronic wrist pain and functional impairment of the hand. CTS, which results from an ischemic compression of the median nerve at the wrist as it passes through the carpal tunnel, has a reported prevalence of 3.72% in the US population.[277] Compression of the nerve in the carpal tunnel is compounded by an increase in synovial fluid pressure and tendon tension, which decreases the available volume. Although it occurs in all age groups, CTS more commonly occurs between the fourth and sixth decades. CTS is the most common compression neuropathy, with a prevalence of 9.2% in women and 0.6% of men.[278,279] Carpal tunnel pressure appears to be an important factor in the pathophysiology of CTS, as increased pressure on the median nerve can produce short-term sensory and motor nerve conduction deficits and elicit symptoms of median nerve neuropathy.

Moersch[280] provided the first description of spontaneous median nerve compression and is credited with coining the term C*T*S.[281] T e compression of the median nerve may result from a wide variety of factors that compromise the tunnel space, such as fluid retention that can occur during pregnancy, infection, or because of renal dysfunction.[282] In addition, several disease conditions, such as gout or pseudogout, acromegaly, or amyotrophy can also decrease the tunnel size.[283,284]

However, about half of the cases of CTS are related to repetitive and cumulative trauma in the workplace.[285,286] Extreme wrist and finger postures can increase the tunnel pressure.[287] In addition, the angle of the MCP joint has been found to have a significant effect on carpal tunnel pressure during active wrist flexion and extension and radioulnar maneuvers. Motions performed in 0 degrees MCP flexion exhibit the highest pressures, followed by an MCP angle of 90 degrees.[288] T is information should be considered in the design of splints for CTS patients. Fingertip loading has also been found to increase the pressure in the carpal tunnel. [289] Forceful and repetitive contraction of the finger flexors can also provoke CTS.[290] Acute wrist trauma has also been associated with CTS. A FOOSH injury or other trauma can cause an anterior (palmar) subluxation of the lunate,[291] or a distal radius fracture.[292,293] T e degree of compression can be so great that profound neurologic deficit can rapidly follow, and if not treated appropriately, it can become permanent due to the decrease in capillary blood flow producing ischemia of the nerve.[294] A manipulative reduction should be carried out. If manipulation fails, the patient should be referred to a surgeon for immediate decompression.

Other causes include collagen disorders,[295,296] flexor tenosynovitis,[297] RA,[298] cervical spine pathology,[299] diabetes, hypothyroidism, and hemodialysis.[300] Less common causes include instances where the lumbrical muscles encroach within the tunnel during finger movements,[301,302] or become hypertrophied.[303] All of these structural causes are located locally with the exception of the cervical spine. Some authors have found that individuals with CTS usually experience pain symptoms in the neck and the shoulder regions.[304,305] Hurst et al.[306] found that the presence of arthritis in the neck may result in compression of the cervical nerve roots in people with CTS, whereas Pierre-Jerome and Bekkelund[307] found that individuals with CTS, compared to a control group, exhibited higher incidence of narrowing of the cervical foramen.[308] A more recent study showed that compared to healthy control participants, individuals with moderate, unilateral CTS exhibited greater forward head posture and decreased cervical range of motion.[309]

T e diagnosis of CTS is typically made after a review of the patient's history and physical examination.[144] T e initial characteristic features of CTS include intermittent pain and paresthesias in the median nerve distribution of the hand (although the symptoms may radiate proximally into the forearm and arm), which progressively become more persistent as the condition progresses.[310–313] If the condition is allowed to progress, muscle weakness and paralysis can occur. T e symptoms of CTS are typically worse at night due to the position of wrist flexion typically adopted during sleep and can be associated with morning stiffness.

T e differential diagnosis for this condition includes cervical dysfunction,[309,314] thoracic outlet syndrome, pronator syndrome,[315] coronary artery ischemia, tendinopathy, fibrositis, and wrist joint arthritis.[316,317] Cervical radiculopathy may be identified by the occurrence of proximal radiation of pain above the shoulder, paresthesias with coughing or sneezing, or a pattern of motor or sensory disturbances outside of the territory of the median nerve.[310] Ulnar neuropathy must be considered since no more than half of patients with CTS can reliably report the location of their paresthesias.[318] T oracic outlet syndrome is occasionally a concern. Transient cerebral ischemia, not a rare occurrence, can be recognized by the absence of pain during an episode of numbness. Finally, when the symptoms persist following conservative or surgical intervention aimed at the site of the carpal tunnel, median nerve neuropathies proximal to the carpal tunnel should be suspected. Median nerve neuropathies can be due to diabetes, human immunodeficiency virus, nutritional deficiencies, and entrapment/compression of the nerve.[319] Median nerve compression proximal to the carpal tunnel may be divided into two major categories: pronator syndrome and anterior interosseous nerve syndrome (see Chapter 17).[319]

T e physical assessment focuses on an examination of the motor and sensory functions of the hand and upper extremity as compared to the uninvolved extremity.[138,310,320]

A study[321] that examined the effect of upper extremity position on median nerve tension found the upper limb

tension test for the median nerve to be specific. Another study[322] described a maneuver that abolishes paresthesias in the carpal tunnel. T e authors of this study suggest that this maneuver could be useful in the diagnosis of the syndrome, as well as providing a means of relieving symptoms and providing the basis for the design of a splint. With the involved hand positioned palm up, the clinician gently squeezes the distal metacarpal heads together.[322] If the basic maneuver does not relieve the symptoms, it may also be necessary to pronate the forearm while simultaneously stretching digits three and four.[322] Special testing may include the Phalen test and Tinel sign.

A number of medical tests can be used to help diagnose CTS. T ese include the median nerve conduction study (NCS) and EMG study. Median nerve conduction studies have been found to be normal in 5% of patients with symptoms.[143] T e EMG study was found in one study[153] to confirm a diagnosis of CTS in only 61% of cases. However, radiculopathy due to disease of the cervical spine, diffuse peripheral neuropathy, or proximal median neuropathy can pose clinical questions that electrodiagnostic testing can settle.[310]

A carpal tunnel view radiograph may be the only view that shows abnormalities within the carpal tunnel. [29]

T e conservative intervention for mild cases typically includes the use of splints, activity modification, diuretics, and NSAIDs.[323] T e rationale for splints is based on observations that CTS symptoms improve with rest and worsen with activity.[324] However, prescription parameters for the type of splint are not standardized,[325] with some advocating neutral positioning,[326] and some recommending 0–15 degrees of wrist extension. T e length of time for wearing the splint is also undetermined, with some recommending day and night use,[327] while others instruct patients to wear the brace at night and during activities stressful to the wrist.[328] Still others recommend only night use.[326] Rigid splints have been found to be superior to flexible ones in controlling carpal tunnel pressure,[329] although the softer flexible ones enhance compliance in RA patients.[330]

Night splints appear to allow the wrist to rest fully, although one study found that night splints did not significantly reduce intracarpal pressure when compared to controls who did not wear them.[331] Splints during the day are helpful only if they do not interfere with normal activity. T e positioning of the splint may be significant.

Yoga that focuses on upper body postures was found to be of benefit in one study,[332] although the sample size was small, and the results were not conclusive.

Ergonomic modifications can help reduce the incidence of CTS and alleviate symptoms in the already symptomatic patient. Patient education is also important to avoid sustained pinching or gripping, repetitive wrist motions, and sustained positions of full wrist flexion.

Isolated tendon excursion exercises for the finger flexor tendons and nerve gliding of the median nerve exercises are performed. T ese include isolated tendon gliding of the FDS and FDP of each digit. T e exercises are thought to have a positive effect by facilitating venous return or edema dispersion in the median nerve.[326]

Contrast baths can be used in 10-minute sessions to assist in the reduction of inflammation and edema.

Evaluation for surgical management is necessary for patients with atrophy of the thenar muscles, decreased sensation, and persistent symptoms that are intolerable despite conservative therapy.[300]

Ulnar Nerve

Entrapment of the ulnar nerve can occur at the elbow in the cubital tunnel (Chapter 17). Entrapment of the ulnar nerve at the wrist can occur at Guyon canal. T e clinical features of an ulnar nerve entrapment at the wrist are described in Chapter 3.

If ulnar neuropathy at Guyon canal is suspected, it is often helpful to evaluate the pisotriquetral joint and the hook of the hamate. Abnormalities may be present at either site, resulting in secondary ulnar neuropathy.[333] In addition, the clinician must ask the patient whether they have any medical history involving diabetes and peripheral neuropathies.

T e intervention for ulnar nerve compression can be surgical or conservative depending on the severity. Indications for surgical intervention include preventing deformity and increasing functional use of the hand. Conservative intervention for mild compression involves the application of a protective splint and patient education to avoid positions and postures that could compromise the nerve.

Hand–Arm Vibration Syndrome

Vibration is a physical stressor to which many people are exposed at work, in the home, or in their social activities. Humans respond characteristically to certain critical vibration frequencies at which there is maximum energy transfer from source to receiver.[334]

Hand–arm vibration syndrome (HAVS) is frequently underdiagnosed and misdiagnosed as CTS since the two entities typically coexist.[335] HAVS is associated with occupations involving exposure to sources of vibration, including air-compressed drilling, grinding, and electric drills and saws.[336]

T e pathophysiology of HAVS is poorly understood, but chronic exposure to vibration may produce circulatory, neurologic–sensory–motor, and musculoskeletal disturbances. Khilberg[337] has studied the acute effects and symptoms of work with vibrating hand-held power tools. He found that workers using nonimpact tools (grinders) had a lower prevalence of elbow and shoulder symptoms than those using low-frequency impact tools (chipping hammers), but it did not differ in this respect from workers using high-frequency impact tools. Working with impact tools, in general, was associated with a higher prevalence of pain in the wrist than work with nonimpact tools.[334]

T e diagnosis of HAVS is based on a history of HAV exposure and sensorineural or vascular signs and symptoms, which include the following[225]:

- Blanching white fingers (Raynaud phenomenon). T is is the most common symptom, and it occurs on exposure to cold. Its extent and frequency of occurrence determines the severity of the vascular grading.[334]
- Episodic tingling and numbness. T e numbness or tingling can be graded.
- Mild to severe sensory deficits.
- Swelling of the digits and forearm tissue.
- Trophic skin changes.

The intervention for HAVS includes maintaining central body temperature, avoiding exposure to cold and vibrating tools, job modification, and splinting at night.[225]

Myofascial Pain Syndrome

The most frequent cause of wrist, hand, and finger pain is a myofascial referral from the forearm flexors and especially from the forearm extensors. Trigger points in these muscles increase tendon tension and, therefore, relative compression of the carpal joints, which causes cracking and crepitus at the wrist due to abnormal joint glide.[338] The patient often reports a sense of stiffness in the wrist and hand, and pain exacerbated with wrist and finger flexion, which stretches these muscles, and on full wrist extension, which shortens these muscles.[338]

Complex Regional Pain Syndrome

The term CRPS refers to a classification of disorders, which can occur even after minor injury to a limb and which is a major cause of disability.[339]

CRPS, originally termed causalgia, has since been referred to by a number of names, including posttraumatic osteoporosis, Sudeck atrophy, transient osteoporosis, algoneurodystrophy, shoulder–hand syndrome, gardenalic rheumatism, neurotrophic rheumatism, reflex neurovascular dystrophy, and reflex sympathetic dystrophy (RSD).[340]

Two types of CRPS are recognized by the International Association for the Study of Pain:

- CRPS 1. This type refers to the pain syndrome, previously termed RSD, which involves a pain syndrome triggered by a noxious event that is not limited to a single peripheral nerve. This type is more commonly seen in physical therapy.
- CRPS 2. This type refers to the pain syndrome, previously termed causalgia, which involves a pain syndrome that involves direct partial or complete injury to a nerve or one of its major branches.

The signs and symptoms for both types include pain, edema, stiffness, skin temperature changes, and sweating.[341] More recently, it has been suggested that a third type may exist. This type is characterized by irreversible changes in the skin and bones, marked muscle atrophy, unyielding pain, and severely limited mobility of the affected area.

Type I CRPS

The pain of type I CRPS is classified as sympathetically maintained pain or sympathetically independent pain, where sympathetically maintained pain is characterized by an abnormal reaction of the sympathetic nervous system.[341]

The edema, which can be pitting or nonpitting, is often present throughout all stages of CRPS and may be the result of vasomotor instability coupled with a lack of motion.[340]

The stiffness is one of the components of CRPS 1 that increases with time and is due to increased fibrosis in the ligamentous structures and adhesion formation around the tendons.[340]

The reported incidence of CRPS 1 is 1–2% following various fractures,[342] 2–5% after peripheral nerve injury,[343] and 7–35% in prospective studies of Colles fracture.[289,344] In 10–26% of cases, no precipitating factor can be found.[290,345] A number of psychological components have been proposed, including the following:

1. A significant period of stress, anxiety, or depression
2. Childhood experiences.
   a. Sexual abuse
   b. Physical abuse
   c. Emotional abuse
   d. Abandonment
   e. Family history of drug or alcohol abuse
3. Adult experiences
   a. Care provider for aging or ill parent(s) or other relative
   b. Problem children, parents, or siblings
   c. Unhappy marriage
   d. Alcoholism
   e. Grief
   f. Abuse of any type
4. A low self-esteem
5. A negative outlook on life

However, there has been no evidence to support such notions. Instead, it is thought that the emotional and behavioral changes noted are a result, rather than a cause, of the prolonged pain and disability.[346]

The diagnosis of CRPS is made from the physical examination and the patient's medical history, which may include past events of trauma, persistent pain, hyperalgesia, allodynia (perception of a nonpainful stimulus as painful), edema, and diminished function of the area.

The type of pain and its duration are perhaps the most important diagnostic signs. The pain is typically burning in nature and is of a much longer duration than would be expected from the injury.[346]

A number of other conditions need to be ruled out before establishing a diagnosis of CRPS 1, and these include, but are not limited to the following:

- Rheumatoid and septic arthritis
- Gout
- Disk herniation
- Peripheral neuropathy
- Peripheral nerve entrapment
- Peripheral vascular disease

Classically, CRPS 1 has been subdivided into three clinical phases[347,348]:

- An acute inflammatory phase that can last from 10 days to 2–3 months. The acute stage of CRPS lasts from 1 to 3 months. This stage is reversible if the patient is treated. The affected limb becomes flushed, warm, and dry because regional blood vessels are relaxed, and stimulation of the sweat glands is reduced.[341] The pain is diffuse, severe, and constant with a burning, throbbing, or aching quality. Edema and increased hair and nail growth can also occur.

By the end of this stage, the limb turns cold, sweaty, and cyanotic from vasoconstriction caused by paradoxical sympathetic stimulation.[341]

- A phase of vasomotor instability that can last for several months. T is is the dystrophic stage, which lasts another 3–6 months. Constricted blood vessels can cool limb temperature by nearly 10 degrees.[341] T e area will be pale, mottled, edematous, and sweaty. Pain remains continuous, burning, or throbbing but is more severe.[341] Nails may crack or become brittle and heavily grooved. Limb movement is limited by muscle wasting and joint stiffness. Osteoporosis and contractures can develop.[341]
- A cold end phase. T e atrophic stage is characterized by irreversible damage to muscles and joints. Over the next 2–3 months the bones atrophy and the joints become weak, stiff, or even ankylosed.[341] T e pain lessens and may become spasmodic or breakthrough but is no longer mediated by the sympathetic nervous system.[341] T e skin is cool and looks glossy and pale or cyanotic.

No prospective studies are available in which this staging is confirmed. However, a prospective study of 829 patients[340] indicated that the following:

- In its early phase, CRPS is characterized by regional inflammation and not of a disturbance of the sympathetic nervous system. T e regional inflammation increases after muscular exercise.
- A tremor was found in 49% and muscular incoordination in 54% of patients.
- Sympathetic signs, such as hyperhidrosis are infrequent.

T ese data support the concept of an exaggerated regional inflammatory response to injury or operation in CRPS.[340,349]

T e most effective intervention for CRPS 1 is disputed. However, most agree that the intervention requires a team approach, in which the physical therapist plays a pivotal role and that the earlier the intervention is instituted, the better the prognosis. Immobilization and overprotecting the affected limb may produce or exacerbate demineralization, vasomotor changes, edema, and trophic changes.[350]

Physical therapy is the first line of intervention, whether it be the sole intervention or performed immediately following a nerve block.[346,351]

T e most important rule is to minimize pain while employing physical therapy. When excessive pain is created, sympathetically mediated pain may worsen.[346] It is vital to not reinjure the region or aggravate the problem with aggressive physical rehabilitation.[352]

T e patient's involved limb must be elevated as often as possible to counteract the vascular stasis and actively mobilized several times per day.[346]

Recovery from muscle dysfunction, swelling, and joint stiffness requires appropriate physical activity and exercise, and pressure and motion are necessary to maintain joint movement and prevent stiffening.[346] T e progression should occur slowly and gently with strengthening, active assisted range-of-motion, and AROM exercises.

Weight-bearing exercises and active stress loading exercises should also be incorporated. Active stress loading exercises include scrubbing and carrying. Scrubbing is a form of closed kinetic chain exercise for the upper or lower extremity in which the patient in a variety of positions performs a scrubbing action on a firm surface. As its name suggests, carrying exercises for the upper extremity involve having the patient carry small objects in the hand on the affected side and gradually increasing the weight of the object. For the lower extremity, stress loading can be achieved through weight bearing.

Sensory threshold techniques can be used. T ese include fluidotherapy, vibration desensitization, transcutaneous electrical nerve stimulation, contrast baths, and desensitization using light and heavy pressure of various textures over the sensitive area.

Topical capsaicin is helpful, as are NSAIDs.

INTEGRATION OF PRACTICE PATTERNS 4G AND 4I

T is includes conditions that result in impaired joint mobility, motor function, muscle performance, and range of motion that are associated with fractures and bony or soft-tissue surgical procedures.

Distal Radius Fractures

Fracture of the distal radius is the most common wrist injury for any age group. While the older patient usually sustains an extraarticular metaphyseal fracture, the younger patient tends to sustain the more complicated intraarticular fracture.[205] Physical examination reveals swelling of the wrist, possible gross deformity, limited range of motion, and point tenderness over the distal radius. Successful management of a distal radius fracture must take into account the integrity and function of the soft tissues while restoring anatomic alignment of the bones. T e clinician should avoid distracting or placing the wrist in a flexed position, so that the mechanical advantage of the extrinsic tendons is maintained, pressure in the carpal canal is not increased, any carpal ligament injury is not exacerbated, and stiffness is not encouraged. T e rehabilitation after fracture of the distal radius is nearly uniform among the various fracture types outlined below. T e more specific guidelines are listed after each fracture description.

Colles Fracture[4]

Colles fracture is a complete fracture of the distal radius with a posterior (dorsal) displacement of the distal fragment. T e typical mechanism of injury is a FOOSH. T e fracture displacement and angulation are evident on the lateral film—the Colles fracture has the characteristic dorsiflexion or "silver fork" deformity. Radiographs of the AP view show the usual comminuted fracture.

Management of this fracture requires a precise reduction of the fracture in order to maintain the normal length of the radius. Although the method of reduction, as well as the position of immobilization, is quite variable, in most cases closed reduction and a cast are chosen. However, the more complicated cases may require open reduction and external fixations.[353] A common sequelae of this fracture is a loss of full rotation of the forearm.

Smith Fracture

A Smith fracture sometimes called a reverse Colles fracture, is defined as a complete fracture of the distal radius with an anterior (palmar) displacement of the distal fragment.[354] T e usual mechanism for this type of fracture is a fall on the back of a flexed hand. Smith fractures are classified into three types[355]:

- *T*ype I. T is is described as a transverse fracture through the distal radial shaft.
- *T*ype II. T is is an oblique fracture through the distal shaft starting at the posterior (dorsal) articulating lip.
- *T*ype III. T is type (also referred to as a reverse Barton fracture) is an oblique fracture beginning more distally on the articular surface of the radius.

T e typical management for a Smith fracture is with closed reduction and long arm casting in supination for 3 weeks, followed by 2–3 weeks in a short-arm cast.[354] As types II and III are frequently unstable, they may require an ORIF.

Barton Fracture. A Barton fracture involves a posterior (dorsal) or anterior (volar) articular fracture of the distal radius resulting in a subluxation of the wrist.[354] T is type of fracture usually results from some form of direct and aggressive injury to the wrist or from a sudden pronation of the distal forearm on a fixed wrist. A technique to reduce these dislocations under anesthesia has been described in the literature.[356] T e technique involves applying traction to the wrist and then placing the patient's wrist in full supination, mid-extension, and ulnar deviation, which closes the diastasis by reducing the scaphoid to its correct anatomic plane. An above-elbow cast is then applied for 4 weeks, followed by a forearm cast for a further 3 weeks with the wrist positioned in ulnar deviation. More complicated fractures may require an ORIF with 16 weeks being the average healing time.

Buckle Fracture. A buckle fracture is an incomplete, undisplaced fracture of the distal radius, which is commonly seen in children. Immobilization for 3–4 weeks in a short-arm cast or anterior (palmar) splint is adequate.[143] T e possibility of abuse should be considered in the child with a fracture. Consultation with an orthopaedist is advisable for fractures in the pediatric population.

T e adult fracture is treated with a cast, external fixation, or ORIF. T e fracture site is immobilized for 6 weeks if casted, 8 weeks with an external fixator, or 2 weeks if an ORIF with plate and screws is performed. If the fracture is nondisplaced, 2–6 weeks of rehabilitation is recommended, whereas displaced fractures typically require 8–12 weeks.

Conservative intervention usually begins while the fracture is immobilized and involves AROM of the shoulder in all planes, AROM of elbow flexion and extension, and finger flexion and extension. T e finger exercises must include isolated MCP flexion, composite flexion (full fist), and intrinsic minus fisting (MCP extension with IP flexion). If a fixator or pins are present, pin site care should be performed.

Following the period of immobilization, extension and supination are commonly limited and need to be mobilized. AROM exercises of wrist flexion and extension and ulnar and radial deviation are initiated at this time. Wrist extension exercises are performed with the fingers flexed (especially at the MCP joints). T e initiation of PROM occurs according to physician preference, either immediately or after 1–2 weeks.

Strengthening exercises are introduced as tolerated, using light weights and tubing. Putty can be used to increase grip strength if necessary.

Plyometrics and neuromuscular re-education exercises are next, followed by return to function or sports activities as appropriate.

Fractured Scaphoid

T e scaphoid is the most commonly fractured carpal bone due to its location and is the only bone fractured in approximately 70% of all carpal fracture cases.[128,143,204,282] Most commonly, the injury results from a FOOSH with the wrist pronated. Although a fracture can occur in any part of the scaphoid, the common areas are at the waist and at the proximal pole.

Patients typically complain of posterior (dorsal) radial-sided wrist pain and have tenderness over the anatomic snuffbox. On physical examination, little swelling may be noted, although a loss of the concavity of the anatomic snuffbox is frequently seen.[357] It may be good practice to treat all cases of wrist sprain that are accompanied by pain and swelling in the anatomic snuffbox as a scaphoid fracture until proven otherwise. Many investigators feel a reliable test for scaphoid injury is axial compression of the thumb along its longitudinal axis.[358,359] Described by Chen,[358] this test translates force directly across the scaphoid and should elicit pain if there is a fracture. Even with appropriate radiographs, fractures of the scaphoid can be difficult to visualize.[357] In cases in which there is a high clinical suspicion, a scaphoid view of the wrist is usually obtained. T is is a clenched fist view with the wrist held in ulnar deviation. T is view reduces the foreshortening of the scaphoid that occurs on a normal PA view and clearly displays the entire length of the scaphoid.[357] If plain radiographs are normal and clinical suspicion is high, MRI is warranted.

Accurate early diagnosis of scaphoid fracture is critical as the morbidity associated with a missed, or delayed diagnosis is significant and can result in long-term pain, loss of mobility, and decreased function.[12] T is degree of morbidity is related to the scant blood supply to the scaphoid, which results in a high incidence of delayed healing or nonunion, and the fact that scaphoid fractures are inherently unstable.

Conservative management of a scaphoid fracture remains controversial. For example, there is no agreement on the optimum position for immobilization. Current management is immobilization in a long-arm or short-arm thumb spica cast, with the wrist position and length of immobilization dependent on the location of the fracture:

- Proximal pole. Immobilization for 16–20 weeks in a long-arm or short-arm thumb spica, with the wrist positioned in slight extension and radial deviation.
- Central third. Immobilization for 6 weeks in a long-arm thumb spica, followed by a further 6 weeks in a short-arm thumb spica.
- Distal third. Immobilization for 6–8 weeks in a short-arm thumb spica.
- *T*uberosity. Immobilization for 5–6 weeks in a long-arm or short-arm thumb spica.

For the patient with pain over the anatomic snuffbox but normal initial radiographs, application of a thumb spica cast for 3 weeks followed by repeat radiographs is indicated. If the radiographs remain normal, but the pain persists, a bone scan is a next step. If the bone scan is positive, management is continued as for an acute fracture. Chronic pain, loss of motion, and decreased strength from prolonged immobilization or early arthritis is common following a scaphoid fracture.

Following the removal of the splint, a capsular pattern of the wrist is usually evident. In addition, there will be a painful weakness of the thumb and/or wrist extension/radial deviation. AROM exercises for wrist flexion and extension and radial and ulnar deviation are initiated as early as possible, with PROM to the same motions beginning after 2 weeks. A wrist and thumb immobilization splint is typically worn between exercises and at night for comfort and protection.

At about the same time as the PROM exercises are initiated, gentle strengthening exercises are introduced using 1- to 2-lb weights or putty. Over a period of several weeks, the exercise program is progressed to include weight-bearing activities, plyometrics, open- and closed-chain exercises, and neuromuscular reeducation, before finally progressing to functional and sport-specific exercises and activities as appropriate.

Because of the precarious nature of the blood supply and potential for movement at the fracture line, nonunion can occur in 8–10% of cases[360,361] with the rate of nonunion varying with the actual fracture site (up to 20–30% of proximal third fractures and 10–20% of middle third fractures),[357] with distal third fractures being relatively rare.[360,361]

SLAC wrist is a late complication of a scaphoid fracture, scapholunate dissociation, Kienböck disease, fracture of the distal radius, Preiser disease, and deposition of crystals of calcium pyrophosphate dehydrate.[362] T e SLAC wrist is thought to result from a loss of the stabilizing effect of the scaphoid, with the development of an arthrosis at the radioscaphoid articulation. When the injury has progressed to this state, proximal row carpectomy or wrist fusion is the only option for the hand surgeon.[363]

Carpal Boss

A carpal boss is a rounded bony prominence that presents between the base of second and third metacarpal and the trapezoid and capitate, resulting from repeated forced extension of the wrist and subsequent irritation of soft tissues. T e ECRL and ECRB are commonly involved. T is prominence resembles a ganglion and is not necessarily pathologic, although it can cause pain and irritation of the local soft tissues.[364] Confirmation is through radiographs.

Conservative intervention includes a wrist immobilization splint with the wrist positioned in slight extension (10–15 degrees) to reduce tension on the radial wrist extensors.

Metacarpal Fractures

Injuries to the metacarpals are the result of either direct or indirect trauma, with nature and direction of the applied force determining the exact type of fracture or dislocation. Most metacarpal fractures occur in the active and working population, particularly adolescents and young adults.[365,366] Specific injury patterns that occur from commonly seen trauma are as follows:

- CMC injuries. Metacarpal base fractures and dislocations of the CMC joint commonly result from an axial load or other stress on the hand with the wrist flexed.[365,366] CMC joints, especially the central joints, are quite stable. T e metacarpal bases are held in position by posterior (dorsal) and anterior (palmar) CMC ligaments, as well as by interosseous ligaments. CMC dislocations may occur with or without fracture. Fracture-dislocation of the fifth metacarpal base is a common intraarticular injury and has been dubbed the reverse Bennett fracture. A direct blow to the ulnar border of the hand tends to cause an extra-articular fifth metacarpal base fracture.
- Metacarpal shaft injuries. Metacarpal shaft fractures are typically produced by either axial loading, direct trauma, or torsional forces on the digits. Usually, the fractures are classified anatomically as transverse, oblique, or spiral.[365,366] T e fracture pattern often denotes the mechanism of injury, with direct or axial injury leading to transverse or oblique fractures and torsion leading to spiral fracture.
- Metacarpal neck fractures. T e most common metacarpal fractures usually result from striking a solid object with a clenched fist and thus are dubbed boxer fractures, although this injury almost never occurs during boxing. Fractures of the fifth metacarpal neck are among the most common fractures in the hand.[365,366]
- Metacarpal head injuries. Metacarpal head fractures, which are rare injuries, result from axial loading or direct trauma. Fractures of the metacarpal head are intraarticular and periarticular.[365,366] If displaced, metacarpal head fractures usually require ORIF.
- Avulsion fracture at the origin of the collateral ligaments. T is type of fracture is caused by forced deviation of the flexed MCP joint.[365,366]
- MCP dislocations. Almost all MCP dislocations occur with the proximal phalanx displaced in a posterior (dorsal) direction on the metacarpal head, as there is no specific posterior (dorsal) restraint to the MCP joint other than the joint capsule and extensor mechanism.[365,366]

T e management of a patient with a metacarpal fracture depends on a variety of factors, including the location, the degree of displacement, angulation, and rotation. In addition, the patient's age, occupation, general health, and concomitant injuries must also be considered. Most metacarpal injuries are managed by closed reduction and immobilization or sometimes controlled mobilization utilizing a posterior (dorsal) block splint. Specific indications are further described below.

- Impaction fractures of the metacarpal bases that are not significantly displaced can be treated with splinting, followed by early mobilization.
- CMC dislocations and fracture dislocations, especially when multiple, are unstable injuries. In the past, these fractures were managed by closed reduction and external immobilization, which frequently led to grip weakness and residual pain. T e current literature supports closed reduction, if joint congruity can be obtained, but with the addition of internal fixation.

- Displaced fracture dislocations of the fourth and fifth metacarpals, which are accompanied by a fracture of the posterior (dorsal) hamate, require ORIF. Reverse Bennett fractures frequently need K-wire stabilization to counteract the deforming forces. If little articular incongruity is present, this may be a closed procedure.

As the major complication of these fractures is adherence of soft tissues, the primary goals of rehabilitation, once bony healing has occurred, are to restore an optimized soft-tissue balance and glide to allow pain-free motion and strength while simultaneously protecting the healing tissues.

Finger Fractures

Fractures of the finger (phalangeal), which are more common than metacarpal or carpal fractures, represent approximately 45% of fractures of the hand and wrist.[367] Phalangeal fractures can be divided into base, shaft, and neck and head fractures. Conservative intervention for the more stable fractures involves closed reduction in as near normal alignment as possible with an appropriate cast or splint[368]:

Distal Phalanx Fractures

Tuft Fracture. T is is the most common fracture of the fingers, frequently resulting from a crush injury. T ese fractures are often associated with injuries to the nail matrix.

Shaft Fracture. T is type of fracture is either longitudinal or more commonly transverse in orientation. If displaced, this type of fracture is usually associated with an injury to the nail matrix.

Intraarticular Fracture. T is fracture in adults usually involves either the volar or posterior (dorsal) lip at the end of the bone, whereas in children an epiphyseal separation also may occur.

Volar Lip Fracture. T is type of fracture also referred to as Jersey finger or sweater finger, is also a tendon avulsion injury where the FDP remains attached to the small fracture fragment.

Unstable displaced articular fractures require surgical intervention. Generally speaking, following a fracture of the distal phalanx, a protective splint is worn for 2–4 weeks until the fracture site is nontender. AROM begins at 2–4 weeks or earlier if the fracture is stable enough. PROM begins at 5–6 weeks. PREs normally begin at 7–8 weeks.

Fractures of the Proximal and Middle Phalanges

Shaft Fracture. T e type of shaft fracture depends largely on the mechanism of injury. A direct blow frequently causes transverse fractures, whereas twisting injuries often cause spiral or oblique fractures.

T e intervention for this type of fracture depends on the location and the severity:

Proximal Phalanx Fractures. Nondisplaced extraarticular fractures are splinted with buddy tape. AROM is initiated immediately, with PROM being initiated at 6–8 weeks. Nondisplaced intraarticular fractures are splinted in the intrinsic plus position for 2–3 weeks. AROM begins at 2–3 weeks, with PROM being initiated at 4–8 weeks. PREs normally begin at clinical union (8–12 weeks).

Middle Phalanx Fractures. If nondisplaced, these fractures are splinted in the intrinsic plus position for approximately 3 weeks. Buddy splinting, the taping of a neighboring finger to the involved finger, may also be an option. AROM is initiated when pain and edema subsides. PROM begins at 4–6 weeks, with PREs normally beginning at 6–8 weeks.

THERAPEUTIC TECHNIQUES

Myofascial Release

Carpal Tunnel Release

A number of myofascial techniques can be used to treat CTS

Opening the Canal. T e patient is positioned in sitting or supine lying with their palms facing upward. T e clinician applies pressure centrally from the posterior (dorsal) surface of the carpal bones simultaneously with pressure applied from the ventral edges of the carpal bones, using a three-point-opposing-pressure technique.[369]

Abductor Brevis Release. T e patient is positioned in sitting or supine lying with their palm facing upward. T e clinician grasps the thumb with one hand and pulls it back into hyperextension with abduction while simultaneously performing the opening canal technique described above.[369]

Carpal Tunnel Stretch. T e patient is positioned in sitting or supine lying with their palm facing upward. T e clinician stabilizes the patient's wrist with one hand and simultaneously hyperextends the digits and wrist of the patient with the other hand.[369]

Techniques to Increase Joint Mobility

T e majority of the joint mobility tests described in the tests and measures section can also be utilized as mobilization techniques. For each of the techniques, the patient is positioned in sitting with their forearm and wrist in a neutral position, with the clinician positioned to the side of the patient. T e amplitude and the velocity of each of the techniques (i.e., grade) are varied according to the stage of healing and the irritability of the joint.

T e clinician must be cognizant of the joints that are responsible for the individual motions that occur at the wrist and hand and which ones present with convex or concave joint surfaces in order to deliver the most specific technique.

- Supination–pronation occurs primarily at the ulnomeniscotriquetral joint and the proximal and inferior radioulnar joints.
- Wrist flexion occurs primarily at the radiocarpal joint (distal radius and the articulating surfaces of the navicular and lunate).
- Wrist extension occurs primarily at the midcarpal joints (articulating surface of the scaphoid, lunate, and triquetral bones proximally, and the trapezium, trapezoid, capitate, and hamate bones distally).

Passive Accessory Mobilizations

Distal Radioulnar Joint

Anterior–Posterior Glide. T e clinician glides the radius in an anterior direction to improve forearm pronation and in a

posterior direction to improve forearm supination. The intensity of the technique (i.e., grade) is varied according to the irritability of the joint.

Radiocarpal

Posterior–Anterior Glide. The posterior glide is used to improve the joint's ability to flex, whereas the anterior glide is used to improve the ability of the joint to extend (Fig. 18-30).

Ulnar and radial glide. The ulnar (medial) glide is used to improve the joint's ability to radially deviate, whereas the radial (lateral) glide is used to improve the ability of the joint to ulnarly deviate (Fig. 18-31).

Ulnocarpal, Midcarpal, CMC, MCP, and IP Joints

Distraction. Using a pinch grip of the index finger and thumb of one hand, the clinician palpates and stabilizes the proximal bone of the joint being distracted. With a pinch grip of the index finger and thumb of the other hand, the clinician palpates and mobilizes the distal bone longitudinally (Fig. 18-36).

Posterior–Anterior Glide (Flexion/Extension). Using a pinch grip of the index finger and thumb of one hand, the clinician palpates and stabilizes the proximal bone of the joint being mobilized in a posterior (dorsal)–anterior (palmar) plane. With a pinch grip, the clinician glides the distal bone along the posterior (dorsal)–anterior (palmar) plane of the corresponding joint. The appropriate conjunct rotation of the bone may be added. For example, to restore flexion at the radioscaphoid joint, the clinician rotates the scaphoid toward the center of the palm, while simultaneously gliding the scaphoid in a posterior (dorsal) direction.

The clinician can make the technique patient-assisted by flexing/extending the distal bone about the appropriate intraarticular axis to the limit of the physiologic range of motion. From this position, the patient is instructed to perform an isometric contraction against the clinician's equal resistance. The contraction is held for 3–5 seconds, following which the patient is instructed to completely relax. The new barrier of flexion/extension is localized and the mobilization repeated.

First CMC (Trapeziometacarpal) Joint

Posterior Glide. This technique is used to improve range of motion into trapeziometacarpal joint abduction.

Anterior Glide. This technique is used to improve range of motion into trapeziometacarpal joint adduction.

Medial–Lateral Glide (Abduction/Adduction). The medial glide technique is used to improve range of motion into trapeziometacarpal joint flexion. The lateral glide technique is used to improve range of motion into trapeziometacarpal joint extension.

The clinician can make the technique patient assisted by abducting/adducting the distal bone about the appropriate intraarticular axis to the limit of the physiologic range of motion. From this position, the patient is instructed to perform an isometric contraction against the clinician's equal resistance. The contraction is held for 3–5 seconds, following which the patient is instructed to completely relax. The new barrier of motion is localized and the mobilization repeated.

Intermetacarpal Joints

Using a pinch grip of the index finger and thumb of one hand, the clinician palpates and stabilizes one metacarpal. With the thumb and index finger of the other hand, the clinician mobilizes the neighboring metacarpal into an anterior or posterior glide, with the appropriate conjunct rotation

MCP Joints

Posterior–Anterior Glide. A posterior glide is used to improve range of motion into extension for digits two through five, whereas an anterior glide is used to improve range of motion into flexion for digits two through five.

Ulnar (Medial)–Radial (Lateral) Glide. An ulnar glide is used to improve range of motion into ulnar deviation for digits two through five, whereas a radial glide is used to improve range of motion into radial deviation for digits two through five.

First MCP/IP Joint. A radial glide is used to improve trapeziometacarpal extension, whereas the ulnar glide is used to improve trapeziometacarpal flexion.

IP Joints. The anterior glide can be used to improve the ability of the joint to move into flexion, whereas posterior glide can be used to improve the ability of the joint to move into extension.

Mobilization with Movement

MWM techniques[370,371] can be used to increase ROM or decrease pain (see Chapter 10).

Wrist Joints. The patient is positioned in sitting with the elbow flexed, and the forearm supinated. The clinician stabilizes the distal radius with one hand around the lateral aspect of the forearm and, using the web space of the other hand, applies a pain-free lateral glide to the proximal row of carpals. The patient is then asked to extend or flex his or her wrist to the end of the available range, and with his or her free hand, to apply a passive stretch at the end of the range. On occasion, an internal or external rotation of the carpals relative to the radius may need to be combined with the glide. Also, the intercarpal joint may require specific anterior–posterior gliding of one the proximal row of carpals relative to its distal neighbor.

MCP and IP Joints. The clinician applies a medial or lateral glide to the involved phalanx in a painless direction after which the patient actively flexes or extends the finger and applies a pain-free, passive end range stretch. On occasion, internal or external rotation of the more distal phalanx may be required in conjunction with the medial or lateral glide to achieve painfree end range overpressure.

High-Velocity, Low-Amplitude Thrusting

High-velocity thrust techniques can be used with any of the carpals. The following example describes the technique for a posteriorly (dorsally) displaced scaphoid:

The patient is positioned in sitting with the forearm of their affected side resting on a table with the anterior (palmar) side facing down. The clinician sits or stands at right angles to the patient's affected side. The clinician grips the patient's scaphoid bone between their thumb and index finger (Fig. 18-86). The clinician reinforces this grip by placing the thumb and the index of the other hand on top of them. The patient's wrist is then passively extended to the end range. At the end of the available range, the scaphoid is thrusted anteriorly (ventrally) while passively extending the wrist slightly.

FIGURE 18-86 High-velocity thrust technique to the scaphoid.

Transverse Friction Massage

Common Sheath of APL and EPB

Transverse friction can be applied to the commonly shared sheath of the APL and EPB (Fig. 18-87) or at the point where the tendons pass over the wrist extensors.

Techniques to Increase Soft-Tissue Extensibility

A number of techniques can be used to increase the extensibility of the soft tissues of the wrist, hand, and forearm. These include passive or AROM exercises that can be performed by the patient:

- Wrist flexion and extension
- Wrist ulnar and radial deviation
- Finger flexion and extension
- Finger adduction and abduction
- Thumb opposition, flexion, extension, abduction, and adduction

Tendon Gliding Exercises

Tendon gliding exercises of the flexor tendons are often prescribed to prevent adhesions of the tendons and nerves.

FIGURE 18-87 TFM to common shared sheath of the abductor pollicis longus and extensor pollicis.

Place and Hold Exercises

These exercises, which are a type of gentle muscle setting exercises that are used before AROM exercises are initiated, to maintain joint mobility and tendon excursion. With the MCP joints maintained in flexion, the IP joints are passively placed in a partially flexed position and the patient holds the position independently for five seconds using a minimum contraction of the finger flexors. The exercise can be combined with active wrist extension.

IP Flexion or "Hook Fist"

The hook, this position describes the hand position where the MCP joints are maintained in extension while the DIP and PIP joints are flexed. This results in maximum gliding between the profundus and superficialis tendons, and between the profundus tendon and the bone.

Straight and/Fingers, Wrist in Neutral

MCP Flexion or "Tabletop". With the wrist maintained in neutral flexion/extension, MCP joints are flexed while maintaining the DIP and PIP joints in extension.

Straight or "Sublimis" Fist. The patient moves from the tabletop position to the straight fist position by flexing the PIP joints while maintaining the DIP joints in extension.

Full Fist. While maintaining the wrist in neutral flexion/extension, the patient flexes all of the MCP and IP joints simultaneously.

Thumb Flexion. The patient flexes the MCP and IP joints of the thumb throughout the full range to promote maximum gliding of the FPL.

Tendon Blocking Exercises

These exercises are a progression of the flexor tendon gliding exercises and are therefore not used in the early stages of flexor tendon healing. The patient is positioned in sitting with the forearm supinated and the back of the hand resting on the table.

MCP Flexion. While stabilizing the rest of the fingers and extension against the table with one hand, the patient flexes only the MCP joint of one digit.

PIP Flexion. The patient stabilizes the proximal phalanx of one digit with the opposite hand and, if possible, flexes just the PIP joint of the one digit while keeping the PIP joint extended and the rest of the fingers on the table.

DIP Flexion. While stabilizing the middle phalanx of one digit with the other hand, the patient attempts to flex just the distal phalanx.

Extensor Tendon Gliding Exercises

The following progression can be used to rehabilitate extensor tendon injuries.

Isolated MCP and IP Joint Flexion. The patient passively flexes the MCP and IP joints of one finger with the opposite hand while actively maintaining the other fingers in extension.

Middle and Ring Finger Flexion. The patient flexes the middle and ring fingers while maintaining the extension of the index and little fingers to promote isolated control of the extensor indicis and EDM tendons.

Terminal Range Extension of IP Joints. The patient passively extends each of the IP joints into terminal extension.

CASE STUDY

Pain in Ful Left Thumb

HISTORY

History of Current Condition

A 23-year-old female patient complained of left thumb pain following a home do-it-yourself project that involved a lot of hammering of nails. The patient described a gradual onset of pain about 2 months ago and described the pain as burning located at the base of the left thumb. The patient also reported some swelling at the wrist. The patient attributed the pain to the hammering of nails as subsequent attempts to use the hammer reproduced the pain. Over time, the pain had worsened to the point where it hurt all of the time, even at night. The NSAIDs prescribed by the physician 2 weeks ago appeared to be helping.

Past History of Current Condition

No past history of left elbow, wrist, or hand pain.

Past Medical/Surgical History

Unremarkable except for removal of ganglion cysts from her right wrist/hand about 1 year ago.

Growth and Development

Right-hand dominant.

Medications

None, except for the prescribed NSAIDs.

Occupational/Employment/School

Office worker. College education.

Functional Status/Activity Level

The patient reported experiencing pain with vacuuming and lifting heavy pots and pans. The patient's goals were to decrease pain with activities of daily living.

Health Status (Self-Report)

In general, good health, but pain interferes with gripping tasks at home and at work.

Questions

1. What are some of the more common diagnoses characterized by thumb pain?
2. What does the history of the gradual onset and of repetitive activity tell the clinician?
3. What findings do you expect to note in the physical examination in terms of palpation, resistive tests, and special tests?
4. What additional questions would you ask to help rule out referral of pain from the cervical spine or shoulder?
5. List the tests you would use to rule out the various diagnoses that you listed in question 1.
6. Does this presentation/history warrant an upper quarter scanning examination? Why or why not?

CASE STUDY

Pain, Weakness, and Numbness of The Hand

HISTORY

History of Current Condition

A 49-year-old female secretary complains of insidious onset of right hand numbness and pain, which began about 5 weeks previously. The symptoms are felt mainly in the right index finger, especially when working at her computer at work but also in her right thumb and middle finger after a day at work and at night. The symptoms are also reported to be worse during the night and early morning. The patient has also noted a slight decrease in her grip strength, which prompted her to see a MD, who prescribed PT, ibuprofen, vitamin B6, and a short course of diuretics. The patient denies any neck pain.

Past Medical/Surgical History

Unremarkable, including no history of previous symptoms or of diabetes mellitus reported by the patient.

Medications

800 mg of ibuprofen daily.

Other Tests and Measures

None. X-rays 1 year ago were unremarkable (per patient). Physician mentioned that further testing may be warranted (nerve conduction velocity, EMG).

Social Habits (Past and Present)

Smoker (1/2 pack per day).

Growth and Development

Right-hand dominant.

Occupational/Employment/School

Full-time secretary at local community hospital for last 6 years. Recently promoted which has meant an increase in computer work.

Functional Status/Activity Level

Symptoms interfering with work and at home with her needle craft. Symptoms also interfering with sleep approximately two times per night.

Questions

1. What are some of the more common diagnoses characterized by symptoms in this distribution?
2. What does the history of the gradual onset and of repetitive activity tell the clinician?
3. What findings do you expect to note in the physical examination in terms of palpation, resistive tests, and special tests?
4. What additional questions would you ask to help rule out referral of pain from the cervical and thoracic spine?
5. What additional questions would you ask to help rule out referral of pain from the shoulder or elbow?
6. List the tests you would use to rule out the various diagnoses that you listed in question 1.
7. Does this presentation/history warrant a scan? Why or why not?

CHAPTER 19 Hip

CHAPTER OBJECTIVES

At the completion of this chapter, the reader will be able to:

1. Describe the anatomy of the joint, ligaments, muscles, and blood and nerve supply that comprise the hip joint complex.
2. Describe the biomechanics of the hip joint, including the open- and close-packed positions, normal and abnormal joint barriers, force couples, and the static and dynamic stabilizers of the joint.
3. Describe the purpose and components of the examination of the hip joint.
4. Perform a comprehensive examination of the hip joint, including palpation of the articular and soft tissue structures, specific passive mobility, passive articular mobility tests, and stability stress tests.
5. Evaluate the total examination data to establish a diagnosis.
6. Describe the relationship between muscle imbalance and functional performance of the hip.
7. Summarize the various causes of hip dysfunction.
8. Develop self-reliant intervention strategies based on clinical findings and established goals.
9. Develop a working hypothesis.
10. Describe and demonstrate intervention strategies and techniques based on clinical findings and established goals.
11. Evaluate the intervention effectiveness in order to progress or modify an intervention.
12. Plan an effective home program and instruct the patient in same.

OVERVIEW

The structure and design of the hip allow for both mobility and stability,[1] the latter of which is particularly important for weight bearing and ambulation. In the human body, the center of gravity is located at the second sacral vertebral level, several segments above and medial to the femoral head. Control of the body mass from such a distant fulcrum requires the generation of significant counterbalance forces as well as the ability of the joint to sustain both high compression and tensile strains.[2] Thus, a major function of the hip joint is to provide a pathway for the transmission of forces between the pelvis and the lower extremities.

ANATOMY

The hip articulation is formed by the head of the femur and the acetabulum of the pelvic bone (Fig. 19-1). This articulation is classified as an unmodified ovoid (or ball and socket) joint. The hip joint which, although similar in nature to the shoulder joint, differs in the fact that the former has a deeper acetabular socket and acts as a weight-bearing joint with a smaller total arc of motion.

Bony Anatomy

Normal hip joint growth and development occur because of a genetically determined balance of growth of the acetabulum and the presence of a strategically located spherical femoral head.[3–7]

The os coxa (hip bone), more commonly referred to as the innominate bone initially begins life as three individual bones: the ilium, the ischium, and the pubis (Fig. 19-1). As life progresses, these three bones fuse together.

Ilium

The ilium (Fig. 19-1) is the largest of these three bones. It is composed of a large fan-like wing (ala) and an inferiorly positioned body. The body of the ilium forms the superior two-fifths of the acetabulum.

- The wing of the ilium spans superiorly from the posterior superior iliac spine (PSIS) to the anterior superior iliac spine (ASIS). The wing serves as the insertion of the gluteus minimus, medius, and maximus.
- The anterior surface of the ilium forms a fossa and serves as the proximal attachment of the iliacus muscle.

Ischium

The ischium (Fig. 19-1) is composed of a body, which contributes to the acetabulum, and a ramus. The ischium forms the posterior two-fifths of the acetabulum. Together, the ischium and the ramus form the ischial tuberosity. The ischial tuberosity is an important landmark for palpation, as it serves as the attachment for several muscles (Table 19-1) and the sacrotuberous ligament. The ischial spine, located on the body of the ischium, serves as the attachment for the sacrospinous ligament.

Pubis

The pubis (Fig. 19-1) is the smallest of the three bones and consists of a body and inferior and superior rami. The pubis forms the anterior fifth of the acetabulum.

Acetabulum

The ilium, ischium, and pubis fuse together within the acetabulum and form a deep-seated depression in the lateral pelvis, which allows for the proximal transmission of weight from the axial skeleton to the lower extremity.[8] The orientation of the surface of the acetabulum faces laterally, inferiorly, and anteriorly (Fig. 19-1). The superior and posterior margins of the acetabulum are reinforced with a compact cortical bone, which extends the peripheral brim of the fossa, enhancing the stability of the joint during weight bearing from both flexed and extended positions.[8] The coverage of the femoral head by the acetabulum is measured by the center edge angle (CEA) of Wiberg (see Clinical Pearl below). The absence of a normal femoral head during growth, such as in developmental dysplasia of the hip (DDH), causes the acetabulum to have a flat shape. A deformed head stimulates the formation of a correspondingly deformed acetabulum if the deformation occurs at a young enough age.[3]

CLINICAL PEARL

The CEA of Wiberg is a common measurement for the depth of the acetabular socket. The CEA is measured from the anterior–posterior radiograph. A line is drawn through the center of the femoral head, and a second line is drawn from the center of the femoral head to the lateral edge of the acetabulum and the CEA is the angle formed between these. Normal coverage is indicated by a CEA of approximately 30 degrees, whereas undercoverage is indicated by a CEA of less than 20 degrees.[9] A protrusion acetabulum, or deep socket, is defined by a CEA of 44 degrees or more.[10] This scenario of overcoverage can cause a condition called pincer impingement, described later in this chapter.

Another way to calculate femoral head coverage is by determining Lequesne's acetabular index (AI) from a radiograph. The angle used to calculate the AI is formed by a horizontal line connecting both triradiate cartilages (the joining seam of the three pelvic bones—ischium, ilium, and pubis) and a second line which extends along the acetabular roofs. The normal AI is less than 10 degrees. An increase in the AI is associated with a higher incidence of hip dysplasia. Dysplasia can also be associated with coxa valgus, and femoral neck shaft angles greater than the normal parameters of 125–139 degrees.

Hip dysplasia is considered to be the result of undercoverage of the femoral head. This bony undercoverage can lead to excessive joint stress during normal function. For example, a situation of edge loading of the acetabulum can lead to premature articular cartilage degeneration, hip dysplasia, anteversion, coxa valga, or acetabular labral injury.[11] Conversely, excessive bone coverage, or overcoverage can predispose an individual to hip injury secondary to alterations in the mechanical loading patterns of the hip joint.[11] Overcoverage usually is indicative of pathologies such as pincer impingement, acetabular retroversion, or profundus/protrusion.

While the majority of acetabular development is determined by the age of eight,[12–14] the depth of the acetabulum increases additionally at puberty, because of the development of three secondary centers of ossification.[3,4,15] Around the periphery of the acetabulum is a thickened collar of fibrocartilage known as the acetabular rim, or labrum (see "The Acetabular Labrum"), that further deepens the concavity and grasps the head of the femur.[8] The transverse acetabular ligament is a fibrous tissue link spanning the inferior acetabular notch that connects the anteroinferior and posteroinferior horns of the semilunar surface of the acetabulum. The posterior aspect of the ligament attaches to the bone beneath the lunate surface, and the anterior aspect attaches to the labrum.[16] The transverse acetabular ligament contains no cartilage cells.[17] The function of this ligament in the hip is currently unknown.

The articular surface of the acetabulum is limited to an inverted horseshoe-shaped area covering the anterior, superior, and posterior margins.[8] The articular cartilage is thickest on the superior aspect of the acetabulum, but thins near the center of the joint, and is absent over the acetabular notch (Fig. 19-1), the area occupied by the ligamentum teres and obturator artery.[18] This is relatively small contact area may contribute to the prevalence of degenerative disease of the hip joint in humans.[19] The diameter of the acetabulum is slightly less than that of the femoral head and results in an incongruous fit of the joint surfaces. This incongruity unloads the joint during partial weight bearing (PWB), by allowing the femoral head to sublux laterally out of the cup, while, in full weight bearing, the femoral head is forced into the acetabulum.[8] In

addition, elastic deformation of the acetabulum increases joint congruency of the two-joint surfaces in weight bearing.[20] Finally, a strong vacuum contributes to the joint coaptation.[1]

Femur

The femur is the strongest and the longest bone in the body. The proximal end of the femur, the femoral head, articulates with the acetabulum to form the hip joint (Fig. 19-1). The femoral head is composed of a trabecular bone core encased in a thin cortical bone shell. Approximately two-thirds of the femoral head is covered with a smooth layer of cartilage except for a depression, the fovea capitis, which serves as the attachment of the ligamentum teres. The articular cartilage is thickest on the superior-posterior aspect of the femoral head.

CLINICAL PEARL

The trabecular bone in the femoral head and the neighboring femoral neck is specially designed to withstand high loads because of the incorporation of both primary and secondary compressive and tensile patterns. However, within this trabecular system, there is a point of weakness called the Ward triangle, which is a common site of osteoporotic fracture.[21]

Both the trabecular framework of the head and its pliable hyaline cartilage covering contribute toward the shaping of the femoral head within the acetabulum during full weight bearing.[8]

The neck of the femur is located between the shaft of the femur and its head. The head–neck offset is measured by the alpha angle. This angle, which determines how spherical the femoral head is, is measured by first drawing a best-fit circle around the femoral head and then drawing a line from this down the femoral neck. The alpha angle is formed between this line and a line drawn from the center of the circle to where the femur deviates from the circle. An alpha angle of greater than 55 degrees is indicative of a condition called cam impingement, described later.

In the frontal plane, the femoral neck lies at an angle to the shaft of the femur. This neck–shaft angle, or angle *of* inclination, is normally 125–139 degrees in the adult population.[22] Femoral varus (coxa varum) occurs when the angle of inclination is less than 125 degrees, and femoral valgus (coxa valgus) occurs when the angle is greater than 139 degrees (see "Biomechanics").

In the transverse plane, the proximal femur is oriented anterior to the distal femoral condyles as a result of a medial portion of the femur.[23] The normal range for femoral alignment in the transverse plane in adults is 15–20 degrees of anteversion, depending on the level of the acetabulum.[24,25] Increased anteversion is greater than 25 degrees, and relative retroversion occurs at less than 10 degrees. Absolute retroversion occurs at an angle less than 0 degree. Typically, an infant is born with about 30 degrees of femoral anteversion.[26,27] This angle usually decreases to 15 degrees by 6 years of age because of bone growth and increased muscle activity.

On the anterior surface of the femoral neck is the rough intertrochanteric line. The femoral neck serves to extend the weight-bearing forces lateral and inferior to the joint fulcrum. The intertrochanteric crest marks the posterior junction between the neck and the shaft of the femur. The greater trochanter serves as the insertion site for several muscles that act on the hip joint (Table 19-2). The lesser trochanter, located on the posteromedial junction of the neck and the shaft of the femur, is created by the pull of the iliopsoas muscle.

TABLE 19-2 Muscles That Attach to the Greater Trochanter

Gemellus inferior

The head of the femur is angled anteriorly, superiorly, and medially. The femoral neck is externally rotated with respect to the shaft. The angle that the femoral neck makes with the acetabulum is called the angle of anteversion/declination (see "Biomechanics").

Joint Capsule

The joint capsule of the hip (Fig. 19-2), a substantial fibrous sleeve, attaches proximally to the pelvis just lateral to the acetabular labrum and extends laterally over the femoral head and neck to attach to the intertrochanteric line anteriorly. Posteriorly, the capsule attaches to the lateral one-third of the femoral neck allowing for the attachment of the obturator externus tendon in the posterior intertrochanteric fossa.[8] The joint capsule is thicker anterosuperiorly, where maximal stress and weight bearing occurs, and thinnest posteroinferiorly. The joint capsule has three thickened regions that constitute the capsular ligaments. These anterior capsular thickenings, which have been studied extensively, include the iliofemoral ligament and the pubofemoral ligament. Despite these studies, the exact functions of each of these ligaments are still debatable.

- The iliofemoral ligament (Y ligament of Bigelow) (Fig. 19-2) is triangular in shape and consists of two parts: an inferior (medial) portion and a superior (lateral) portion making it resemble an inverted Y. The iliofemoral ligament is the strongest ligament in the body and reinforces the anterior aspect of the hip joint. The ligament, which attaches to the anterior inferior iliac spine (AIIS) at its apex, is oriented superior laterally and blends with the iliopsoas muscle. The medial portion inserts into the inferior aspect of the trochanteric line, while the lateral portion inserts onto the superior aspect of the trochanteric line. By limiting the range of hip extension, this ligament, with the assistance of the pubofemoral ligament, allows maintenance of the upright posture and reduces the need for contraction of the hip extensors in a balanced stance. The ligament exhibits the greater stiffness and prevents anterior translation during extension and external rotation,[28] in both flexion and extension.[29] Myers et al.[30] reported that the iliofemoral

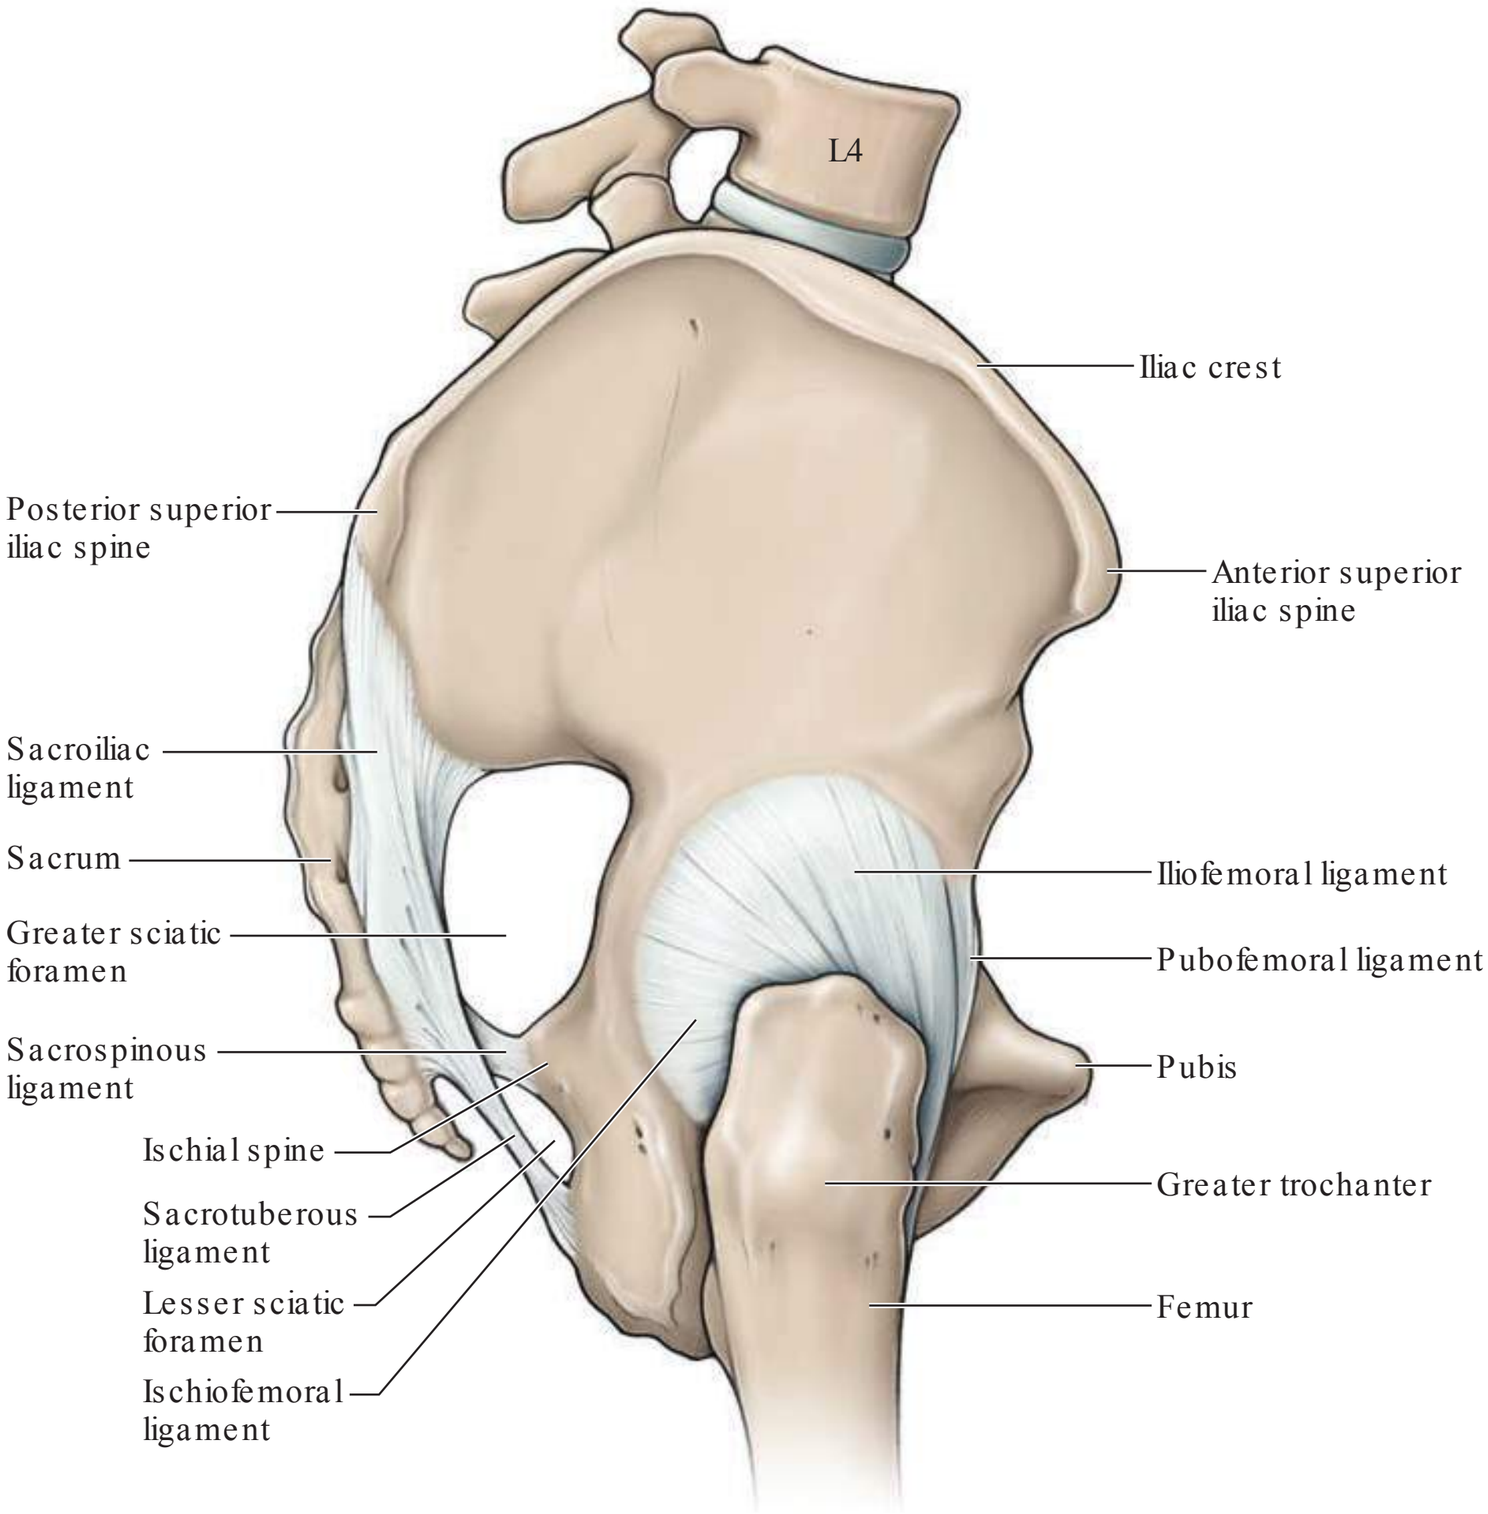

FIGURE 19-2 The hip joint capsule. (Reproduced, with permission, from Chapter 35. Gluteal Region and Hip. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

ligament significantly limited external rotation and anterior translation of the femoral head and was supported by the labrum acting as a secondary stabilizer.[9] Hip adduction tightens the superior portion of the iliofemoral ligament.

- T e pubofemoral ligament (Fig. 19-2) blends with the inferior band of the iliofemoral, and with the pectineus muscle. T e orientation of the pubofemoral ligament is more inferior-medial. T e ligament attaches medially to the iliopectineal eminence, the superior pubic ramus, and the obturator crest and membrane, and laterally to the anterior surface of the trochanteric line. Its fibers tighten in extension, as with the other hip ligaments, and also tighten in external rotation[29] and reinforce the joint capsule along the medial surface.
- T e ischiofemoral ligament, which accounts for the posterior thickening of the capsule (Fig. 19-2), winds posteriorly around the femur and attaches anteriorly, strengthening the capsule. T is ligament, which tightens with internal rotation of the hip in flexion and extension, as well as adduction of the flexed hip, is more commonly injured than the other hip ligaments.

All of these capsular thickenings/ligaments are taut in hip extension, especially the inferior portion of the iliofemoral ligament. Conversely, all the ligaments are relaxed in hip flexion. Because of their inherent strength, the hip ligaments are only usually compromised with severe macrotrauma involving a fracture/dislocation of the hip.

T e ligamentum teres, or capitis femoris ligament (Fig. 19-3), an embryonic remnant, is a structure seen only in the hip joint.[8] T is ligament spans the hip joint running from the edges of the acetabular notch to the fovis capitis of the femur, attaching the femoral head to the inferior acetabular rim. T e ligament is entirely enclosed by a synovial membrane, which forms a sheath around the ligament. Within this sheath, vessels and nerves pass to the femoral head, providing an important source of arterial blood from a tiny posterior branch of the internal iliac artery during femoral head vascular development. Although this arterial supply is a significant source of blood to the femoral head in infants and children,[31] it becomes less significant in adulthood, because of collateral circulation from the circumflex arteries (see "Vascular Supply") surrounding the femoral neck, although chronic interruption of the blood supply to the femoral head has been associated with osteonecrosis and degenerative arthritis.[32]

Cl INICAl PEARl

Patients with ligamentum teres injuries may complain of deep posterior hip joint pain with hip flexion activities.[33]

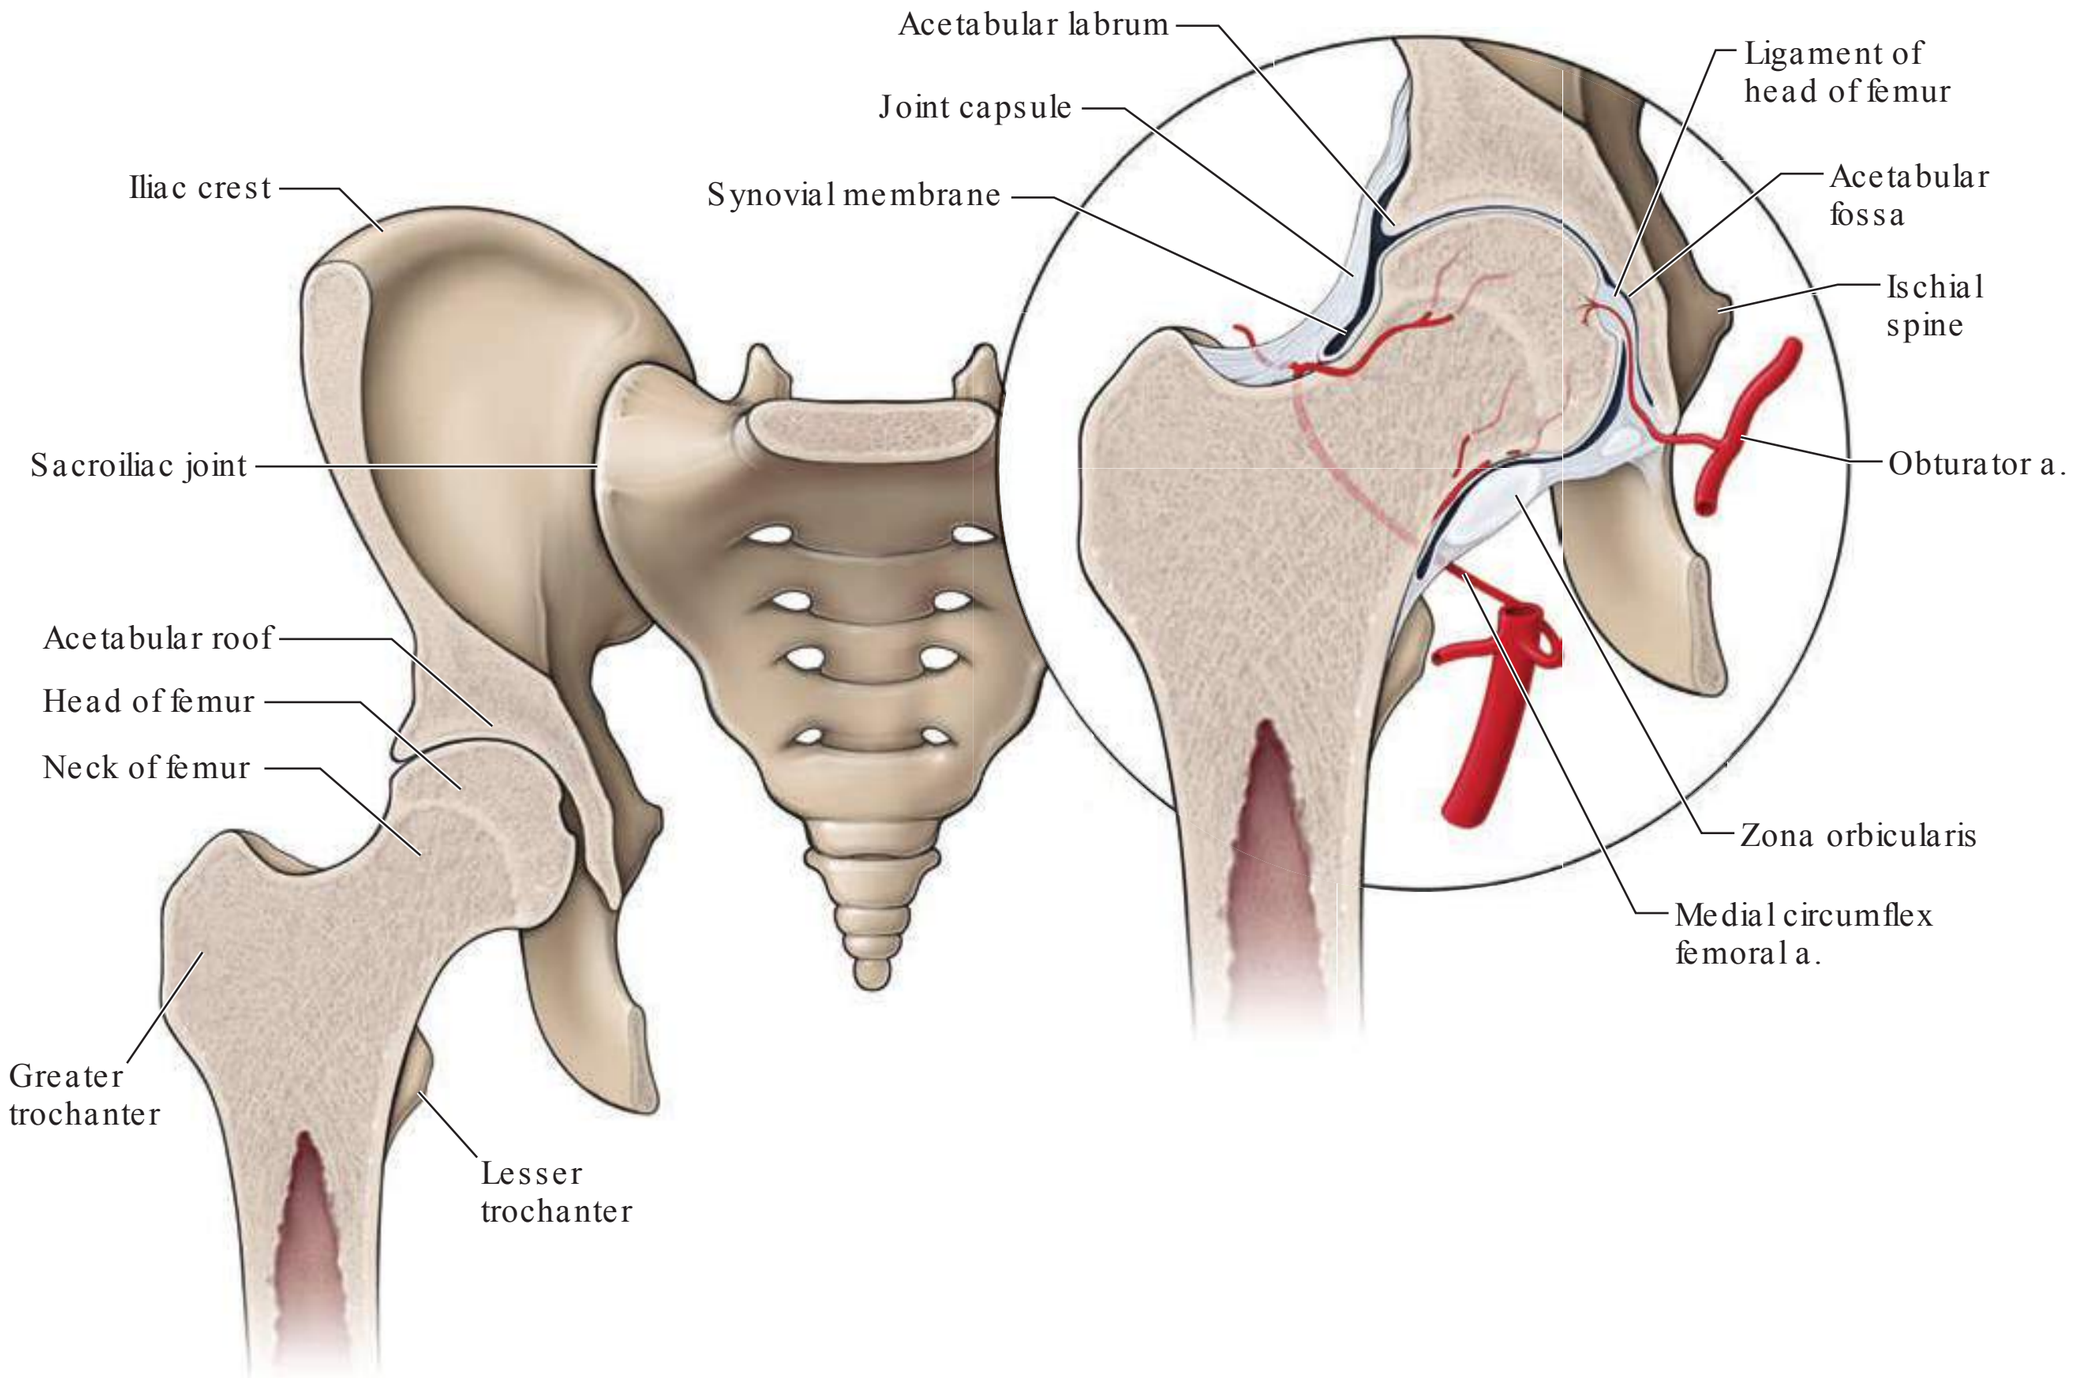

FIGURE 19-3 The hip joint. (Reproduced, with permission, from Chapter 35. Gluteal Region and Hip. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

Though traditionally thought to play a minimal role in joint function, more recent findings suggest that the ligamentum teres may play a number of key roles in stabilization.[34–37] It would appear that the ligamentum teres can function analogous to the anterior cruciate ligament as a stabilizer against subluxation of the hip, particularly when the hip is externally rotated in flexion or internally rotated in extension.[38] Although not a major stabilizer, a patient with a tear of the ligamentum teres may develop hip microinstability which, when combined with recreational and sports activities, may result in damage to the labrum and cartilage.[39] In addition, the ligamentum teres forms a sling-like structure that supports the femoral head inferiorly as the hip goes into flexion and abduction (i.e., squat).[9] Finally, Gray and Villar[40] have proposed that the ligamentum teres has a windshield wiper effect in distributing synovial fluid within the hip joint. The ligament tightens during adduction, flexion, and external rotation, and it can become injured during subluxation.[41]

The Acetabular Labrum

The acetabular labrum (Fig. 19-3) is a semicircular ring consisting of fibrocartilage and dense connective tissue[42] that encases the femoral head and is attached to the acetabular margin. The labrum, which varies greatly in form and thickness, has a triangular cross section: an internal articular surface, an external surface contacting the joint capsule, and a basal surface attached to the acetabular bone and transverse ligaments.[43] Most of the labrum is composed of thick, type I collagen fiber bundles principally arranged parallel to the acetabular rim, with some fibers scattered throughout this layer running obliquely to the predominant fiber orientation.[44] The normal microvasculature of the acetabular labrum consists of a group of small vessels located in the substance of the labrum traveling circumferentially around the labrum at its attachment site on the outer surface of the bony acetabular extension.[45] In addition, the labrum is surrounded by highly vascularized synovium that is present in the capsular recess.[45] The central portion is contiguous with the cartilaginous surface of the acetabulum, and the periphery is continuous with the hip capsule.[33] The majority of the acetabular labrum on the articular side was thought to be avascular. However, cadaver studies have shown it to contain sensory and vascular innervations with the blood vessels entering primarily the peripheral part of the labrum, and with penetration only into the outer one-third of the substance of the labrum.[42] Nerve endings and sensory end organs in the superficial layers of the labrum participate in nociceptive and proprioceptive mechanisms.[46,47] The acetabular labrum of the hip, to a large extent, is analogous to the meniscus of the knee (see Chapter 20) and the labrum of the glenohumeral joint (see Chapter 16) in that it enhances joint stability by deepening the socket, and decreasing the forces transmitted to the articular cartilage.[46,47] The osseous acetabulum in the hip provides substantial static stability to the hip joint.[48] Deepening of the socket that is provided by the labrum would, therefore, appear to be less

important at the hip. Past research does indicate, however, that the labrum may enhance stability by providing negative intra-articular pressure in the hip joint so that it serves as a suction-seal mechanism.[49]

In addition, the labrum functions as a force distributor and shock absorber.[33] Another proposed function of the labrum is to improve the mobility of the hip by providing an elastic alternative to the bony rim.[20]

CLINICAL PEARL

Injuries to the acetabular labrum can occur through a variety of mechanisms.[9]

- The posterior aspect of the labrum undergoes the greatest circumferential strain, with peak force in hip flexion.
- The anterior aspect of the labrum undergoes the greatest force in combined hip flexion and adduction.

Muscles

The hip joint is surrounded by a wide variety of muscles that accelerate, decelerate, and stabilize the hip joint by providing dynamic and passive resistance to external forces that may contribute to excessive motion. Indeed 21 muscles cross the hip, providing both triplanar movement and stability between the femur and the acetabulum.[50] Consequently, abnormal performance of the muscles of the hip may alter the distribution of forces across the joint articular surfaces, potentially causing, or at least predisposing, degenerative changes in the articular cartilage, bone, and surrounding connective tissues.[50] The origin, insertion, and innervation of these muscles are outlined in Table 19-3. Since the hip joint is able to move through a wide range of motion (ROM), a muscle's line of pull may be altered with changing hip position, which makes describing a muscle's action difficult. For example, the orientation of the gluteus medius allows it to work as an internal rotator in hip flexion yet as a weak external rotator in hip extension.[51] Similarly, the tensor fascia latae (TFL) is a hip abductor and flexor, depending upon the hip position, while being a weak internal rotator in all positions.[52] The hip muscles and their respective actions are outlined in Tables 19-3 and 19-4.

CLINICAL PEARL

The soft tissue structures around the hip are most resistant to distraction of the hip joint in the lateral and inferior directions,[53] which indicate the importance of the capsule and the labrum to joint stability.[9]

Iliopsoas

The iliopsoas muscle, formed by the iliacus and psoas major muscles (Fig. 19-4), is the most powerful hip flexor while also functioning as a weak adductor and external rotator of the hip. The iliopsoas attaches to the hip joint capsule, thereby giving it some support anteriorly. Since the muscle spans both the axial and appendicular components of the skeleton, it also functions as a trunk flexor, and affords an important element of the vertical stability of the lumbar spine, especially when the hip is in full extension, and passive tension is greatest in the muscle.[50,54] Functionally, the hip flexors assist with foot clearance during level ambulation and stair negotiation. Theoretically, a sufficiently strong and isolated bilateral contraction of any hip flexor muscle will either rotate the femur toward the pelvis, the pelvis (and possibly the trunk) toward the femur, or both actions simultaneously.[50] Intermuscular cooperation between the iliopsoas group and the rectus abdominis to prevent an anterior tilt and reinforce a neutral pelvis is fundamental to creating a stable proximal platform of the lumbopelvic region for effective therapeutic exercise.[50]

Iliocapsularis
